This man has suffered a right ventricular infarction, leading to the classical picture of elevated JVP, no signs of left ventricular failure, and systemic hypotension.

The majority of patients improve after a fluid challenge, but this should not be continued if blood pressure fails to improve, as excessive fluid loading may contribute to worsening cardiogenic shock.

In patients who do not improve, monitoring of right-sided pressures is the next most appropriate step, with consideration of inotropes. Most patients with right ventricular infarction improve after 48-72 hours.

[Q: 1877] OnExamination 2012 - Cardiology

An 18-year-old with cerebral palsy is admitted after a respiratory arrest having been intubated by paramedics.

Nobody can gain intravenous access as the patient is too shut down. A femoral line is not possible due to contractures. You do not have the experience to perform central venous cannulation.

Which of the following is the best option for administering intravenous fluids/emergency

drugs in this situation of inability to gain venous access?

- 1- Down the endotracheal tube
- 2- Intramuscular (IM)
- 3- Intraosseous
- 4- Nasogastric
- 5- Subcutaneous

Answer & Comments

Answer: 3- Intraosseous

Nasogastric, IM and subcutaneous are too slow and unreliable for emergency situations (although in cardiac arrest the endotracheal route is recognised).

Venous cut down is a possibility but requires skill in the procedure.

Intraosseous is still perfectly viable in the adult patient 2 cm below the tibial tuberosity on the antero-medial side or 2 cm proximal to the medial malleolus.

[Q: 1878] OnExamination 2012 - Cardiology

A 59-year-old lady is admitted with a 30 minute history of heavy central chest pain associated with nausea and sweating.

Her ECG shows ST elevation in leads V1, V2, V3 and V4.

Which of the following coronary arteries is most likely to be occluded?

- 1- Circumflex artery
- 2- Left anterior descending artery
- 3- Obtuse marginal artery
- 4- Posterior descending artery
- 5- Right coronary artery

Answer & Comments

Answer: 2- Left anterior descending artery

An antero-septal myocardial infarction (MI) is due to an infarct in the territory of the left anterior descending artery.

[Q: 1879] OnExamination 2012 - Cardiology

An 54-year-old male re-develops chest pain 72 hours after treatment for an anterior myocardial infarction.

Which of the following markers will be the most sensitive in detecting reinfarction?

- 1- CK-MB
- 2- LDH
- 3- Myoglobin
- 4- Troponin I
- 5- Troponin T

Answer & Comments

Answer: 1- CK-MB

Although troponin is highly sensitive and specific it remains elevated for at least one week after infarction.

Similarly lactate dehydrogenase (LDH) will be present for approximately one week after infarction.

After myocardial infarction (MI), CK-MB levels become elevated within three to eight hours, peak within nine to 30 hours, and return to normal after 48 to 72 hours.

Although myoglobin has a short half life and rises quickly after an MI and is cleared after an MI, it is not specific enough for diagnostic use.

[Q: 1880] OnExamination 2012 - Cardiology

A publication reports the outcome of a new statin therapy in a placebo controlled primary prevention of ischaemic heart disease in a diabetic population.

1000 patients were randomised to receive the new therapy and 1000 allocated to placebo. The study was completed over a five year period.

In the placebo group there were 150 myocardial infarcts (MI) and in the group treated with the new statin there were 100 myocardial infarcts.

What is the number needed to treat to prevent one MI over the course of this study?

- 1- 10
- 2- 20
- 3- 30
- 4- 40
- 5- 50

Answer & Comments

Answer: 2- 20

You treat 1000 patients for five years with the new statin and prevent 50 MIs.

Thus the number needed to treat (NNT) to prevent one MI is 20 (1000/50).

This statistical figure provides us with a lot of information regarding the efficacy of a treatment rather than purely statistically significant data.

As it stands, you may expect to prevent an infarct by treating as few as 20 patients over five years from these data.

Furthermore, cost economic data can be calculated from such results by factoring in how much the drug costs against all the costs of treating and rehabilitating a patient with an MI.

[Q: 1881] OnExamination 2012 - Cardiology

A 69-year-old man is treated for chest infection.

He has been on a stable dose of warfarin for the last six months as a treatment for atrial fibrillation, with INR recordings between 2-2.5. However, his most recent INR was 5 (<1.4).

Which one of the following drugs that has recently been started is likely to be responsible for the increased INR?

- 1- Clarithromycin
- 2- Co-dydramol
- 3- Digoxin
- 4- Rifampicin
- 5- Temazepam

Answer & Comments

Answer: 1- Clarithromycin

Clarithromycin induces the anticoagulant effect of warfarin, whereas rifampicin would reduce the anticoagulant effect.

Ciprofloxacin and sulphonamides will also increase the anticoagulant effect of warfarin.

Temazepam, digoxin and codeine have no appreciable effect.

[Q: 1882] OnExamination 2012 - Cardiology

A 50-year-old politician presented with a strange fluttering sensation in his chest, but no chest pain. The symptoms had lasted 24 hours.

An ECG revealed atrial fibrillation with a ventricular rate of 130 beats per minute.

Which one of the following drugs is most likely to restore sinus rhythm?

- 1- Adenosine
- 2- Bisoprolol
- 3- Digoxin
- 4- Flecainide
- 5- Verapamil

Answer & Comments

Answer: 4- Flecainide

Flecainide is the drug most likely to restore sinus rhythm in atrial fibrillation.

Care is required in patients who may have left ventricular (LV) dysfunction, although this is unlikely in a previously fit, relatively young, patient.

Adenosine is used to cardiovert supraventricular tachycardia (SVT).

Digoxin and bisoprolol are indicated for rate control and are not normally associated with the restoration of sinus rhythm.

Verapamil can be used for rate control in atrial fibrillation, and may be used in the treatment of SVT.

[Q: 1883] OnExamination 2012 - Cardiology

A 72-year-old man noted to have a systolic murmur undergoes an echocardiogram which demonstrates aortic stenosis.

Which of the following is associated with a poor prognosis in this patient?

- 1- Aortic regurgitation
- 2- Cardiomegaly on chest x ray
- 3- Clinical features of left ventricular failure
- 4- ECG evidence of left ventricular hypertrophy
- 5- Severe valvular calcification on echocardiogram

Answer & Comments

Answer: 3- Clinical features of left ventricular failure

Aortic stenosis is associated with a worse prognosis when accompanied by left ventricular (LV) dysfunction.

Other predictors of a poorer prognosis include:

Increasing gradient across the valve (above 70 mmHg)

Age of patient and

Symptomatology.

Although the severity of valvular calcification is prognostically important in an asymptomatic patient the most important predictor is LV function.

[Q: 1884] OnExamination 2012 - Cardiology

A 69-year-old woman admitted for a surgical procedure is noted to have a soft systolic murmur at the left sternal edge.

Her ECG and chest x ray were normal and transthoracic echocardiography revealed a small posterior pericardial effusion with normal valves.

Which of the following would be the most appropriate next step in this patient's management?

- 1- A diagnostic pericardial aspiration
- 2- Mammography
- 3- Purified protein derivative test for tuberculosis
- 4- Reassurance
- 5- Right heart catheterisation

Answer & Comments

Answer: 4- Reassurance

The presence of a small pericardial effusion on echo is quite common and in this patient who otherwise appears well, no further action is required.

[Q: 1885] OnExamination 2012 - Cardiology

A 60-year-old man's echocardiogram shows a dilated left ventricular (LV) cavity with the

remainder of the other chamber sizes normal.

Which of the following is the most likely diagnosis?

- 1- Aortic regurgitation (AR)
- 2- Aortic stenosis (AS)
- 3- Hypertensive heart disease
- 4- Mitral regurgitation (MR)
- 5- Mitral stenosis (MS)

Answer & Comments

Answer: 1- Aortic regurgitation (AR)

No echocardiographic data are provided regarding the valves, but a volume overload as with AR would result in dilatation of the left ventricle.

MR, AS, and hypertension would have the effect of causing hypertrophy and a smaller LV cavity.

MS would have little effect on LV dimensions.

[Q: 1886] OnExamination 2012 - Cardiology

A 60-year-old man has a three month history of worsening dyspnoea. He has been healthy all his life with no major illnesses.

His blood pressure is 118/92 mmHg, he has a murmur and has audible crackles at both bases. His serum glucose is 5.6 mmol/L (3.0-6.0). His total serum cholesterol is 4.8 mmol/L (<5.2). The serum creatine kinase is not elevated.

What is the most likely explanation for these findings?

- 1- Alcoholic cardiomyopathy
- 2- Aortic dissection
- 3- Calcified bicuspid aortic valve
- 4- Mitral valve annulus calcification
- 5- Tricuspid valve endocarditis

Answer & Comments

Answer: 3- Calcified bicuspid aortic valve

The clinical signs point to a left-sided heart failure which would discount alcoholic cardiomyopathy as it would be biventricular and tricuspid valve endocarditis which would be right sided.

There are no acute symptoms and the history is not sudden to suggest aortic dissection.

Mitral valve calcification is an incidental finding at echocardiography (ECHO).

This leaves a calcified bicuspid aortic valve leading to aortic stenosis as the likely explanation.

[Q: 1887] OnExamination 2012 - Cardiology

An elderly gentleman is brought to the Emergency department after suffering a witnessed collapse in a supermarket. A passerby came to his aid immediately and he regained consciousness quickly. His usual state of health is good and he is independent.

On arrival his GCS is 15/15. Blood pressure is 101/72 mmHg. Pulse is 40 regular. Cardiovascular, respiratory and neurological examination is normal.

A 12 lead ECG demonstrates a bradycardia with no obvious association between the QRS complexes and P waves. You call the cardiology registrar for help. You talk to the patient about his problem and when pacemakers are needed.

With regard to this, from the list below, which is an absolute indication for a permanent pacemaker?

- 1- Bifascicular block
- 2- Mobitz Type I with symptoms
- 3- First degree heart block without symptoms
- 4- Acquired third degree heart block without symptoms

5- Trifascicular block

Answer & Comments

Answer: 4- Acquired third degree heart block without symptoms

Indications for permanent pacemakers are a common cardiology topic in examinations.

There is a long list of relative and absolute indications for permanent pacemakers. These are based on international guidelines.

Complete heart block (whether symptomatic or not) is a indication for a permanent pacemaker as there is an inherent risk of asystole.

Option B is a relative indication (Mobitz type I) with symptoms.

Generally, permanent pacing can be justified for any degree of heart block associated with symptoms of bradycardia.

Options A and E are only absolute indications if they are associated with heart block.

[Q: 1888] OnExamination 2012 - Cardiology

A 17-year-old boy was seen in the Emergency department for worsening shortness of breath and wheeze.

He has a two year history of asthma which responds to high doses of oral steroids. Further history revealed tingling and numbness affecting his toes for few months. He was given a full course of antibiotics and oral steroids by the GP but this did not help.

He does not have any other co-morbidities. There is no family history of note. He does not smoke and does not drink alcohol. His exercise tolerance has been gradually deteriorating. There is no history of foreign travel.

The examination revealed pulse 104/min, BP 125/70 mmHg, respiratory rate 22/min, apyrexial, and oxygen saturations 97% on

room air. There was bilateral wheeze in the chest and vesicular breath sounds.

Neurological examination revealed decreased sensation in a stocking distribution. The rest of the neurological and systemic examination was normal.

The initial blood results reveal:

Hb 10.5 g/l (13.0 - 18.0 g/dL)

WCC 10.4 ($4 - 11 \times 10^9/L$)

Neutrophils 2.06 ($1.5 - 7 \times 10^9/L$)

Lymphocytes 1.77 ($1.5 - 4 \times 10^9/L$)

Eosinophils 4.0 ($0.04 - 0.4 \times 10^9/L$)

Urea 4.4 (2.5 - 7.5 mmol/L)

Creatinine 115 (60 - 110 $\mu\text{mol/L}$)

Urine dipstick was positive for blood. Chest x ray was normal.

What is the most likely diagnosis?

- 1- Atopic asthma
- 2- Atypical pneumonia
- 3- Churg-Strauss syndrome
- 4- Goodpasture's syndrome
- 5- Glomerulonephritis

Answer & Comments

Answer: 3- Churg-Strauss syndrome

Churg-Strauss syndrome is a rare type of vasculitis affecting small to medium sized vessels.

It typically presents with asthma and high eosinophilic count. It can involve other systems as in this question, inflammation of vasa nervosum giving rise to symptoms of peripheral neuropathy, vasculitis of renal vessels giving rise to microscopic haematuria and mild renal impairment. Multisystem abnormality should raise the possibility of vasculitis.

Regarding the options:

A. Asthma would not explain the other symptoms in the patient such as peripheral neuropathy, raised eosinophils, impaired renal functions along with microscopic haematuria.

B. Similarly atypical pneumonia would not explain all the symptoms. The patient has a normal CXR which would make this choice less likely.

C. Churg-Strauss syndrome is a rare vasculitis. This question presents the typical picture of a patient with Churg-Strauss syndrome with asthma, mild renal impairment, microscopic haematuria, raised eosinophilic count. This vasculitis involves small to medium sized blood vessels (capillaries, venules, arterioles).

The American College of Rheumatology (ACR) has proposed six criteria for the diagnosis of Churg-Strauss syndrome. The presence of four or more criteria yields a sensitivity of 85% and a specificity of 99.7%.

These criteria include:

Asthma (wheezing, expiratory rhonchi)

Eosinophilia of more than 10% in peripheral blood

Paranasal sinusitis

Pulmonary infiltrates (may be transient)

Histological proof of vasculitis with extravascular eosinophils, and

Mononeuritis multiplex or polyneuropathy.

Management includes glucocorticoids, and immunosuppressant drugs (cyclophosphamide, azathioprine, mycophenolate).

D. Normal CXR and absence of haemoptysis are against Goodpasture's syndrome. Patients with Goodpasture's syndrome have positive anti-GBM antibodies.

E. Evidence of microscopic haematuria does suggest underlying glomerulonephritis, but again this diagnosis alone is not sufficient to explain the whole picture.

[Q: 1889] OnExamination 2012 - Cardiology

A 70-year-old known hypertensive and diabetic patient presents with dyspnoea on moderate exertion.

On examination he is pale, his pulse rate is 98/min regular, BP is 160/70 mmHg and there are fine basal crepitations in the lungs. ECG showed left ventricular hypertrophy and renal functions were slightly deranged.

What is the most appropriate treatment for cardiac failure in this patient?

1- ACE-I alone

2- Furosemide alone

3- Spironolactone, ramipril and aspirin

4- Spironolactone, ramipril and carvedilol

5- Spironolactone, ramipril and digoxin

Answer & Comments

Answer: 4- Spironolactone, ramipril and carvedilol

All patients with cardiac failure should be on ACE-I if there is no contraindication.

In this patient there will be an additional benefit for hypertension and prevention of diabetic nephropathy. Once stable β blocker should be added. It is proven that cardioselective β blockers have important beneficial effects especially in patients with underlying coronary artery disease. Randomised Aldactone evaluation study (RALES) trial showed 30% reduction in mortality when spironolactone (25 mg) was added to the standard therapy.

Digoxin is used in heart failure with atrial fibrillation. As it is a weak positive inotrope, its role in heart failure with sinus rhythm may be best reserved if the patient remains symptomatic despite optimal therapy. Old people with renal impairment are at increased risk of toxicity.

[Q: 1890] OnExamination 2012 -
Cardiology

A 57-year-old man develops deep venous thrombosis during a hospitalisation for prostatectomy.

He exhibits decreased mental status with right hemiplegia, and a CT scan of the head suggests an acute cerebral infarction in the distribution of the left middle cerebral artery.

A chest x ray reveals cardiac enlargement and prominence of the main pulmonary arteries that suggests pulmonary hypertension. His serum troponin I is <0.4 ng/ml.

Which of the following lesions is most likely to be present on echocardiography?

- 1- Coarctation of the aorta
- 2- Dextrocardia
- 3- Pulmonary stenosis
- 4- Tetralogy of Fallot
- 5- Ventricular septal defect

Answer & Comments

Answer: 5- Ventricular septal defect

This is 'paradoxical embolus' from right to left. This can only happen if there is a defect that allows passage from right to left. This can happen across a patent foramen ovale.

In this case, the pulmonary hypertension suggests that there may have been a shunt persistent for a long time - Eisenmenger complex.

An atrial or a ventricular septal defect can provide the shunt.

[Q: 1891] OnExamination 2012 -
Cardiology

A 55-year-old man is being treated for hyperlipidaemia with atorvastatin 40 mg nocte.

He has a history of ischaemic heart disease.

His fasting lipids show:

Total cholesterol 3.8 mmol/l (<5.2)

Triglycerides 1.3 mmol/l (0.5-1.7)

LDL-cholesterol 1.9 mmol/l (<2.6)

HDL-cholesterol 0.7 mmol/l (0.7-1.7)

Which of the following changes of treatment would be expected to raise his HDL cholesterol level by the greatest amount?

- 1- Add cholestyramine
- 2- Add ezetimibe
- 3- Add fenofibrate
- 4- Add nicotinic acid
- 5- Switch atorvastatin to rosuvastatin

Answer & Comments

Answer: 4- Add nicotinic acid

Nicotinic acid is highly effective at raising high density lipoprotein (HDL) cholesterol but it is often poorly tolerated. Sustained release versions are less likely to induce flushing.

It is important to remember that although low HDL-C is associated with increased cardiovascular risk in large epidemiological studies, it is still unclear if giving treatment to increase HDL-C will reduce mortality. A large trial is underway to establish if pharmacologically raising HDL-C with nicotinic acid improves outcomes.

"Nicotinic acid is the most powerful HDL-cholesterol raising agent currently available, and a combination of this agent with a statin facilitates simultaneous control of both HDL-cholesterol and LDL-cholesterol."

Reference:

European Heart Journal Supplements, 2006, Volume 8, Suppl F, pages F23-F29

[Q: 1892] OnExamination 2012 -
Cardiology

A 60-year-old lady is taking warfarin for stroke prevention in atrial fibrillation.

She presents with a markedly raised INR.

Which of the following medications is the most likely to be the reason?

- 1- Aspirin
- 2- Carbamazepine
- 3- Ciprofloxacin
- 4- Flucloxacillin
- 5- St John's wort

Answer & Comments

Answer: 3- Ciprofloxacin

Ciprofloxacin is an inhibitor of p450 and therefore prolongs the half life of warfarin and raises the international normalised ratio (INR).

Even patients are aware of the increased risk of bleeding with aspirin but it does not have a clear relationship with INR.

[Q: 1893] OnExamination 2012 -
Cardiology

A 65-year-old male presents with arthralgia and sleep disturbance following the introduction of simvastatin.

He has a history of hypertension and ischaemic heart disease for which he is receiving aspirin, atenolol and eprosartan together with simvastatin 40 mg OD which has been introduced in the last one month. Previously, he had been taking atorvastatin but this was changed to simvastatin after he complained of arthralgia.

Investigations reveal:

Creatine phosphokinase (CPK) 156 U/l (40-170)

Total cholesterol 5.1 mmol/l (<5.2)

LDL-cholesterol 3.1 mmol/l (<2.5)

Triglycerides 1.7 mmol/l (0.45-1.69)

HDL-cholesterol 1.2 mmol/l (>1.55)

Which is the most appropriate treatment for his lipid profile?

- 1- Ezetimibe
- 2- Fenofibrate
- 3- Nicotinic acid slow release
- 4- Omega-3 fatty acids
- 5- Rosuvastatin

Answer & Comments

Answer: 1- Ezetimibe

The primary treatment target in this case is a total cholesterol (TC) less than 4 mmol/l and low-density lipoprotein cholesterol (LDL C) less than 2.5 mmol/l. Plasma triglyceride and high-density lipoprotein cholesterol (HDL-C) are already at the currently accepted target levels.

This patient describes typical statin-associated side effects which are generally a class effect and dose related. The most common adverse event with statin therapy is arthralgia or myopathy, often with normal CPK levels.

Myositis and rhabdomyolysis are rare statin-associated myopathy side effects and are defined on the basis of CPK levels greater than 10x normal along with features of muscle pain and myoglobinuria (for rhabdomyolysis).

Risk factors predisposing to statin myopathy include advanced age, trauma, thyroid dysfunction and concomitant medication that can raise statin bioavailability including amiodarone, verapamil and many other agents that are metabolised by the cytochrome P450 enzyme system.

Ezetimibe monotherapy produces reductions in TC and LDL-C of around 20%, and since tolerability issues are likely to occur with another statin ezetimibe is the best treatment option.

Clinical trial data have demonstrated continuing event rate reduction to LDL-C levels below 2 mmol/l, and a meta-analysis of lipid lowering trials has demonstrated a 1 mmol/l reduction in LDL-C is associated with a 23% RRR in CHD events, irrespective of baseline risk and the method of cholesterol reduction.

[Q: 1894] OnExamination 2012 - Cardiology

You are on call for hospital at night and are urgently called to a patient on the ward who is choking on a piece of steak visible in his oropharynx. He is in extremis with saturations of 87%.

Which of the following is the most appropriate immediate management for this patient?

- 1- Finger sweep
- 2- Heimlich manoeuvre
- 3- High flow oxygen
- 4- Cricothyroidotomy
- 5- Removal with forceps

Answer & Comments

Answer: 2- Heimlich manoeuvre

A finger sweep is more likely to push the obstruction further into the airway and is no longer advocated.

High flow oxygen is the breathing part of A, B, C, and the airway is not clear.

Nasopharyngeal airways will not help in this situation.

Removal with forceps is potentially hazardous.

A Heimlich manoeuvre should be performed with the possibility of cricothyroidotomy in mind immediately thereafter if this procedure fails.

[Q: 1895] OnExamination 2012 - Cardiology

A 65-year-old man is admitted with central crushing chest pain, sweating and vomiting of one hour duration.

He is conscious with a pulse rate of 100 bpm and a blood pressure of 180/110 mmHg. An ECG shows >2 mm ST elevation in leads II, III, aVF.

FBC: normal

U & E: normal

Troponin T: 100 ng/ml

Apart from the presence of xanthelasma (+) there are no other positive findings on clinical examination.

He is given oxygen, aspirin, clopidogrel, morphine and intravenous 5 mg atenolol.

What is the best next step?

- 1- Give thrombolysis immediately
- 2- Immediate referral to cardiologist for primary angioplasty
- 3- Prescribe low molecular weight heparin
- 4- Prescribe simvastatin
- 5- Transfer to coronary care unit for closer monitoring

Answer & Comments

Answer: 2- Immediate referral to cardiologist for primary angioplasty

This is a case of acute inferior ST elevation myocardial infarction (MI), so the next appropriate management in this case is urgent referral for primary angioplasty.

Early revascularisation for ST elevation MI improves prognosis and outcome.

Thrombolysis is less successful than primary angioplasty at restoring flow and has higher bleeding complications.

Monitoring on CCU is appropriate after revascularisation.

Low molecular weight has no benefit in ST elevation MI.

Statin therapy is not required immediately.

[Q: 1896] OnExamination 2012 - Cardiology

A 17-year-old female loses consciousness whilst out jogging one afternoon.

She has had similar blackouts over the last two to three years which have all occurred during exertion. There is no family history of note. She is taken to the Emergency department, where a chest x ray, CT brain scan, FBC, and biochemistry are all normal. Her ECG shows changes of left ventricular hypertrophy and broad Q waves. An echocardiogram reveals left ventricular and septal hypertrophy, small left ventricle, and reduced septal excursion. The septum has a "ground glass" appearance.

Which of the following conditions is she most likely to have?

- 1- Diabetes mellitus
- 2- Hypertrophic cardiomyopathy
- 3- Rheumatic heart disease
- 4- Systemic lupus erythematosus
- 5- Viral myocarditis

Answer & Comments

Answer: 2- Hypertrophic cardiomyopathy

The history of collapses in this young woman with echocardiographic features of hypertrophy are highly suggestive of hypertrophic obstructive cardiomyopathy.

Hypertrophic cardiomyopathy is defined as the unexplained, asymmetrical or concentric hypertrophy of the undilated left ventricle.

There is also hypertrophy of the right ventricle.

Incidence is approximately 1 in 500. It is inherited as an autosomal dominant trait but

often an inheritance pattern is not found on questioning.

[Q: 1897] OnExamination 2012 - Cardiology

A 54-year-old man presents with central crushing chest pain. Examination is normal.

12-lead ECG shows ST segment elevation in leads II, III, aVF and ST depression in V1, V2 and V3.

Which coronary artery is occluded?

- 1- Circumflex
- 2- Left anterior descending
- 3- Left main stem
- 4- Obtuse marginal
- 5- Right coronary artery

Answer & Comments

Answer: 5- Right coronary artery

The ECG describes an infero-posterior myocardial infarction (MI). This territory is supplied by a dominant right coronary artery. The concept of coronary dominance refers to which coronary artery supplies the posterior descending coronary artery.

In the case of approximately 85% of patients this is the right coronary artery with about 15% of patients having a dominant left circumflex. The territories supplied by the arteries are as follows:

Circumflex: lateral

Left anterior descending: anterior and septum

Left main stem: branches into the left anterior descending artery and circumflex and supplies most of the left ventricle. Complete left main stem occlusion is invariably fatal.

Obtuse marginal: one of the branches of the circumflex and supplies the 'high lateral'

region of the left ventricle (ECG leads I and aVR).

Basic understanding of coronary anatomy is important, as this is predictive of problems following MI.

For example, the right coronary artery supplies the AV node, so heart block following inferior MI is common. However, heart block following anterior MI is a grave prognostic marker as this indicates a large anterior wall infarct.

The right coronary system also supplies the right ventricle, hence problems relating to a right ventricular infarct are commonly associated with an inferior MI.

[Q: 1898] OnExamination 2012 - Cardiology

A 47-year-old lady is admitted to the coronary care unit with symptoms suggestive of decompensated heart failure. She has a history of severe mitral regurgitation secondary to mitral prolapse and is awaiting valve surgery. You are asked to admit the patient and the medical student attached to the firm asks to come with you. You take a full history and examine the patient, making sure to point out all the relevant clinical features to the medical student.

After you finish seeing the patient you discuss the case with the medical student. She asks you the most common cause of mitral regurgitation (MR).

What should be your response to the medical student's question?

- 1- Collagen vascular disease
- 2- Infective endocarditis
- 3- Myxomatous degeneration
- 4- Rheumatic fever
- 5- Rupture of the chordate tendinae

Answer & Comments

Answer: 3- Myxomatous degeneration

Myxomatous degeneration of the mitral valve is by far the most common cause of MR in the United Kingdom. The others listed are less common causes.

The management of severe MR is surgery; either replacement or repair, depending on the anatomy.

A percutaneous repair with clips is possible in some patients unsuitable for conventional surgery.

[Q: 1899] OnExamination 2012 - Cardiology

Which of the following mechanisms best explains the action of ezetimibe?

- 1- Activates PPAR-alpha
- 2- Bile acid sequestration
- 3- Decreases hepatic cholesterol synthesis
- 4- Increases peroxisomal beta-oxidation of fatty acids
- 5- Inhibits cholesterol absorption

Answer & Comments

Answer: 5- Inhibits cholesterol absorption

Ezetimibe localises at the brush border of the small intestine, where it inhibits the absorption of cholesterol from the diet.

[Q: 1900] OnExamination 2012 - Cardiology

A 60-year-old woman has a systolic murmur.

As part of the evaluation you listen to the murmur during a Valsalva manoeuvre and the murmur becomes louder.

Which of the following systolic murmurs becomes louder with a Valsalva?

- 1- Aortic stenosis

- 2- Hypertrophic obstructive cardiomyopathy
- 3- Mitral flow murmur
- 4- Mitral regurgitation
- 5- Ventricular septal defect

Answer & Comments

Answer: 2- Hypertrophic obstructive cardiomyopathy

Most murmurs of stenosis or regurgitation are exaggerated during squatting and get softer with the Valsalva manoeuvre.

The exceptions are hypertrophic cardiomyopathy (HOCM) where the opposite occurs and mitral valve prolapse where the murmur gets longer.

[Q: 1901] OnExamination 2012 - Cardiology

A 57-year-old male is admitted with acute dyspnoea and chest pain. A pulmonary embolism (PE) is confirmed.

Which of the following is a recognised feature of a significant pulmonary embolism?

- 1- An arterial pH less than 7.2
- 2- An increase in serum troponin levels
- 3- Blood gases show increased pCO₂ on air
- 4- Normal D-dimer levels
- 5- Reduced plasma lactate levels

Answer & Comments

Answer: 2- An increase in serum troponin levels

Cardiac troponins are reliable markers of myocardial injury that are increasingly being used to diagnose an acute coronary syndrome in patients presenting with undifferentiated chest pain or dyspnoea.

If elevated cardiac troponin levels also occur in patients with pulmonary embolism because

of right ventricular dilation and myocardial injury, such patients could be misdiagnosed.

'We performed a prospective cohort study to determine the prevalence of elevated cardiac troponin I (cTnI) levels in patients with submassive pulmonary embolism.

Methods: Consecutive patients with objectively confirmed submassive pulmonary embolism and no previous history of ischemic heart disease, other cardiac disease or renal insufficiency, were included. Creatine kinase and cTnI levels were measured within 24 hours of clinical presentation on two occasions eight to 12 hours apart.

Results: Of 24 patients with submassive pulmonary embolism, five (20.8%) had elevated cTnI levels of 0.4 microg/L or higher (95% confidence interval, 7.1-42.2%). One of these patients had a cTnI level higher than 2.3 µg/L that was suggestive of myocardial infarction.

Conclusion: Pulmonary embolism should be considered in the differential diagnosis of patients presenting with undifferentiated chest pain or dyspnoea and an elevated cardiac troponin level.'

Hypoxaemia and hypocapnoea are common after major pulmonary embolism and may also be found after more minor events. Absence of these phenomena, on the other hand, by no means excludes embolism and their presence is non-specific.

In suspected minor embolism this investigation is, at best, only of marginal value. The precise stimulus to hyperventilation is unknown and there is also difficulty in understanding the reasons for hypoxaemia when it is present.

Reference:

Arch Intern Med, 162(1): 79-81 2002

[Q: 1902] OnExamination 2012 - Cardiology

A 45-year-old man presents with a rash.

On examination you find he has eruptive xanthoma.

Which of the following is the most likely diagnosis?

- 1- Familial combined hyperlipidaemia
- 2- Familial hypercholesterolaemia
- 3- Familial hypertriglyceridaemia
- 4- Hyperlipidaemia associated with nephrotic syndrome
- 5- Remnant hyperlipidaemia

Answer & Comments

Answer: 3- Familial hypertriglyceridaemia

Eruptive xanthomas occur in a number of types of hypertriglyceridaemia often with high chylomicrons.

They are yellow papules affecting the extensor surfaces, buttocks and legs. Affected patients may also have fatty liver on ultrasound and foam cells in the bone marrow due to the high triglyceride concentrations.

Causes include types I & V hyperlipidaemia, type III hyperlipidaemia (remnant disease) and hypertriglyceridaemia due to secondary causes such as alcohol, diabetes and obesity.

Of those listed the most likely is familial hypertriglyceridaemia.

[Q: 1903] OnExamination 2012 - Cardiology

A 58-year-old man presents with sudden onset chest pain. He has a known history of ischaemic heart disease.

ECG shows ST segment elevation in V1-V5 without reciprocal depression.

In which territory is the infarction most likely to have taken place?

- 1- Anterior
- 2- Inferio-lateral
- 3- Inferior
- 4- Lateral
- 5- Posterior

Answer & Comments

Answer: 1- Anterior

This myocardial infarction (MI) is likely to be in the left anterior descending coronary artery (LAD) and represents an anterior MI.

[Q: 1904] OnExamination 2012 - Cardiology

A 58-year-old male presents with acute dyspnoea following a convulsion.

On examination his blood pressure was 240/120 mmHg and fundal examination reveals papilloedema with haemorrhages and cotton wool spots. His urea, electrolytes and creatinine are normal but chest x ray reveals pulmonary oedema and cardiomegaly.

Which one of the following is the most appropriate immediate treatment?

- 1- Atenolol 50 mg orally
- 2- Intravenous labetalol
- 3- Intravenous sodium nitroprusside
- 4- Nifedipine 5 mg sublingually
- 5- Nifedipine LA 30 mg orally

Answer & Comments

Answer: 3- Intravenous sodium nitroprusside

This patient has malignant hypertension with papilloedema, convulsions and pulmonary oedema (thus excluding the use of a β -blocker in the acute setting).

This constitutes a medical emergency, with nitroprusside being the treatment of choice.

[Q: 1905] OnExamination 2012 -
Cardiology

A 65-year-old man has long-standing stable heart failure treated with furosemide and enalapril.

He complains of swelling in his left knee and his GP treats him with celecoxib, a cyclo-oxygenase-2 (COX-2) inhibitor. Two weeks later the patient has increasing breathlessness and ankle oedema.

Which one of the following effects of celecoxib is the most likely to explain his symptoms?

- 1- Decreased absorption of furosemide from the gut
- 2- Decreased myocardial contractility
- 3- Reduced effective action of enalapril
- 4- The onset of anaemia
- 5- The onset of fluid retention

Answer & Comments

Answer: 5- The onset of fluid retention

Celecoxib (rofecoxib has been withdrawn) acts by inhibiting prostaglandin synthesis via inhibition of cyclo-oxygenase-2 (COX-2).

It causes fluid retention and can worsen an already pre-existing heart failure as in this case.

The CSM reminds prescribers that celecoxib is contraindicated in patients with severe congestive heart failure, active peptic ulceration or gastrointestinal bleeding.

[Q: 1906] OnExamination 2012 -
Cardiology

A new antihypertensive drug needs to be investigated to establish its relative potency.

Which of the following techniques is most appropriate for this purpose?

- 1- Bioassay
- 2- Case-control study

- 3- Double blind, randomised, placebo controlled study
- 4- Postmarketing surveillance
- 5- Sequential trial

Answer & Comments

Answer: 1- Bioassay

Biological assays are designed to measure the relative potency of different preparations.

Blood pressure is highly variable and is subject to variability because of the patient's level of anxiety and the method used by the observer to measure it.

In a test of efficacy of an antihypertensive drug, a double blind, randomised design would be favourable.

A sequential trial (a trial in which the data are analysed after each participant's results become available and the trial continues until a clear benefit is seen in one of the comparison groups) could also be used to assess efficacy, but there would have to be a large expected difference from placebo.

[Q: 1907] OnExamination 2012 -
Cardiology

Which of the following concerning congenital heart disease is correct?

- 1- ASD is the commonest malformation at birth
- 2- Congenital complete heart block is not usually associated with anti-Ro antibodies in the mother
- 3- Ebstein's anomaly is associated with maternal exposure to lithium carbonate
- 4- Hypoplastic left heart syndrome is characterised by a large, dilated left ventricle
- 5- Osteogenesis imperfecta is associated with aortic stenosis

Answer & Comments

Answer: 3- Ebstein's anomaly is associated with maternal exposure to lithium carbonate

A ventricular septal defect (VSD) is the commonest at 30%, atrial septal defect (ASD) is 10%.

Aortic regurgitation may be a feature of osteogenesis imperfecta.

Ebstein's anomaly is associated with maternal LiCO₃ use if exposed in the first trimester.

The majority of cases of neonates with complete heart block may be caused by autoimmune disease, particularly anti-Ro antibodies in the mother.

Left ventricular (LV) hypoplasia occurs when the left-sided chambers fail to develop and blood enters the systemic circulation from the right ventricle via the pulmonary artery and a patent ductus arteriosus.

[Q: 1908] OnExamination 2012 - Cardiology

A 15-year-old female presents following a sore throat with chest pain, fever, and a skin rash.

Examination reveals a diastolic murmur. Her ASO titre is elevated.

Which of the following is a major criterion for the diagnosis of rheumatic fever?

- 1- Fever
- 2- Migratory erythema
- 3- Polyarthrititis
- 4- Prolonged PR interval
- 5- Raised ESR

Answer & Comments

Answer: 3- Polyarthrititis

Polyarthrititis together with:

Erythema marginatum
Sydenham's chorea

Carditis and

Subcutaneous nodules

constitute the major criteria associated with rheumatic fever.

Minor criteria include:

Raised erythrocyte sedimentation rate (ESR)

Arthralgia

Pyrexia and

A prolonged PR interval.

Migratory erythema is associated with a glucagonoma.

[Q: 1909] OnExamination 2012 - Cardiology

A 38-year-old patient with recent onset fatigue and prior hypertension presents to the endocrinology clinic as his potassium remains low on oral supplements. He has no medical history of note.

A full endocrine profile is requested at the clinic, though the most recent available blood tests demonstrate ongoing hypokalaemia:

Full blood count normal

Serum Sodium 138[132 - 144 mmol/l]

Serum potassium 2.6[3.5 - 5.0 mmol/l]

Urea 6.4[2.5 - 7.5 mmol/l]

Creatinine 70[50 - 120 µmol/l]

What imaging would you carry out?

- 1- Abdominal x ray
- 2- Barium swallow
- 3- Chest x ray
- 4- CT abdomen
- 5- CT brain

Answer & Comments

Answer: 4- CT abdomen

Low potassium in conjunction with hypertension points toward the diagnosis of

primary hyperaldosteronism, or Conn's syndrome.

A more complete biochemical profile would demonstrate alkalosis. The hypokalaemia is often refractory to supplements. As the name suggests, aldosterone levels are high and this suppresses renin levels.

Liddle's syndrome, a rare genetic abnormality of Na⁺ channels, has a similar clinical presentation of fatigue, hypertension and hypokalaemia, though the sodium is usually higher.

Aldosterone levels are high in Conn's syndrome and low-normal in Liddle's syndrome, and were likely checked prior to imaging.

CT or MRI of the abdomen readily identifies a secretory adrenal adenoma, which is not readily evident on abdominal x ray, subsequently managed by adrenalectomy.

CT brain may be indicated in hypokalaemia, with and without hyponatraemia (which may have been corrected too rapidly), to look for central pontine myelinolysis in the very different setting of alcoholic Korsakoff's syndrome with vitamin and electrolyte deficiencies.

None of the other options are of relevance.

Reference:

Moser M et al. NEJM 2006; 355: 385-92: Review on resistant hypertension.

[Q: 1910] OnExamination 2012 - Cardiology

Which of the following is an absolute contraindication to β blockers?

- 1- Psoriasis
- 2- Diabetes
- 3- Peripheral vascular disease
- 4- Mild COPD
- 5- Heart block

Answer & Comments

Answer: 5- Heart block

The JBS 2005 guidelines list asthma or heart block as 'compelling contraindications' to β blockers as life-threatening complications may occur.

All the other options may be exacerbated by β blockers and so are considered 'relative' contraindications.

[Q: 1911] OnExamination 2012 - Cardiology

A 70-year-old man presented with a 40 minute history of heavy chest pain and sweating.

On examination his pulse is 85 bpm and BP 200/110 mmHg. ECG shows ST elevation in leads V2 - V5 and ST depression in leads II and aVF. Diamorphine, oxygen and aspirin have been given.

Which of the following is the most appropriate next step?

- 1- Anticoagulation
- 2- CT thorax
- 3- Intravenous nitrate infusion
- 4- Observe and repeat ECG
- 5- Thrombolysis

Answer & Comments

Answer: 3- Intravenous nitrate infusion

This man is presenting with an acute myocardial infarction (MI) which should be thrombolysed. However, his blood pressure is a contraindication.

Intravenous nitrate infusion is often used in these circumstances (along with adequate analgesia to control pain) to manage the BP before thrombolysis.

[Q: 1912] OnExamination 2012 -
Cardiology

In Down's syndrome, which is the most common congenital heart defect?

- 1- Atrial septal defect
- 2- Atrioventricular septal defect
- 3- Patent ductus arteriosus
- 4- Tetralogy of Fallot
- 5- Ventricular septal defect

Answer & Comments

Answer: 2- Atrioventricular septal defect

Fifty per cent of Down's syndrome births have congenital heart disease.

Defects in order of decreasing frequency are:
B, E, C, D and A.

[Q: 1913] OnExamination 2012 -
Gastroenterology

A 35-year-old obese Afro-Caribbean lady presents with mild jaundice. She claims to be a teetotaler and her BMI is 30 kg/m².

Investigations reveal the following results.

Haemoglobin 14 g/dL (11.5-16.5)

U+Es Normal

Bilirubin 25 µmol/L (1-22)

Aspartate transaminase 140 U/L (1-31)

Alanine transaminase 155 U/L (5-35)

Alkaline phosphatase 160 U/L (60-110)

Random blood glucose 11.2 mmol/L (3.0-6.0)

Hepatitis A IgG Positive

Hepatitis B and C screening Negative

Anti-nuclear antibodies 1:16 titre

Ultrasound abdomen reveals hyperechogenic hepatic parenchyma.

Liver biopsy reveals lesions suggestive of alcoholic liver disease.

On review of her notes, liver function tests performed six months previously showed similar values.

Which of the following is the most likely diagnosis?

- 1- Alcoholic liver disease
- 2- Autoimmune hepatitis
- 3- Non-alcoholic steatohepatitis
- 4- Primary biliary cirrhosis
- 5- Viral hepatitis

Answer & Comments

Answer: 3- Non-alcoholic steatohepatitis

This is a case of non-alcoholic steatohepatitis, the diagnosis of which is made only by histology of liver biopsy which shows lesions suggestive of ethanol intake in a patient known to consume less than 40g of alcohol per week.

The diagnosis is supported by the presence of obesity, hyperglycaemia and hyperechogenic hepatic parenchyma.

In alcoholic hepatitis, the AST is normally raised more than the ALT typically with a ratio of at least 2:1.

[Q: 1914] OnExamination 2012 -
Gastroenterology

A 24-year-old man with chronic diarrhoea and malabsorption is suspected of having coeliac disease.

A jejunal biopsy is taken.

Which of the following findings would be expected in coeliac disease?

- 1- Appearances may resemble severe tropical sprue
- 2- Characteristically shows epithelial cells distended with fat globules
- 3- Shows fissures penetrating into the submucosa
- 4- Shows flattening of the crypts
- 5- Shows leaf-shaped villi

Answer & Comments

Answer: 1- Appearances may resemble severe tropical sprue

In coeliac disease the villi are shortened and the crypts lengthened with increased lymphocytic infiltrate.

Tropical sprue may also cause subtotal villous atrophy.

Fissures are not found and epithelial cells are normal.

[Q: 1915] OnExamination 2012 -
Gastroenterology

A 67-year-old man with known aortic valvular disease is admitted with deteriorating dyspnoea.

Investigations show:

Haemoglobin 9 g/dL (12-16)

MCV 70 fL (80-96)

Upper gastrointestinal tract endoscopy:
Normal

Duodenal biopsy: Normal

Which one of the following investigations is most likely to provide the diagnosis?

- 1- Barium enema
- 2- Colonoscopy
- 3- CT abdomen
- 4- Mesenteric angiography
- 5- Small bowel enema

Answer & Comments

Answer: 2- Colonoscopy

In the older age group investigation of the lower gastrointestinal (GI) tract is vital to exclude a lower GI malignancy. There is an association between aortic stenosis and angiodysplasia it has been debated and is likely to be present but weak. Angiodysplasia are more common in severe aortic disease and may regress upon treatment of the valvular lesion. There is evidence that angiodysplasia are more frequently present in patients with aortic stenosis as compared those with other valvular dysfunction and also that patients with aortic stenosis are over-represented in those with occult GI bleeding. This however does not extrapolate to mean that angiodysplasia is the most common underlying lesion in patients with aortic stenosis and GI bleeding.

Colonoscopy would have the greatest diagnostic yield in this setting. After this capsule endoscopy would probably be the most appropriate. Mesenteric angiography may be useful if there is active bleeding - generally a bleeding rate of at least 0.5mls/min is required to obtain a diagnostic scan, or a large arteriovenous malformation.

CT scans do not demonstrate colonic pathology as well as colonoscopy which is still considered the gold standard.

[Q: 1916] OnExamination 2012 -
Gastroenterology

A 22-year-old man returned from a back-packing holiday three weeks ago. While abroad he developed bloody diarrhoea with abdominal pain. Stool cultures have confirmed *Salmonella typhi*.

Which of the following antibiotics would be first line treatment?

- 1- Ampicillin
- 2- Ciprofloxacin
- 3- Erythromycin
- 4- Metronidazole
- 5- Tetracycline

Answer & Comments

Answer: 2- Ciprofloxacin

Ciprofloxacin is the antibiotic of choice for the treatment of *Salmonella* - 500 mg bd for 10-14 days.

Diarrhoea occurs due to increased water in the stool. The definition of chronic diarrhoea is the abnormal passage of three or more loose or liquid stools per day for more than four weeks and/or a daily stool volume > 200ml/day (weight > 200g/day).

Ampicillin or ciprofloxacin can be used for the treatment of *Shigella*.

Erythromycin is used in *Campylobacter jejuni*.

Metronidazole is used for *Clostridium difficile*.

Tetracycline is given for *Yersinia enterocolitica*.

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

Travis SPL, Ahmad T, Collier J, Steinhart AH. *Pocket Consultant Gastroenterology*. Blackwell Publishing 2005.

[Q: 1917] OnExamination 2012 - Gastroenterology

A 25-year-old man who is known to have diabetes mellitus and suffers from recurrent chest infections is referred to the gastroenterology team with chronic diarrhoea.

The letter from his GP states the patient has had persistently abnormal liver function tests over the last three months and an abdominal ultrasound scan showed a fatty liver and gallstones.

Given the most likely diagnosis, what is the disease prevalence in northern Europe?

- 1- 1:300
- 2- 1:1000
- 3- 1:3000
- 4- 1:5000
- 5- 1:10000

Answer & Comments

Answer: 3- 1:3000

This patient has cystic fibrosis which has a disease prevalence of 1:3000 northern Europeans and gene carriage 1:25.5

Cystic fibrosis (CF) is an autosomal recessive disorder which results from mutations in the gene for the CFTR (cystic fibrosis transmembrane conductance regulator). This is a cAMP-activated chloride channel found in secretory epithelia.

Patients have dry protein-rich secretions which lead to complications of the pulmonary and gastrointestinal systems.

CF is the commonest cause of exocrine pancreatic insufficiency. The disease presents with failure to thrive, steatorrhoea and abdominal pain. Diabetes mellitus can occur.

Twenty per cent have a fatty liver and gallstones are seen in 15% of young adults with the disease. Patients may also develop secondary biliary cirrhosis with mucus plugging of bile ducts and portal hypertension.

Diagnosis is usually clinical based on the pulmonary and gastrointestinal manifestations, family history and a positive sweat test. Confirmation is with genetic studies.

Management requires a multi-disciplinary team approach with attention to nutrition. Vitamin deficiencies require replacement and pancreatic enzyme supplements are given for exocrine insufficiency.

There has been success with lung and liver transplantation; gene therapy remains the ultimate goal for treatment.

Reference:

Bloom S, Webster G, *Oxford Handbook of Gastroenterology and Hepatology*, Oxford University Press 2006.

[Q: 1918] OnExamination 2012 - Gastroenterology

Which of the following is a recognised cause of gingival hyperplasia?

- 1- Allopurinol
- 2- Hyoscine
- 3- Penicillamine
- 4- Phenytoin
- 5- Prednisolone

Answer & Comments

Answer: 4- Phenytoin

A rare adverse effect of allopurinol includes a metallic taste.

Hyoscine commonly causes a dry mouth.

Penicillamine can cause oral ulceration and loss of taste.

Prednisolone commonly results in Candida infection.

Reference:

Tofield C, Milson A, Chatu S. *The hands-on guide to clinical pharmacology*. Blackwell Publishing 2005.

[Q: 1919] OnExamination 2012 - Gastroenterology

A 42-year-old female with ulcerative colitis is found to have anti-smooth muscle antibodies.

Which is the next most appropriate test for this patient?

- 1- Abdominal ultrasound
- 2- Colonoscopy
- 3- Full blood count
- 4- Liver biopsy
- 5- Liver function tests

Answer & Comments

Answer: 5- Liver function tests

The most appropriate investigation for this woman is liver function tests (LFTs) to begin with to assess if there are any features of autoimmune hepatitis, that is,

Raised bilirubin

Aspartate aminotransferase (AST)

Alanine aminotransferase (ALT)

Alkaline phosphatase.

If this is the case then liver biopsy may be required or further diagnostic imaging.

[Q: 1920] OnExamination 2012 - Gastroenterology

A 70-year-old male is admitted with haematemesis.

He is currently being treated with warfarin for atrial fibrillation and his INR returns as 10 (<1.4).

Which of the following is the most appropriate immediate treatment of his INR?

- 1- Cryoprecipitate
- 2- Fresh frozen plasma
- 3- Intravenous vitamin K
- 4- Oral vitamin K
- 5- Recombinant factor VIII concentrate

Answer & Comments

Answer: 2- Fresh frozen plasma

This patient has had a bleed related to a grossly elevated international normalised ratio (INR). Consequently the INR needs correction as rapidly as is possible.

Vitamin K will correct the INR over a few days, whereas fresh frozen plasma will correct the bleeding time rapidly.

[Q: 1921] OnExamination 2012 - Gastroenterology

A 68-year-old male presents with alcoholic cirrhosis complicated by mild ascites.

Which of the following features is likely in this patient?

- 1- Increased serum sodium
- 2- Increased vascular resistance
- 3- Reduced renin concentrations
- 4- Reduced urinary potassium excretion
- 5- Reduced urinary sodium excretion

Answer & Comments

Answer: 5- Reduced urinary sodium excretion

Remember that he has secondary hyperaldosteronism which results in sodium retention with consequent potassium loss.

There is decreased vascular resistance, increased plasma volume and low serum sodium.

[Q: 1922] OnExamination 2012 -
Gastroenterology

A 35-year-old woman with a history of recurrent anaemia was noted to have target cells and Howell-Jolly bodies on a blood film examination.

Investigations revealed:

Haemoglobin 7.0 g/dL(11.5-16.5)

MCV 77 fL(80-96)

MCH 26.2 pg(28-32)

Serum B₁₂ 140 µg/L(160-760)

Red cell folate 95 µg/L(160-640)

Serum ferritin 10 µg/L(15-300)

What disease specific antibody is most likely to be present?

- 1- Antiendomysial
- 2- Antigastric parietal cell
- 3- Antiglutamic acid decarboxylase
- 4- Anti-intrinsic factor
- 5- Antimitochondrial

Answer & Comments

Answer: 1- Antiendomysial

The patient has hyposplenism as suggested by the blood film and a mixed anaemia.

Coeliac disease could therefore fit the above picture with antiendomysial antibodies being the most appropriate selection from the above list.

Antimitochondrial antibodies are seen in PBC

Anti-gastric and anti intrinsic Abs are seen in pernicious anaemia

Anti-GAD abs are found in auto-immune DM.

Screening for coeliac disease should include high-risk groups such as anaemia (iron or folate deficiency), hyposplenism, reduced bone density and infertility.

[Q: 1923] OnExamination 2012 -
Gastroenterology

A 63-year-old man with known alcohol related cirrhosis presented with ascites, abdominal tenderness and peripheral oedema. A diagnostic tap revealed a neutrophil count of 400/ mm³ (<250mm³).

Which of the following would be of most immediate benefit?

- 1- Fluid restriction and a no-added-salt diet
- 2- Intravenous antibiotics
- 3- Oral spironolactone
- 4- Therapeutic paracentesis
- 5- Transjugular intrahepatic portosystemic shunt (TIPSS)

Answer & Comments

Answer: 2- Intravenous antibiotics

This man has spontaneous bacterial peritonitis (SBP). Appropriate treatment is IV antibiotics.

He is likely to have a decreased intravascular volume and require IV albumin as volume expansion.

Fluid restriction, diuretics, or large volume paracentesis are likely to cause further hypovolaemia and precipitate renal failure.

There is no stated indication for a TIPSS, indications are: diuretic resistant ascites, intractable portal hypertensive bleeding and hepato-renal failure.

[Q: 1924] OnExamination 2012 -
Gastroenterology

Which of the following is not true of a patient with ascites due to liver cirrhosis?

- 1- Cardiac output is often elevated
- 2- Hepatic intrasinusoidal pressure is elevated
- 3- Spontaneous bacterial peritonitis is a recognised feature

- 4- The usual source of the ascitic fluid is mainly from the exudation from the surface of the liver
- 5- Urinary sodium concentration is usually less than 10 mmol/l

Answer & Comments

Answer: 4- The usual source of the ascitic fluid is mainly from the exudation from the surface of the liver

Hepatocellular failure is associated with hyperdynamic circulation and systemic vasodilatation with increased vascular capacitance.

Most patients have sodium and water retention.

[Q: 1925] OnExamination 2012 - Gastroenterology

Ten individuals are admitted to casualty with profuse vomiting after attending a retirement dinner in a Chinese restaurant.

They all ate at roughly 7 pm and became ill at roughly midnight. Nine ate a mixture of dishes except one female who ate vegetarian dishes with her rice.

What is the most likely infective organism?

- 1- Salmonella enteritidis
- 2- Staphylococcus aureus
- 3- E. Coli
- 4- Clostridium perfringens
- 5- Bacillus cereus

Answer & Comments

Answer: 5- Bacillus cereus

This is a typical case of Bacillus cereus, with profuse vomiting which occurs approximately one to five hours after eating.

In this case it is likely that the rice itself had been infected.

Another possibility is Staph. aureus although this is less likely.

[Q: 1926] OnExamination 2012 - Gastroenterology

A 55-year-old post-menopausal woman presents with tiredness and lethargy, she denies any other symptoms. Her blood tests show that she is anaemic.

Tests reveal:

Haemoglobin 10.3 g/dl 11.5-16.5

Mean corpuscular volume 76 fl 80 - 96

Ferritin 5 µg/l 15 - 300

Anti-tissue transglutaminase IgA antibodies are negative. Gastroscopy and CT colonography are both performed and do not reveal any cause for iron deficiency.

She is commenced on oral ferrous sulphate and three months later her haemoglobin is 11.5 g/dl. She comes to see you three months after this asking whether it is possible to stop the oral iron as she feels it is making her nauseous.

According to the British Society of Gastroenterology guidelines on the management of iron deficiency anaemia what is the most appropriate course of action?

- 1- Change to parenteral iron
- 2- Offer transfusion as required
- 3- Refer for further investigation
- 4- Stop oral iron and monitor haemoglobin
- 5- Trial of alternative oral iron preparation

Answer & Comments

Answer: 4- Stop oral iron and monitor haemoglobin

Parenteral iron replacement should be considered where iron replacement is necessary but oral preparation cannot be tolerated or absorbed.

There is no indication for transfusion and there has been a response to iron supplementation that is likely to be replicated, if necessary, in the future.

Initial investigations for a gastrointestinal cause for the iron deficiency have been completed and are negative, in the absence of other symptoms to suggest an alternative source for blood loss and in the presence of a good response to oral iron further investigation is not warranted.

Supplementary iron is no longer required at this stage in the patient's management so switching to an alternative is not required.

Alternative preparations and dose reduction may help where oral iron is not well tolerated.

[Q: 1927] OnExamination 2012 - Gastroenterology

Mutation of STK11/LKB1 gene is associated with which of the following diseases?

- 1- Familial adenomatous polyposis
- 2- Hereditary non-polyposis colorectal cancer
- 3- Neurofibromatosis
- 4- Peutz-Jeghers syndrome
- 5- Tuberous sclerosis

Answer & Comments

Answer: 4- Peutz-Jeghers syndrome

Mutation of APC gene leads to familial adenomatous polyposis.

Defective mismatch repair genes hMLH1 and hMSH2 leads to hereditary non-polyposis colorectal cancer.

Mutation of tumour suppressor genes NF1 (neurofibromin) and NF2 (merlin) results in neurofibromatosis type 1 and type 2, respectively.

In tuberous sclerosis there is mutation of TSC1 or TSC2 genes.

Reference:

Green AJ, Johnson PH, Yates JR. The tuberous sclerosis gene on chromosome 9q34 acts as a growth suppressor. *Hum Mol Genet.* 1994 Oct;3(10):1833-4.

Travis SPL, Ahmad T, Collier J, Steinhart AH. *Pocket Consultant Gastroenterology.* Blackwell Publishing 2005.

Yohay KH. The genetic and molecular pathogenesis of NF1 and NF2. *Semin Pediatr Neurol.* 2006;13:21-6.

[Q: 1928] OnExamination 2012 - Gastroenterology

Which of the following stimulates bicarbonate secretion from the pancreas and liver?

- 1- Cholecystikinin (CCK)
- 2- Gastrin
- 3- Motilin
- 4- Secretin
- 5- Vasoactive intestinal peptide (VIP)

Answer & Comments

Answer: 4- Secretin

Secretin is secreted from the small intestine when there is acid in the small intestine.

It inhibits gastric motility and acid production, and stimulates bicarbonate secretion from the pancreas and liver.

[Q: 1929] OnExamination 2012 - Gastroenterology

A 32-year-old female presents with pruritis and jaundice. She is 30 weeks gestation in her first pregnancy.

Two weeks earlier she had been treated by the ENT surgeons after presenting to the Emergency department with intractable nose bleeds.

The liver function tests are shown below:

ALT 72 U/L (5-40)

Alkaline phosphatase 700 U/L (30-110)

Bilirubin 80 $\mu\text{mol/L}$ (1-18)

Serum bile acids 100 times normal titre.

Which of the following statements is correct concerning this patient?

- 1- ALP does not increase in a normal pregnancy
- 2- Maternal hepatic blood flow does not increase in pregnancy
- 3- Treatment options include IV N-acetylcysteine
- 4- Varices are diagnostic of liver disease in pregnancy
- 5- Viral hepatitis is the likely diagnosis

Answer & Comments

Answer: 2- Maternal hepatic blood flow does not increase in pregnancy

The diagnosis here is intrahepatic cholestasis which presents with markedly elevated serum bile acids (cholyglycine).

It presents in the second or third trimester, and usually the alkaline phosphatase (ALP) is 7-10 times normal, with raised alanine transaminase (ALT), aspartate transaminase (AST) and bilirubin.

Cardiac output and blood volume increase in pregnancy, but hepatic blood flow does not.

Treatment options include ursodeoxycholic acid, cholestyramine, phenobarbital and vitamin K to treat the coagulopathy.

ALP rises in pregnancy but not to this extent. The placenta is the source of the raised ALP.

Viral hepatitis is the commonest cause of jaundice in pregnancy, but the elevated bile acids make this unlikely in this case.

[Q: 1930] OnExamination 2012 - Gastroenterology

A 25-year-old man who had a long history of heavy alcohol intake is admitted with nausea

and frequent vomiting four hours after a meal in a restaurant.

During review in the Emergency department he vomits a cupful of blood.

What is the cause of his haematemesis?

- 1- Duodenal ulceration
- 2- Haemorrhagic gastritis
- 3- Mallory-Weiss tear
- 4- Oesophageal varices
- 5- Oesophagitis

Answer & Comments

Answer: 3- Mallory-Weiss tear

Persistent vomiting can eventually lead to small tears in the oesophagus leading to the vomiting of red blood.

Varices would produce large volumes of blood (much more than just a cupful).

[Q: 1931] OnExamination 2012 - Gastroenterology

A male teacher who is 31-years-old attends clinic with his partner who tells you that he has memory problems. The only other symptom is intermittent diarrhoea over the preceding four months.

He has limited vertical eye movements and exhibits rhythmic simultaneous eye and mouth movements.

Which pathogen is most likely to be the cause of his symptoms?

- 1- Clostridium botulinum
- 2- HIV
- 3- Prion protein
- 4- Salmonella enteritidis
- 5- Tropheryma whippelii

Answer & Comments

Answer: 5- Tropheryma whippelii

This is a tough question.

The suggestion here is that the patient has Whipple's disease, due to intestinal infection with *Tropheryma whipplei*.

Non-neurological manifestations of Whipple's disease are more common and include chronic diarrhoea, malabsorption with steatorrhoea and associated abdominal distension and tenderness.

Neurological manifestations involve a chronic progressive impairment of higher mental function in association with seizures, myoclonus ataxia and oculomasticatory myorhythmia found uniquely in Whipple's.

The diagnosis is made by duodenal or jejunal biopsy and demonstrating the bacilli within the mucosa on PAS staining.

Characteristically, there is accumulation of glycoprotein and fat filled (PAS +ve) macrophage within the lamina propria.

Botulism does not produce this clinical picture.

An AIDS related dementia is possible, but abnormal facial movements would be unusual.

Creutzfeldt-Jakob disease (CJD) could also produce this picture, although myoclonus is usually more of a feature and cognitive impairment is more generalised and acute.

Salmonella enteritidis usually causes only an acute diarrhoeal illness, but may lead to bacteraemia and chronic long term carriage and excretion.

[Q: 1932] OnExamination 2012 - Gastroenterology

A routine ultrasound at 18 weeks' gestation in a diabetic mother reveals a male fetus with an endocardial cushion defect. Other abnormalities include increased nuchal thickening and a 'double bubble' sign.

Which of the following conditions is most likely to have contributed to this set of findings?

- 1- Congenital syphilis
- 2- Marfan syndrome
- 3- Maternal folate deficiency
- 4- Maternal use of ACE inhibitor
- 5- Trisomy 21

Answer & Comments

Answer: 5- Trisomy 21

Diabetic mothers are more likely to have children with congenital abnormalities depending on preconception and first trimester blood sugar control.

Forty per cent of Down's syndrome babies have atrioventricular septal defects, as in this fetus.

The double bubble sign suggests duodenal atresia, which again suggests Down's syndrome.

GI malformations occur in 6% of Down's patients - most commonly duodenal atresia and Hirschsprung's disease.

[Q: 1933] OnExamination 2012 - Gastroenterology

Which of the following statements is characteristic of acute hepatitis B infection?

- 1- It commonly presents with distal joint arthritis.
- 2- It confers immunity to hepatitis A.
- 3- Most patients present with splenomegaly.
- 4- Pruritis is an important early symptom.
- 5- There is increased infectivity in the presence of the hep B e antigen.

Answer & Comments

Answer: 5- There is increased infectivity in the presence of the hep B e antigen.

Clinical features of hepatitis B are as follows:

Most are asymptomatic.

Symptoms: Lethargy, anorexia, arthralgia, rash (any type), papular acrodermatitis (Gianotti-Crosti), polyarthrititis, glomerulonephritis, aplastic anaemia. Twenty five per cent have jaundice.

Complications:

Acute fulminant hepatitis.

Chronic hepatitis.

Membranous glomerulonephritis.

Hepatitis B e antigen is present in the acute phase and indicates a highly infectious state.

Pruritis is characteristic of chronic hepatitis.

[Q: 1934] OnExamination 2012 - Gastroenterology

A 35-year-old woman with alcoholic cirrhosis is admitted with deteriorating encephalopathy and abdominal discomfort.

An ascitic tap revealed a polymorphonuclear cell count of 350 cells per mm³.

Which of the following is the most appropriate therapy?

- 1- Intravenous amoxicillin
- 2- Intravenous cefotaxime
- 3- Intravenous metronidazole
- 4- Oral neomycin
- 5- Oral norfloxacin

Answer & Comments

Answer: 2- Intravenous cefotaxime

This lady has spontaneous bacterial peritonitis as suggested by the typical history, ascites and raised polymorphonuclear count within the ascitic tap.

It is most commonly seen in alcoholic cirrhosis and the causative organism is usually

Escherichia coli, Klebsiella, S pneumoniae or Enterococci. (Compare this with the mixed growth seen in other forms of peritonitis).

Sending some ascitic fluid in blood culture bottles increases the yield.

Initial treatment is with broad spectrum antibiotics such as cefotaxime.

Norfloxacin is recommended for short term prophylaxis.

[Q: 1935] OnExamination 2012 - Gastroenterology

A 54-year-old woman presented with an eighteen month history of chest pain and dysphagia for both solids and liquids. She smokes 20 cigarettes per day and drinks 16 units of alcohol per week.

Clinical examination was normal.

What is the most likely diagnosis?

- 1- Achalasia.
- 2- Bronchial neoplasm.
- 3- Oesophageal neoplasm.
- 4- Oesophageal web.
- 5- Pharyngeal pouch.

Answer & Comments

Answer: 1- Achalasia.

A longstanding history of dysphagia to both solids and liquids suggests a functional rather than mechanical cause for the dysphagia. Hence a neoplasm or other obstructive lesion is unlikely.

Chest pain is not a typical feature of a pharyngeal pouch.

Achalasia, in which there is failure of oesophageal peristalsis and of relaxation of the lower oesophageal sphincter, typically causes the symptoms described above.

[Q: 1936] OnExamination 2012 -
Gastroenterology

A 65-year-old woman presents with a one month history of jaundice.

She reports her urine is darker than normal and her stools are a pale colour. On direct questioning she admits to pruritis but denies abdominal pain. There is no history of foreign travel. She has lost approximately 1 stone in weight.

On examination she is jaundiced, there are no stigmata of chronic liver disease and no asterixis. Abdominal examination reveals hepatomegaly 4 cm below the costal margin.

Given the most likely diagnosis, which tumour marker is most likely to be elevated?

- 1- AFP
- 2- Beta-hCG
- 3- CA 19-9
- 4- CA 125
- 5- CEA

Answer & Comments

Answer: 3- CA 19-9

The most likely diagnosis in this case is pancreatic carcinoma. The most useful tumour marker for pancreatic cancer is CA 19-9, of which the sensitivity and specificity for pancreatic carcinoma are 80% and 90% respectively.

These figures are closely related to tumour size and the accuracy of using CA 19-9 to identify patients with small surgically resectable tumours is limited.

CA 19-9 does not distinguish between cholangiocarcinoma, pancreatic or gastric carcinoma and may also be raised in patients with severe liver injury due to any other cause.

Concentrations of alpha fetoprotein (AFP) and/or the beta subunit of human chorionic

gonadotrophin (beta-hCG) are raised in 80-85% of men who have non-seminomatous germ cell tumours. These markers (as well as lactate dehydrogenase [LDH]) are useful in prognosis, risk stratification and assessing response to treatment in testicular cancer.

The serum concentration of AFP is usually raised in patients with hepatocellular carcinoma (HCC). However the levels do not correlate well with other clinical features such as the size of the tumour, stage or prognosis of the disease. Levels greater than 500 microg/L (normal range 10-20 microg/L) in a high-risk patient is diagnostic of HCC.

AFP may also be elevated in patients with chronic liver disease without HCC for example, acute or chronic viral hepatitis.

Measurement of the CA 125 is the most widely studied biochemical method of screening for ovarian cancer. The level is raised in approximately 50% of women with early stage disease and in more than 80% of women who have advanced ovarian carcinoma.

Carcinoembryonic antigen (CEA) and CA 19-9 are associated with colorectal cancer (CRC), but they have low diagnostic ability to detect primary CRC in view of overlap with benign disease and low sensitivity for early stage disease.

Other causes of raised CEA include gastritis, peptic ulcer disease, diverticulitis, liver disease, COPD and diabetes mellitus as well as any acute or chronic inflammatory condition.

Reference:

Khan SA, Davidson BR, Goldin R, et al. Guidelines for the diagnosis and treatment of cholangiocarcinoma: consensus document. Gut 2002;51(Suppl VI):vi1-vi9.

[Q: 1937] OnExamination 2012 -
Gastroenterology

A 34-year-old man with ulcerative colitis is admitted with severe bloody diarrhoea. He is

opening his bowels approximately 15 times a day and has abdominal pain.

His current medication includes Mezavant and on admission he is commenced on intravenous hydrocortisone. You are asked to request a thiopurine methyltransferase (TPMT) level as the plan is to start azathioprine at a later date.

What percentage of the population has normal or high TPMT activity?

- 1- 1%
- 2- 10%
- 3- 25%
- 4- 50%
- 5- 90%

Answer & Comments

Answer: 5- 90%

Ninety per cent of the population have normal or high enzyme activity, that is, are homozygous for the wild-type allele.

The enzyme activity of thiopurine methyltransferase (TPMT) is under the control of a genetic polymorphism.

Ten per cent of the population have intermediate levels of TPMT activity, that is, one wild-type and one variant allele.

One in 300 people have no functional enzyme activity.

Several groups of patients - not only those with Inflammatory bowel disease - have developed azathioprine induced myelosuppression linked to TPMT deficiency.

Reference:

Mowat C, Cole A, Ahmad T, et al. Guidelines for the management of inflammatory bowel disease in adults. *Gut* 2004;53(Suppl V):v1-v16.

[Q: 1938] OnExamination 2012 - Gastroenterology

Which of the following is consistent with a diagnosis of insulinoma?

- 1- High fasting glucose, low insulin, high C peptide
- 2- Low fasting glucose, high insulin, high C peptide
- 3- Low fasting glucose, high insulin, low C peptide
- 4- Low fasting glucose, low insulin, high C peptide
- 5- Low fasting glucose, low insulin, low C peptide

Answer & Comments

Answer: 2- Low fasting glucose, high insulin, high C peptide

In contrast, insulin overdose will cause high insulin levels but a low C peptide.

[Q: 1939] OnExamination 2012 - Gastroenterology

Which of the following hormones stimulates contraction of the gallbladder?

- 1- Cholecystokinin
- 2- Gastrin
- 3- Secretin
- 4- Somatostatin
- 5- Vasoactive intestinal peptide (VIP)

Answer & Comments

Answer: 1- Cholecystokinin

Gastrin leads to the release of gastric acid.

Secretin stimulates the release of pancreatic fluid and bicarbonate.

Somatostatin inhibits gastrointestinal endocrine secretion.

Vasoactive intestinal peptide (VIP) functions as a vasodilator and also regulates smooth muscle activity, epithelial cell secretion and gastrointestinal blood flow.

[Q: 1940] OnExamination 2012 - Gastroenterology

Which of the following stimulates the secretion of gastrin?

- 1- Amino acids
- 2- Fasting
- 3- High level gastric acid in the stomach
- 4- Low gastric pH
- 5- Somatostatin

Answer & Comments

Answer: 1- Amino acids

Gastrin is released from specialised endocrine cells, called G cells, in response to a meal. Protein, peptides and amino acids are specific components which will stimulate gastrin release.

Fasting and increased gastric acid in the stomach both inhibit the release of gastrin. High gastric pH is a strong stimulus for the secretion of gastrin.

G cells are tightly regulated by two hormones - gastrin-releasing peptide has a stimulatory effect causing the secretion of gastrin, while somatostatin is inhibitory.

[Q: 1941] OnExamination 2012 - Gastroenterology

A 40-year-old woman with a history of Crohn's disease and multiple previous operations presents to the gastroenterology clinic.

She has begun suffering from increasing symptoms of early satiety, loss of appetite, bloating and diarrhoea over the past few months. She has lost weight, and is worried as

she finds it very difficult to maintain her weight anyway.

On examination her BMI is 18.5 kg/m². Physical examination is unremarkable apart from mild abdominal distension, and a number of old scars related to previous surgery.

Investigations show:

Haemoglobin 10.2 g/dl(11.5-16.5)

Mean corpuscular volume 104 fl(80-96)

White cell count 6.1 x 10⁹/L (4-11)

ESR 11 mm/hr(<10)

Platelets 175 x 10⁹/L (150-400)

Serum Sodium 136 mmol/l (135-146)

Serum Potassium 3.9 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Serum albumin 32 g/l (35-50)

Hydrogen breath test Positive

Which of the following is the most likely diagnosis?

- 1- Bacterial overgrowth syndrome
- 2- Exacerbation of Crohn's disease
- 3- Functional diarrhoea
- 4- Pernicious anaemia
- 5- Short bowel syndrome

Answer & Comments

Answer: 1- Bacterial overgrowth syndrome

Symptoms of bloating, abdominal distension and diarrhoea are very consistent with a diagnosis of bacterial overgrowth syndrome. The hydrogen breath test further supports the diagnosis.

The fact that the ESR is normal significantly reduces the likelihood that this is an exacerbation of Crohn's.

The raised MCV is related to B12 deficiency, which is also caused by bacterial overgrowth.

Both metronidazole and tetracyclines are used in the management of the condition.

[Q: 1942] OnExamination 2012 - Gastroenterology

A 17-year-old man presents to the Emergency department complaining of intense pain on defecation, which persists for some hours after the event. The pain recurs with each bowel movement, and is so severe that he is now scared to defecate.

He is passing harder stools over the past few months and has noticed fresh blood on the paper and occasionally even drips of blood into the toilet.

From the history, which of the following is the most likely diagnosis?

- 1- Anal fissure
- 2- Crohn's disease
- 3- Irritable bowel syndrome
- 4- Rectal carcinoma
- 5- Ulcerative colitis

Answer & Comments

Answer: 1- Anal fissure

The history is of an anal fissure, which arises as a mucosal tear following passage of a hard stool. Most anal fissures occur in the posterior midline.

The majority of cases respond to conservative therapy which includes stool softeners and bulking agents.

Topical GTN treatment may also be useful for sphincter relaxation.

Surgery is reserved for resistant cases.

[Q: 1943] OnExamination 2012 - Gastroenterology

A patient is referred to the hepatology department for possible treatment of

hepatitis B.

He has stigmata of chronic liver disease. There is portal hypertension and ascites. His INR is 2.2 (<1.4) and albumin 25 g/L (37-49). HBsAg and HBeAg positive. Hepatitis C screen is negative.

What will you suggest for treatment?

- 1- Beta interferon
- 2- Tenofovir alone
- 3- Tenofovir plus interferon alpha
- 4- Ribavirin alone
- 5- Ribavirin plus interferon alpha

Answer & Comments

Answer: 2- Tenofovir alone

Beta interferon is used in the treatment of multiple sclerosis not hepatitis B.

Alpha interferon cannot be used in this case as it can initially worsen hepatic decompensation and increase the risk of sepsis in patients with cirrhosis.

Tenofovir alone is generally considered safe in decompensated hepatitis B virus (HBV) infection and should be able to produce a rapid reduction in the viral DNA load and may even produce recompensation of liver disease.

Ribavirin is used for hepatitis C infection. Its combination with interferon confers more success in treating HCV infection.

[Q: 1944] OnExamination 2012 - Gastroenterology

A 51-year-old man was brought to the Emergency department for loose stools.

He was dehydrated, weak and in shock. He had previously been complaining of large stool volumes for a one month period. Stool colour was normal. There was no history of laxative abuse and no significant past medical history.

What is the most likely diagnosis?

- 1- Carcinoid syndrome
- 2- Diabetic diarrhoea
- 3- Gastrinoma
- 4- Systemic mastocytosis
- 5- VIPoma

Answer & Comments

Answer: 5- VIPoma

VIPomas are endocrine tumours that secrete excessive amounts of VIP32 which causes a distinct syndrome characterised by large-volume watery diarrhoea, hypokalaemia, and dehydration.

This syndrome is also called Verner-Morrison syndrome, pancreatic cholera, or WDHA syndrome for watery diarrhoea, hypokalaemia, and achlorhydria, which some patients develop.

The mean age of patients is 49 years; however it can occur in children and when it does is usually caused by a ganglioneuroma or ganglioneuroblastoma.

A stool volume of less than 700 mL/d excludes the diagnosis of VIPoma.

[Q: 1945] OnExamination 2012 - Gastroenterology

A 50-year-old ex-footballer with a long history of alcohol excess presents with epigastric pain.

Which of the following suggests a diagnosis of peptic ulceration rather than chronic pancreatitis?

- 1- Back pain
- 2- Exacerbation with alcohol
- 3- Loose stool
- 4- Relieved by food
- 5- Weight loss

Answer & Comments

Answer: 4- Relieved by food

Relief with food suggests peptic (and specifically) duodenal ulceration. It is likely that food would precipitate the pain of chronic pancreatitis.

Loose stool is suggestive of pancreatitis/malabsorption. Pain referred to the back occurs in both situations and hence is not suggestive.

Weight loss can occur in both gastric ulcers and pancreatitis and is not very suggestive.

Alcohol may well exacerbate both types of pain.

[Q: 1946] OnExamination 2012 - Gastroenterology

A 30-year-old woman presents with jaundice and her investigations reveal:

Haemoglobin 9.0 g/dl(11.5-16.5)

Reticulocyte count $180 \times 10^9/L$ (25-85)

Serum bilirubin 50 $\mu\text{mol/l}$ (1-22)

Her blood film reveals the presence of spherocytes.

Which of the following is the next most useful investigation?

- 1- Abdominal ultrasound scan
- 2- Direct antiglobulin test
- 3- Glucose-6-phosphate dehydrogenase activity
- 4- Haemoglobin electrophoresis
- 5- Red cell osmotic fragility

Answer & Comments

Answer: 2- Direct antiglobulin test

The results given indicate a haemolytic anaemia of which spherocytes are typical and given the age of the patient the most likely cause is immune.

Therefore the most useful test is the direct antiglobulin test.

[Q: 1947] OnExamination 2012 - Gastroenterology

A 55-year-old female who had a long history of alcohol abuse presents with back pain and mild diarrhoea one month after having a pacemaker inserted.

On examination she had a fever of 39°C and her abdomen was soft and non-tender.

What is the most likely diagnosis?

- 1- Diverticulitis
- 2- Ischaemic colitis
- 3- Pancreatitis
- 4- Pseudomembranous colitis
- 5- Staphylococcal discitis

Answer & Comments

Answer: 5- Staphylococcal discitis

All patients with alcohol dependence have an increased risk of pancreatitis, but this is less likely without any abdominal signs.

Ischaemic colitis classically presents with bloody diarrhoea.

The prophylactic antibiotics given four weeks previously for her pacemaker insertion would not really have predisposed her to pseudomembranous colitis.

Staphylococci are skin organisms most commonly introduced during pacemaker insertion and such a discitis would present with back pain.

[Q: 1948] OnExamination 2012 - Gastroenterology

A 78-year-old female with diabetes presented with a two day history of melaena and dizziness. She had taken an unknown analgesic four days previously.

On examination she was pale with a pulse of 90 beats per minute, a blood pressure of 100/65 mmHg and a lower midline scar from an operation for intermittent claudication three months previously.

Investigations revealed:

Haemoglobin 8 g/dl(13.0-18.0)

Faecal occult blood Strongly positive

Upper gastrointestinal tract endoscopy Normal

What is the most likely cause of her upper gastrointestinal (GI) haemorrhage?

- 1- Aorto-enteric fistula
- 2- Gastric erosions
- 3- Gastric ulcer
- 4- Mallory-Weiss syndrome
- 5- Oesophageal varices

Answer & Comments

Answer: 1- Aorto-enteric fistula

The upper GI endoscopy is normal, therefore GU, gastric erosions, varices and Mallory-Weiss syndrome are unlikely.

The strongly positive faecal occult blood (FOB) suggests significant GI haemorrhage.

Aorto-enteric fistulae (AEF) are now known to occur following endovascular repair of abdominal aortic aneurysms (AAA), and secondary to aortic grafting of any kind, presumably because of mechanical forces of dislodged or migrating devices.

This patient may well have had an aorto-bifemoral graft, as treatment for peripheral vascular disease.

[Q: 1949] OnExamination 2012 - Gastroenterology

A 29-year-old male presents with symptoms of severe gastro-oesophageal reflux.

Which one of the following is most useful in assessing the role of surgery?

- 1- Cardiac sphincter manometry
- 2- Gastric emptying study
- 3- Intra-gastric pH monitoring of therapy
- 4- Oesophageal motility study
- 5- Oesophageal pH monitoring of therapy

Answer & Comments

Answer: 4- Oesophageal motility study

Laparoscopic fundoplication is the treatment of choice for patients with gastro-oesophageal reflux disease (GORD) refractory to or intolerant of, proton pump inhibitor therapy.

The patient should have had an endoscopy at least six months prior to surgery to exclude any unsuspected pathology - Barrett's oesophagus or adenocarcinoma.

An oesophageal transit study is indicated to rule out a primary motor disorder (for example, achalasia, scleroderma) when suspected and to rule out aperistalsis, which may result in post-operative dysphagia after some forms of fundoplication.

[Q: 1950] OnExamination 2012 - Gastroenterology

Which one statement is true regarding the treatment of iron deficiency anaemia?

- 1- Iron is absorbed in the distal jejunum
- 2- Absorption of iron is increased by ascorbic acid
- 3- Sustained release iron is a useful way of giving larger doses
- 4- Ferrous sulphate 200 mg has less elemental iron than the same dose of ferrous gluconate
- 5- Parenteral iron is indicated when the anaemia responds slowly to oral iron

Answer & Comments

Answer: 2- Absorption of iron is increased by ascorbic acid

- A. Iron is absorbed in the upper small intestine.
- B. Absorption of oral iron is improved by ascorbic acid.
- C. Sustained release preparations may improve tolerance of oral iron but do not aid absorption.
- D. Ferrous sulphate has more elemental iron by mass.
- E. Parenteral iron acts no faster than oral iron. It is indicated when oral iron cannot be tolerated or is not absorbed.

[Q: 1951] OnExamination 2012 - Gastroenterology

A 24-year-old man with chronic diarrhoea and malabsorption is suspected of having coeliac disease.

A jejunal biopsy is taken.

Which of the following findings would be expected in coeliac disease?

- 1- Appearances may resemble severe tropical sprue
- 2- Characteristically shows epithelial cells distended with fat globules
- 3- Shows fissures penetrating into the submucosa
- 4- Shows flattening of the crypts
- 5- Shows leaf-shaped villi

Answer & Comments

Answer: 1- Appearances may resemble severe tropical sprue

In coeliac disease the villi are shortened and the crypts lengthened with increased lymphocytic infiltrate.

Tropical sprue may also cause subtotal villous atrophy.

Fissures are not found and epithelial cells are normal.

[Q: 1952] OnExamination 2012 - Gastroenterology

Which of the following is activated by cholera toxin?

- 1- Adenylate cyclase
- 2- Guanylate cyclase
- 3- Peroxisome proliferator receptor (PPAR) gamma
- 4- Sodium/potassium ATPase
- 5- The glucose-sodium transporter

Answer & Comments

Answer: 1- Adenylate cyclase

Cholera toxin activates adenylate cyclase with generation of cyclic adenosine monophosphate (cAMP).

[Q: 1953] OnExamination 2012 - Gastroenterology

Which of the following concerning the conjugation of bilirubin is correct?

- 1- It is catalysed by a glucuronyl transferase
- 2- It occurs in the Kupfer cells of the liver
- 3- It is increased by valproate
- 4- It is inhibited by rifampicin
- 5- It is impaired in Dubin-Johnson syndrome

Answer & Comments

Answer: 1- It is catalysed by a glucuronyl transferase

- B. Bilirubin is conjugated in the hepatocytes.
- C. Sodium valproate is an enzyme inhibitor.
- D. Rifampicin is an enzyme inducer.

E. In Dubin-Johnson syndrome conjugation is normal, but excretion from the hepatocyte into the bile is impaired, resulting in a conjugated bilirubinaemia.

(In Gilbert's syndrome, bilirubin cannot enter the hepatocyte and unconjugated bilirubinaemia occurs, as it does in Crigler-Najjar syndrome, where bilirubin does not conjugate due to malproduced bilirubin glucuronyl transeferase.)

[Q: 1954] OnExamination 2012 - Gastroenterology

A 46-year-old man with a family history of haemochromatosis presented to outpatients for advice.

Investigations revealed.

Serum ferritin 453 g/L (15-300)

Serum iron 29 mol/L (12-30)

Serum iron binding capacity 46 mol/L (45-75)

Iron saturation 63 per cent (20-50)

What is the most appropriate next step in management?

- 1- Arrange for DNA analysis
- 2- Begin a venesection programme
- 3- Monitor his serum ferritin regularly
- 4- Take no action unless the iron saturation exceeds 90 per cent
- 5- Undertake a liver biopsy

Answer & Comments

Answer: 1- Arrange for DNA analysis

This man is likely to have hereditary haemochromatosis (HHC).

Homozygous mutation (C282Y mutation) of the human iron gene (HFE gene) accounts for over 80% of cases of HHC.

The diagnosis is made on DNA analysis.

If the diagnosis is confirmed then treatment with venesection to achieve and maintain a ferritin of 50-100µg/l is indicated.

A liver biopsy is not required to make the diagnosis of HHC although may be indicated for prognostic reasons if cirrhosis is suspected.

[Q: 1955] OnExamination 2012 - Gastroenterology

A 75-year-old woman is admitted with headache and vomiting. She denies abdominal pain. She reports weight loss of one stone over the last six weeks.

On further questioning it becomes apparent that she has noticed the vomitus contains food from several days ago. Abdominal x ray reveals a prominent gastric bubble.

Which of the following is the most likely diagnosis?

- 1- Acute cholecystitis
- 2- Colon carcinoma
- 3- Gastric outflow obstruction
- 4- Peptic ulceration
- 5- Raised intracranial pressure

Answer & Comments

Answer: 3- Gastric outflow obstruction

Vomiting of food from several meals ago suggests gastric stasis or gastric outflow obstruction. In this case, with the history of weight loss, an underlying malignancy such as antral gastric carcinoma is likely.

Patients with acute cholecystitis typically have abdominal pain, usually in the right upper quadrant or epigastrium. Nausea and vomiting may also occur. Patients are often febrile.

Abdominal pain and change in bowel habit are the common clinical presentations of colorectal cancer.

Upper abdominal pain or discomfort is the most prominent symptom in patients with

peptic ulcer disease; occasionally there may be vomiting.

Clinical features of raised intracranial pressure include headache, reduced consciousness and vomiting. Signs include sixth cranial nerve palsy and papilloedema. Hypertension and bradycardia (Cushing's reflex) may also be seen.

Reference:

Firth JD, Keshav SC, Atkinson RJ, Hirschfield GM, Leeds JS, Medical Masterclass Gastroenterology and Hepatology, Royal College of Physicians of London 2008.

[Q: 1956] OnExamination 2012 - Gastroenterology

You are asked to review the blood results of an 18-year-old woman who is known to have anorexia nervosa. She is under close review by the dietician who has asked you to ensure electrolytes are checked daily.

Which of the following is a feature of the potentially life-threatening complication this lady is at risk of developing?

- 1- Hypercalcaemia
- 2- Hyperkalaemia
- 3- Hypermagnesaemia
- 4- Hyperphosphataemia
- 5- Hypophosphataemia

Answer & Comments

Answer: 5- Hypophosphataemia

There are potentially fatal complications which can result from refeeding patients who have had periods of starvation, including those with anorexia nervosa. Hypophosphataemia is a key feature of refeeding syndrome.

Refeeding syndrome is defined as the clinical complications which arise as a consequence of fluid and electrolyte shifts during the nutritional support of malnourished patients.

Refeeding syndrome comprises

Hypophosphataemia

Hypokalaemia

Hypomagnesaemia

Deficiencies in vitamins, for example, thiamine and trace minerals and

Fluid overload with oedema.

The fluid retention may contribute to cardiac failure.

[Q: 1957] OnExamination 2012 - Gastroenterology

A 17-year-old man presents to the clinic with intermittent severe pain passing a motion, accompanied by bright red rectal bleeding. The pain often lasts for hours afterwards and he is afraid of going to the toilet.

He says he does not like eating fruit and vegetables and that his motion is usually very hard and he only passes faeces every two to three days. He has not lost any weight and otherwise feels well, holding down a job in a computer shop whilst doing his A levels.

His BP is 122/72mmHg, pulse is 72, general physical examination is normal.

Investigations show

Hb 13.1 g/dl(13.5-18)

WCC $6.2 \times 10^9/L$ (4-10)

PLT $203 \times 10^9/L$ (150-400)

Na 138 mmol/l (134-143)

K 4.4 mmol/l (3.5-5)

Cr 102 $\mu\text{mol/l}$ (60-120)

Given these findings, which of the following is the most likely diagnosis?

1- Anal fissure

2- Anal fistula

3- Irritable bowel syndrome

4- Piles

5- Ulcerative colitis

Answer & Comments

Answer: 1- Anal fissure

Paroxysms of pain, accompanied by episodes of bleeding are typical of anal fissure. The initiating factor for formation of an anal fissure is thought to be passage of a particularly hard motion which leads to trauma.

In most people acute tears in the anal mucosa heal spontaneously but in some they lead to a chronic anal fissure.

Stool softeners are the mainstay of therapy, with surgery reserved for those who fail medical intervention.

[Q: 1958] OnExamination 2012 - Gastroenterology

A 35-year-old woman comes to the clinic for review. She has been suffering from abdominal bloating, very strongly smelling bowel gas and intermittent diarrhoea over the past two months since returning from honeymoon in Africa.

On examination her BP is 125/82 mmHg, and her temperature is 37.2°C. Her BMI is 23 kg/m², and her abdomen is mildly distended.

Investigations show

Hb 11.1 g/dl(13.5-18)

WCC $8.1 \times 10^9/L$ (4-10)

PLT $271 \times 10^9/L$ (150-400)

Na 139 mmol/l (134-143)

K 4.6 mmol/l (3.5-5)

Cr 104 $\mu\text{mol/l}$ (60-120)

Stool sample: Trophozoites in the fresh stool sample.

Which of the following is the most likely diagnosis?

1- Giardiasis

- 2- Schistosomiasis
- 3- Shigellosis
- 4- Tropical sprue
- 5- Whipple's disease

Answer & Comments

Answer: 1- Giardiasis

The history of abdominal bloating with intermittent diarrhoea and strong smelling bowel gas is typical of giardiasis. As long as a fresh stool sample is examined, trophozoites are found in 60%+ of samples.

A single dose of tinidazole or a course of metronidazole is the treatment of choice.

Adequate sanitation is the key to reducing the risk of infection, although the infection rate from uncooked foods is high in areas where Giardia is endemic.

[Q: 1959] OnExamination 2012 - Gastroenterology

A 72-year-old man is discharged from hospital following a stroke.

During his stay he was started on several new medications. He presents with diarrhoea.

Which of the following medications is most likely to be the cause?

- 1- Clopidogrel
- 2- Enalapril
- 3- Metformin
- 4- Pioglitazone
- 5- Simvastatin

Answer & Comments

Answer: 3- Metformin

Although all the medications listed could cause gastrointestinal disturbances it is metformin that is by far the most likely.

[Q: 1960] OnExamination 2012 - Gastroenterology

Which one of the following require urgent referral for upper endoscopy?

- 1- A 35-year-old male who has a history of waterbrash and dyspepsia which has responded to a course of ranitidine but since stopping has recurred
- 2- A 45-year-old male with a one month history of persistent dyspepsia
- 3- A 56-year-old male with a one month history of dyspepsia and a pulsatile central abdominal mass
- 4- A 62-year-old male with a three month history of unexplained weight loss, tenesmus and a right abdominal mass
- 5- A 73-year-old male with a three month history of dyspepsia which has failed to respond to a course of proton pump inhibitors

Answer & Comments

Answer: 5- A 73-year-old male with a three month history of dyspepsia which has failed to respond to a course of proton pump inhibitors

Criteria for referral for urgent endoscopy include

Dysphagia (at any age)

Dyspepsia at any age combined with any one of weight loss, anaemia or vomiting

Dyspepsia in a patient aged 55 or above with onset of dyspepsia within one year and persistent symptoms

Dyspepsia with one of Barrett's oesophagus, familial hypercholesterolaemia (FH) of upper gastrointestinal (GI) carcinoma, pernicious anaemia or upper GI surgery more than 20 years ago

Jaundice

Abdominal mass.

With regard to the presented cases, the 56-year-old man has dyspepsia with what seems to be an aortic aneurysm. This requires an ultrasound and vascular opinion.

In the case of unexplained weight loss, tenesmus and upper right mass the problem is likely to be a colonic carcinoma.

[Q: 1961] OnExamination 2012 - Gastroenterology

A 75-year-old patient presents with watery diarrhoea.

He is passing large volumes of watery diarrhoea, approximately 3 litres a day, with no noticeable blood. It has been present for approximately five months and is gradually becoming more frequent. It often wakes him at night with the urge to defecate.

Liver function tests, calcium and urea and electrolytes are normal. Stool microscopy and culture are normal, and Clostridium difficile toxin is negative.

A flexible sigmoidoscopy is organised, and the investigator reports to you that the large bowel appears normal.

From which of the following treatments may this patient benefit?

- 1- Gluten free diet
- 2- High fibre diet
- 3- Low residue diet
- 4- Oral cholestyramine
- 5- Oral prednisolone

Answer & Comments

Answer: 4- Oral cholestyramine

In the absence of infection and with this typical history in an elderly individual the diagnosis is likely to be microscopic colitis.

This does not fulfil the ROME II criteria for irritable bowel syndrome (IBS).

Although coeliac disease is a possibility, this is unlikely, given the patient's age, and the presentation.

Microscopic colitis can only be diagnosed by colonoscopy and mucosal biopsy because, macroscopically, the colon appears normal. The incidence is increasing as the use of colonoscopy increases - almost certainly due to better diagnostic workup.

Microscopic colitis is diagnosed in up to 10% of all patients undergoing colonoscopy for unexplained diarrhoea, an incidence which increases to 20% in those aged over 70 years.

Microscopic colitis may be associated with bile acid malabsorption and may respond to either budesonide or cholestyramine.

[Q: 1962] OnExamination 2012 - Gastroenterology

A 50-year-old male with a history of alcohol dependence syndrome presents with a two week history of confusion.

Which of the following strongly suggests a diagnosis of Korsakoff's psychosis?

- 1- Delusional jealous beliefs
- 2- Epileptic seizures
- 3- Impaired long term memory
- 4- Inventing recent events
- 5- Visual hallucinations

Answer & Comments

Answer: 4- Inventing recent events

Korsakoff's is associated with short term memory loss with subsequent compensatory confabulation by the patient.

Other symptoms may include:

Delirium

Anxiety

Fear

Depression

Confusion

Delusions

Insomnia.

Painful extremities, sometimes bilateral wrist drop but more frequently bilateral foot drop with pain or pressure over the long nerves are also symptoms.

The treatment is intravenous thiamine and attention to the consequences of alcohol withdrawal.

[Q: 1963] OnExamination 2012 - Gastroenterology

A 55-year-old male is admitted with vomiting.

He has a long history of alcohol abuse, appears slightly jaundiced and is dishevelled and unkempt. He was started on an intravenous glucose infusion and diazepam and he symptomatically improved.

One day later he becomes confused, develops vomiting, diplopia and is unable to stand.

What is the most likely diagnosis?

- 1- Benzodiazepine intoxication
- 2- Delirium tremens
- 3- Hepatic encephalopathy
- 4- Subdural haematoma
- 5- Vitamin B deficiency

Answer & Comments

Answer: 5- Vitamin B deficiency

This patient is manifesting signs of Wernicke's encephalopathy with confusion, oculomotor signs and ataxia affecting gait and stance. Wernicke's encephalopathy is a medical emergency, requiring urgent intravenous thiamine.

The episode has been precipitated by intravenous dextrose administration which

has exhausted his vitamin B reserves, hence B vitamins must be administered to all alcoholic patients requiring dextrose.

[Q: 1964] OnExamination 2012 - Gastroenterology

A 67-year-old man with known aortic valvular disease is admitted with deteriorating dyspnoea.

Investigations show:

Haemoglobin 9 g/dL (12-16)

MCV 70 fL (80-96)

Upper gastrointestinal tract endoscopy: Normal

Duodenal biopsy: Normal

Which one of the following investigations is most likely to provide the diagnosis?

- 1- Barium enema
- 2- Colonoscopy
- 3- CT abdomen
- 4- Mesenteric angiography
- 5- Small bowel enema

Answer & Comments

Answer: 2- Colonoscopy

In the older age group investigation of the lower gastrointestinal (GI) tract is vital to exclude a lower GI malignancy.

CT scans do not demonstrate colonic pathology as well as colonoscopy which is still considered the gold standard.

Angiography is only helpful if the patient is bleeding briskly at the time of the examination.

[Q: 1965] OnExamination 2012 - Gastroenterology

A 24-year-old woman who has a long history of ulcerative colitis and takes mesalazine 3 g

per day discovers that she is 10 weeks pregnant.

She is also a smoker of 15 cigarettes daily. She now presents with a deterioration of symptoms with six bloody stools per day.

Which one of the following statements is correct?

- 1- Azathioprine would be contraindicated
- 2- Initiating an elemental diet predisposes to fetal malnutrition
- 3- Mesalazine therapy should be withdrawn
- 4- Steroid therapy is contraindicated
- 5- Termination of the pregnancy is advised

Answer & Comments

Answer: 1- Azathioprine would be contraindicated

Azathioprine should not generally be started in pregnancy.

Well controlled ulcerative colitis is more important for the baby from a nutritional point of view.

An elemental diet simply contains pre-digested food and would not lead to fetal malnutrition.

The safety of the 5-aminosalicylic acid (5-ASA) drugs in pregnancy is best supported by the data on Salazopyrin which have been available for the longest.

[Q: 1966] OnExamination 2012 - Gastroenterology

A 22-year-old man presented to the casualty department one week after returning from a six month visit to Pakistan.

He complained of fever, rigors and headache.

On examination he was febrile (38°C) with a blood pressure of 115/65 mmHg, and a pulse of 100/minute. His abdomen was tender in the right upper quadrant.

Investigations showed:

Hb 11.0 g/dL (13.0-18.0)

WBC $15.5 \times 10^9/L$ (4-11 $\times 10^9$)

Neutrophils $13.5 \times 10^9/L$ (1.5-7 $\times 10^9$)

Platelets $350 \times 10^9/L$ (150-400 $\times 10^9$)

Blood film No malaria parasites seen

Alk Phos 450 U/L (45-105)

AST 50 U/L (1-31)

CRP 88 mg/L (<10)

Stool culture Negative

Chest x ray: Small right pleural effusion noted

Which of the following investigations would be of most diagnostic value?

- 1- Hepatitis E serology
- 2- Sigmoidoscopy
- 3- Stool microscopy for ova, cysts and parasites
- 4- Typhoid serology
- 5- Ultrasound scan of the abdomen

Answer & Comments

Answer: 5- Ultrasound scan of the abdomen

The presentation is not consistent with hepatitis E infection.

Typhoid serology is unreliable.

The differential diagnosis is mainly pyogenic or amoebic liver abscess.

Pyogenic abscesses present with:

Swinging pyrexia

Neutrophilia and

High inflammatory markers.

Right-sided pleural effusions are common and blood cultures are often positive.

The presentation of amoebic liver abscess (ALA) is very similar. Most patients do not have bowel symptoms at any time and

amoebic cysts are found in stool in less than 50% of proven cases of ALA.

Serology is the mainstay of diagnosis.

Ultrasound scan would confirm most moderate-sized to large liver abscesses and could guide a diagnostic aspiration.

Small lesions are best demonstrated by computerised tomography (CT) or magnetic resonance imaging (MRI).

[Q: 1967] OnExamination 2012 - Gastroenterology

A 60-year-old woman with known alcoholic liver cirrhosis presents with vague abdominal pains, malaise and nausea.

She has been abstinent since she was diagnosed eight months ago.

On examination she had moderate ascites and mild, generalised abdominal tenderness.

Investigations show:

Haemoglobin 11.2 g/dL (11.5-16.5)

WCC $15 \times 10^9/L$ ($4-11 \times 10^9$)

Prothrombin time 21 secs (11.5-15.5)

Serum Albumin 28 g/L (37-49)

Serum total bilirubin 56 $\mu\text{mol/L}$ (1-22)

Ascitic fluid protein 26 g/L

Ascitic fluid amylase Normal

Ascitic fluid white cell count $500 \times 10^9/L$

What is the most likely reason for her current problem?

- 1- Hepatic vein thrombosis
- 2- Pancreatic pseudocyst rupture
- 3- Portal vein thrombosis (PVT)
- 4- Primary liver cancer
- 5- Spontaneous bacterial peritonitis

Answer & Comments

Answer: 5- Spontaneous bacterial peritonitis

The high white cell count in the ascites makes spontaneous bacterial peritonitis (SBP) much more likely than Budd-Chiari syndrome (BCS), PVT, hepatocellular carcinoma (HCC), or a ruptured pancreatic pseudocyst.

Abdominal pain is often only mild, or even absent in SBP, with patients often presenting with otherwise unexplained hepatic decompensation.

[Q: 1968] OnExamination 2012 - Gastroenterology

Which of the following is true concerning a hepatitis E infection?

- 1- CT scan of the liver with contrast shows diagnostic appearances.
- 2- It can be transmitted with hepatitis B.
- 3- It does not result in a carrier state.
- 4- It is a recognised cause of chronic liver disease.
- 5- The incidence of chronic liver disease is reduced by administration of alpha interferon.

Answer & Comments

Answer: 3- It does not result in a carrier state.

Five hepatitis viruses form a heterogeneous group causing similar clinical illnesses.

Hepatitis A, C, D, and E are all ribonucleic acid (RNA) viruses coming from four different families; and hepatitis B is a deoxyribonucleic acid (DNA) virus.

Hepatitis A and E cause acute illness, with the former causing most hepatitis in childhood and hepatitis E being very rare.

Hepatitis B, C, and D cause chronic morbidity and mortality, with B causing a third of cases, hepatitis C a fifth of cases, and D being very rare.

Hepatitis D illness cannot occur without B as a helper virus.

Hepatitis B can be treated with interferon-alpha, which improves liver disease.

[Q: 1969] OnExamination 2012 - Gastroenterology

Which of the following statements regarding colon cancer is correct?

- 1- In non-familial cases gene mutations in the cancer cells are unusual
- 2- In familial cases the inheritance pattern is typically autosomal recessive
- 3- It occurs most commonly in the ascending colon
- 4- It is a characteristic feature of the Peutz-Jegher syndrome
- 5- In familial polyposis coli the increased cancer risk is due to inheritance of a mutated suppressor gene

Answer & Comments

Answer: 5- In familial polyposis coli the increased cancer risk is due to inheritance of a mutated suppressor gene

A. Quantitative and qualitative alterations in gene expression accumulate in colorectal cancer cells. These include alterations of proto-oncogene expression and chromosomal abnormalities (deletions at 17p and 18q are seen in 70% of colorectal carcinomas).

B. Both familial polyposis coli and Gardner's syndrome are autosomal dominant.

C. The rectum and sigmoid colon are the commonest sites.

D. Peutz-Jegher's syndrome is dominantly inherited pigmentation of skin and mucous membranes and hamartomatous polyps in the stomach and larger intestine. The polyps only rarely undergo malignant change.

E. An allelic deletion of a putative tumour suppressor gene located 5q21-q22. Familial adenomatous polyposis (FAP) is an autosomal

dominant disorder causing extensive adenomatous polyps of the colon and early onset colorectal cancer.

[Q: 1970] OnExamination 2012 - Gastroenterology

Which of the following statements is correct of hepatitis C virus infection?

- 1- Cell cultures of virus are routinely used to assess response to drug therapy
- 2- High antibody titres are an indication for therapy
- 3- Less than 5% of cases lead to chronic infection
- 4- Treatment with ribavirin and interferon alpha is more effective than interferon alpha alone
- 5- More likely to be transmitted by the sexual route than hepatitis B virus

Answer & Comments

Answer: 4- Treatment with ribavirin and interferon alpha is more effective than interferon alpha alone

In hepatitis C infection, the criteria for treatment are:

Abnormal liver function tests and

Detectable hepatitis C ribonucleic acid (RNA) in plasma with

Evidence of moderate inflammation on liver biopsy.

Response to therapy is determined by normalisation of hepatic transaminases and undetectability of hepatitis C RNA in plasma.

Hepatitis C is generally transmitted by inoculation or vertically from mother-to-child.

In contrast to hepatitis B, sexual transmission is uncommon.

Around 85% of acute hepatitis C infections lead to chronic infection.

Treatment with interferon alpha alone has around a 10-15% success rate in achieving long term undetectability of plasma hepatitis C RNA.

Combination treatment with ribavirin and interferon alpha has been found to have approximately a 45% success rate.

[Q: 1971] OnExamination 2012 - Gastroenterology

A 45-year-old woman is diagnosed with a duodenal ulcer.

Which one of the following is the most sensitive test for detecting current infection with Helicobacter pylori?

- 1- Culture of a gastric biopsy
- 2- Gastric fundal biopsy
- 3- Presence of Helicobacter pylori serum antibodies
- 4- The (13C) urea breath test
- 5- Urease test on gastric biopsy

Answer & Comments

Answer: 4- The (13C) urea breath test

The gold standard for diagnosis of H. pylori remains culture of a gastric biopsy. Yet this test is only 72% sensitive.

The rapid urease test on a biopsy is 80-95% sensitive and 95-100% specific. Histology is 80-90% sensitive and 95% specific.

The urease breath test is approximately 95% sensitive and 98-100% specific. Therefore the most specific and clinically applicable would be the urease breath test.

The presence of IgG antibodies to H. pylori could indicate previous infection.

A gastric antral biopsy can give false negative results following proton pump inhibitor (PPI) treatment.

[Q: 1972] OnExamination 2012 - Gastroenterology

A 29-year-old man presents with anaemia, bleeding tendency, diarrhoea and abdominal pain.

Examination reveals a palpable mass in the right lower quadrant and anal skin tags.

What is the most likely underlying condition?

- 1- Chronic pancreatitis
- 2- Coeliac disease
- 3- Crohn's disease
- 4- Intestinal lymphoma
- 5- Ulcerative colitis

Answer & Comments

Answer: 3- Crohn's disease

Crohn's disease commonly presents with diarrhoea, abdominal pain and weight loss. It can affect the whole gastrointestinal tract, the commonest being ileocolitis.

Anaemia is usually due to blood loss and less commonly B12/folate malabsorption.

An abdominal mass is often palpable in the presence of small bowel disease, which can lead to vitamin K malabsorption.

Anal tags, fissures, perianal fistulae and abscesses are associated with Crohn's disease and not ulcerative colitis.

[Q: 1973] OnExamination 2012 - Gastroenterology

A 43-year-old male presents with weight loss and watery diarrhoea.

Investigations reveal hypokalaemia with a pancreatic mass.

Which of the following would support the diagnosis of a VIPoma?

- 1- Achlorhydria
- 2- Hypoglycaemia
- 3- Increased pancreatic polypeptide
- 4- Migratory erythema
- 5- Pellagra

Answer & Comments

Answer: 1- Achlorhydria

Achlorhydria is classically associated with VIPoma together with profuse diarrhoea, a hypokalaemic acidosis and hyperglycaemia.

Migratory erythema is associated with a glucagonoma.

Although raised pancreatic polypeptide is seen with a VIPoma it is unusual and is more commonly associated with its own syndrome.

Pellagra is associated with the carcinoid syndrome.

[Q: 1974] OnExamination 2012 - Gastroenterology

Which of the following is correct regarding reflux of gastric contents into the oesophagus?

- 1- Can be excluded by a normal appearance at endoscopy
- 2- Can be improved by Helicobacter pylori eradication
- 3- Is a cause of asthma
- 4- Is neutralised by bicarbonate secreted by the oesophageal mucosa
- 5- Occurs during transient relaxation of the lower oesophageal sphincter

Answer & Comments

Answer: 5- Occurs during transient relaxation of the lower oesophageal sphincter

Diagnosis is based predominantly on history, with a proportion of patients with reflux disease having a normal endoscopy.

H. pylori eradication is indicated in long term healing of gastric and duodenal ulceration, but not reflux disease.

Whilst it is true the oesophagus secretes bicarbonate, the statement here is not true. It is a fairly weak defence, and is not able to neutralise any gastric contents which reflux up the oesophagus. More effective Brunner's glands which secrete alkaline mucus are found in the duodenum.

The link between asthma and gastro-oesophageal reflux disease is a complex one, but a recent systemic review indicates that there is a significant association but there is a lack of data on the direction of causality. It is therefore not possible to conclude that GORD is a cause of asthma.

[Q: 1975] OnExamination 2012 - Gastroenterology

A 55-year-old man is admitted with frank haematemesis.

The patient is a poor historian but a recent discharge summary reports he was under the gastroenterology team two months previously with decompensated alcoholic liver disease.

On examination he appears anxious; he is tachycardic at 105 beats per minute with a blood pressure of 122/90 mmHg. There is evidence of palmar erythema and spider naevi. Abdominal examination reveals hepatosplenomegaly and mild ascites.

There is no evidence of melaena on rectal examination. He has a further episode of haematemesis while in the Emergency department which the nursing staff estimates at approximately 500 ml.

Which class of hypovolaemic shock is applicable to this patient's clinical state?

- 1- Class I

- 2- Class II
- 3- Class III
- 4- Class IV
- 5- Class V

Answer & Comments

Answer: 2- Class II

Class II of hypovolaemic shock by blood loss in adults is where there is 750-1500 ml blood loss with 15-30% loss of circulating blood volume. Systolic blood pressure may be normal but the diastolic is raised, heart rate is 100-120 beats per minute. Patients may have a normal respiratory rate but they are anxious or aggressive in view of the hypovolaemia.⁴

This patient is likely to have had a variceal haemorrhage. There are four classes of hypovolaemic shock by blood loss in adults - I to IV (not five). The criteria are determined by volume of blood lost, vital signs and conscious state.⁴

Classification of haemorrhage:

Parameter	I	II	III	IV
Blood loss (ml)	<750	750-1500	1500-2000	>2000
Blood loss (%)	<15%	15-30%	30-40%	>40%
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14-20	20-30	30-40	>35
Urine output (ml/hour)	>30	20-30	5-15	Negligible
CNS symptoms	Normal	Anxious	Confused	Lethargic

CNS = central nervous system.

Modified from Committee on Trauma [Committee on Trauma Advanced Trauma Life Support Manual. Chicago: American College of Surgeons; 1997. pp. 103-112.] 4

[Q: 1976] OnExamination 2012 - Gastroenterology

A 45-year-old woman presents with pruritis.

On examination she has clubbing, palmar erythema and spider naevi. There is also evidence of excoriations and xanthelasma.

Blood results demonstrate deranged liver function tests with a predominantly cholestatic picture but the abdominal ultrasound scan is normal. A subsequent autoimmune screen is positive for antimitochondrial antibodies.

Given the likely diagnosis, which of the following HLA antigens is associated with this disease?

- 1- HLA-A3
- 2- HLA-B5
- 3- HLA-B27
- 4- HLA-B35
- 5- HLA-DR8

Answer & Comments

Answer: 5- HLA-DR8

HLA-A3 is associated with haemochromatosis.

HLA-B5 is associated with Behcet's disease.

Subacute thyroiditis has an association with HLA-B35.

Ankylosing spondylitis is associated with HLA-B27.

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 1977] OnExamination 2012 - Gastroenterology

Which of the following dermatological conditions is associated with oesophageal carcinoma?

- 1- Acanthosis nigricans
- 2- Ichthyosis
- 3- Necrolytic migratory erythema
- 4- Tylosis

5- Vasculitis

Answer & Comments

Answer: 4- Tylosis

Acanthosis nigricans is associated with gastric adenocarcinoma.

Ichthyosis is associated with lymphoma.

Glucagonoma is associated with necrolytic migratory erythema.

Malignancy-associated vasculitis is associated with haematological rather than solid malignancies.

[Q: 1978] OnExamination 2012 - Gastroenterology

A 23-year-old man presents with steatorrhoea and weight loss.

On examination he is found to have a vesicular rash over his elbows and knees which he describes as extremely pruritic.

Which of the following immunoglobulins is characteristically present at the dermo-epidermal junction?

- 1- IgA
- 2- IgD
- 3- IgE
- 4- IgG
- 5- IgM

Answer & Comments

Answer: 1- IgA

Dermatitis herpetiformis is characterised by IgA at the dermo-epidermal junction.

Dermatitis herpetiformis is associated with coeliac disease which is the underlying diagnosis in this patient.

The rash which is pruritic and vesicular is found over the elbows, knees, buttocks,

sacrum, trunk, face and neck. Treatment is with dapsone and a gluten-free diet.

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 1979] OnExamination 2012 - Gastroenterology

A 28-year-old woman presents with a six month history of diarrhoea and weight loss.

On examination her abdomen is mildly distended. She is found to be anaemic, liver function tests are abnormal and iron and folate levels are both low.

Tissue transglutaminase antibody level is elevated and duodenal biopsies demonstrate increased intraepithelial lymphocytes and villous atrophy consistent with a diagnosis of coeliac disease.

Which cell type is responsible for the hypersensitivity response against gluten?

- 1- B cell
- 2- Macrophage
- 3- Monocytes
- 4- Natural killer (NK) cell
- 5- T cell

Answer & Comments

Answer: 5- T cell

Coeliac disease results from small bowel inflammation and atrophy due to T cell mediated hypersensitivity reaction to the alpha-gliadin component of gluten.⁹

[Q: 1980] OnExamination 2012 - Gastroenterology

Which of the following drugs is an inhibitor of cytochrome P450 hepatic enzymes?

- 1- Carbamazepine
- 2- Griseofulvin

- 3- Omeprazole
- 4- Phenytoin
- 5- Rifampicin

Answer & Comments

Answer: 3- Omeprazole

The correct answer is omeprazole.

The remainder of the listed options are all cytochrome P450 inducers.

[Q: 1981] OnExamination 2012 - Gastroenterology

Which of the following demonstrates autosomal co-dominant inheritance?

- 1- Alpha-1-antitrypsin deficiency
- 2- Cowden's disease
- 3- Familial adenomatous polyposis
- 4- Hereditary haemorrhagic telangiectasia
- 5- Peutz-Jeghers syndrome

Answer & Comments

Answer: 1- Alpha-1-antitrypsin deficiency

Alpha-1-antitrypsin (A1AT) deficiency is an autosomal co-dominant disorder - both alleles contribute to the phenotype. The most common allele is M (normal), whilst there are over 100 abnormal alleles (leading to decreased A1AT levels) the most common are Z and S. Individuals with a single normal allele may have reduced levels of A1AT but still produce sufficient normal protein to prevent development of a disease phenotype, this is why some texts will refer to the condition as autosomal recessive. In the disease state there is impaired cellular transport of alpha-1-antitrypsin leading to accumulation within the liver and hepatic injury.

Cowden's disease is an autosomal disorder resulting in multiple hamartomas of skin and mucous membranes.

Familial adenomatous polyposis is the commonest adenomatous polyposis syndrome demonstrating autosomal dominant inheritance.

Hereditary haemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) demonstrates autosomal dominant inheritance and is characterised by telangiectasia affecting the skin and mucous membranes; severe gastrointestinal haemorrhage may occur.

Peutz-Jeghers syndrome demonstrates autosomal dominant inheritance. There is characteristic mucocutaneous pigmentation; polyps can occur anywhere in the gastrointestinal tract but are commonly in the small bowel.

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 1982] OnExamination 2012 - Gastroenterology

A 54-year-old man comes to the gastroenterology clinic for follow up of his ulcerative colitis. Over the past few months he has suffered problems with increasing lethargy, and most recently has been off his food and has begun to suffer from intense itching.

On examination his BP is 145/82 mmHg and pulse 78. He has mildly jaundiced sclerae, and some scratch marks, predominantly on his arms. The rest of the physical examination was unremarkable.

Investigations showed

Haemoglobin 12.0 g/dl(13.5-17.7)

White cells $7.8 \times 10^9/L$ (4-11)

Platelets $189 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

Albumin 35 g/l (35-50)

Alanine aminotransferase 85 U/l (5-40)

Alkaline phosphatase 395 U/l (39-117)

pANCA Positive

Which of the following is the most likely diagnosis?

- 1- Autoimmune hepatitis
- 2- Churg-Strauss syndrome
- 3- Pancreatic carcinoma
- 4- Primary biliary cirrhosis
- 5- Primary sclerosing cholangitis

Answer & Comments

Answer: 5- Primary sclerosing cholangitis

This man's history of lethargy and itching and a blood picture consistent with obstructive liver disease is typical of the condition.

In total between 75 and 90% of patients with primary sclerosing cholangitis (PSC) are thought to have co-existent inflammatory bowel disease, although only around 4% of patients with inflammatory bowel disease develop the condition.

There is often an increase in IgM; and pANCA, aCL antibodies, and ANA are present in up to 84%, 66%, and 53% of patients, respectively.

Endoscopic retrograde cholangiopancreatography (ERCP), the gold standard investigation, demonstrates multiple intrahepatic and extrahepatic bile duct strictures and dilatations, although the non-invasive magnetic resonance cholangiopancreatography (MRCP) is often performed initially.

PSC is chronically progressive with median time to liver failure put at around 12 years. Patients are additionally at increased risk of developing cholangiocarcinoma.

[Q: 1983] OnExamination 2012 - Gastroenterology

In which part of the body is conjugated bilirubin metabolised to urobilinogen?

- 1- Common bile duct
- 2- Hepatic sinusoids
- 3- Large intestine
- 4- Small intestine
- 5- Splenic macrophages

Answer & Comments

Answer: 3- Large intestine

Unconjugated bilirubin is conjugated to glucuronic acid in the hepatocyte.

Conjugated bilirubin passes into the enterohepatic circulation and the bilirubin which evades this system is metabolised by bacteria, primarily in the large intestine, to urobilinogen, then stercobilinogen and eventually oxidised to stercobilin.

Stercobilin gives faeces its brown colour.

[Q: 1984] OnExamination 2012 - Gastroenterology

A 17-year-old girl is commenced on nasogastric feeding due to severe anorexia nervosa. Five days later she becomes increasingly confused.

On examination she was afebrile, appeared appropriately hydrated, with a pulse of 98 beats per minute and blood pressure 96/60 mmHg.

Which one of the following investigations should be requested forthwith?

- 1- Arterial blood gases
- 2- Phosphate
- 3- Serum calcium
- 4- Serum magnesium
- 5- Vitamin B concentrations

Answer & Comments

Answer: 2- Phosphate

The patient appears to have developed the refeeding syndrome.

Refeeding malnourished patients increases basal metabolic rate, with glucose being the predominant energy source.

This anabolic response causes intracellular movement of minerals, and serum levels may fall significantly. These rapid changes in metabolism and electrolyte movement may lead to severe cardiorespiratory and neurological problems resulting in:

Cardiac and respiratory failure

Oedema

Lethargy

Confusion

Coma

Convulsions

Death.

The symptoms of the refeeding syndrome are thought to be due predominantly to hypophosphataemia, but metabolic changes in potassium, magnesium, glucose, and thiamine can also contribute.

The probable answer here is therefore phosphate as hypophosphataemia seems probable.

Calcium depletion is possible but there is absence of tetany.

Zinc deficiency causes skin rashes periorally and around nostrils.

It is extremely difficult to measure vitamin B concentrations, plus her presentation does not sound like Wernicke's neuro-ophthalmological features.

[Q: 1985] OnExamination 2012 - Gastroenterology

Which of the following statements regarding jejunal biopsy is correct?

- 1- Electron microscopy is necessary to confirm the presence of villous atrophy
- 2- Sub-total villous atrophy is diagnostic of gluten-sensitive enteropathy and is not found in other conditions
- 3- It is contraindicated over the age of 70 years
- 4- In tropical countries apparently healthy people have a mucosal structure which would be regarded as abnormal in Europe
- 5- It can be used to diagnose Whipple's disease

Answer & Comments

Answer: 5- It can be used to diagnose Whipple's disease

A. The villus atrophy may be seen with a magnifying glass.

B. Sub-total villus atrophy is seen in a number of conditions other than coeliac disease, for example:

Severe tropical sprue

Cow's milk/soya sensitivity in children

Gastroenteritis

Whipple's disease

Hypogammaglobulinaemia

Neomycin therapy

Laxative abuse

Norwalk agent.

C. There is a group of patients who present with coeliac disease in older age - sometimes in their 90s. They present with iron deficiency anaemia, osteoporosis or weight loss.

D. They would not be 'healthy'.

[Q: 1986] OnExamination 2012 -
Gastroenterology

A 70-year-old man is admitted with pruritus and jaundice of two weeks duration and 2 kg weight loss over the last 2 years.

He had not drunk any alcohol for at least eight years.

One month ago he had completed a course of co-amoxiclav which had been prescribed by his GP for sinusitis and he was also taking ibuprofen for hip osteoarthritis.

Investigations reveal:

Albumin 38 g/l (37-49)

Bilirubin 200 mol/l (1-22)

AST 150 U/l (5-35)

Alkaline phosphatase 200 U/l (45-105)

Abdominal ultrasound reveals gallstones but no biliary duct dilatation.

What is the most likely cause of his jaundice?

- 1- Cholangio-carcinoma
- 2- Co-amoxiclav
- 3- Hepatitis B infection
- 4- Hepatitis C infection
- 5- Ibuprofen

Answer & Comments

Answer: 2- Co-amoxiclav

Co-amoxiclav (Augmentin) is notorious for causing drug-induced jaundice, often with a mixed hepatitic/cholestatic picture. A four week delay in symptoms and signs is not unusual.

Flucloxacillin is another common culprit.

The patient must be warned that this could reoccur if he is given co-amoxiclav again.

There is nothing in the history (risk factors) to suggest that this might be acute hepatitis B infection and there is no evidence of chronic

liver disease to suggest that this might be a result of chronic viral hepatitis.

Non-steroidal anti-inflammatory drugs such as ibuprofen and diclofenac may cause a drug-induced hepatitis however the pattern of abnormality if a transaminitis and hyperbilirubinaemia is not usually seen.

Cholangiocarcinoma may present with an obstructive jaundice and weight loss however it is a relatively rare condition in those without risk factors for the disease and in a case such as this whilst ultrasound may not demonstrate the actual lesion one would expect it to show evidence of biliary duct obstruction and more likely than not evidence of hepatic metastases.

[Q: 1987] OnExamination 2012 -
Gastroenterology

A 58-year-old man presents to your clinic with dysphagia for solids for the past three months. He also complains of weight loss and loss of appetite. There is no other past medical history, apart from symptoms of indigestion and heartburn for the past five years.

He regularly takes Gaviscon and Rennie tablets. He is a heavy smoker and a regular drinker. He undergoes endoscopy, which reveals a small tumour at the lower end of the oesophagus.

What is the most likely aetiological cause for the tumour?

- 1- Alcohol
- 2- Barrett's oesophagus
- 3- Helicobacter pylori
- 4- Oesophageal candidiasis
- 5- Oesophageal pouch

Answer & Comments

Answer: 2- Barrett's oesophagus

The history suggests a five year history of gastro-oesophageal reflux. This can cause a

columnisation of the oesophageal mucosa known as Barrett's oesophagus, which is a premalignant state. Surveillance endoscopies are recommended every three years.

The development of dysphagia for solids and weight loss suggests the presence of oesophageal carcinoma.

[Q: 1988] OnExamination 2012 - Gastroenterology

A 38-year-old woman presents with a recent history of pruritis, fatigue and jaundice.

Investigations revealed:

Liver biopsy: Shows periportal fibrosis with periportal inflammation and prominent enlargement of the portal tracts.

Which one of the following antibodies is most likely to be found in the blood?

- 1- Anticardiolipin
- 2- Anticentromere
- 3- Antimitochondrial
- 4- Antimyeloperoxidase
- 5- Antinuclear

Answer & Comments

Answer: 3- Antimitochondrial

Primary biliary cirrhosis (PBC) is a slowly progressive autoimmune disease of the liver that primarily affects women in their fifth decade. It is characterised by portal inflammation and immune-mediated destruction of the intrahepatic bile ducts, which results in reduced bile secretion and retention of toxic substances. This leads to further hepatic damage, fibrosis and cirrhosis. Serologically, PBC is characterised by antimitochondrial antibodies, which are present in 90-95% of patients (often before clinical signs develop) and have a specificity of 98%. These antibodies are specific for the E2 subunit of the pyruvate dehydrogenase complex, and it is unclear why they only affect

the liver when all nucleated cells contain mitochondria. Twin and family studies suggest there is a significant genetic predisposition. Treatment is empirical, and patients may go on to require a liver transplant.

Anticardiolipin antibodies are most commonly associated with antiphospholipid syndrome, which increases the risk of thrombosis.

Anticentromere antibodies are associated with limited systemic sclerosis.

Myeloperoxidase is the antigen which p-ANCA (anti-neutrophil cytoplasmic antibodies) targets. It is associated with a number of vasculitides, but most classically microscopic polyangiitis.

Antinuclear antibodies are associated with 80-90% of cases of systemic lupus erythematosus, but are also found with Sjögren's syndrome, rheumatoid arthritis, autoimmune hepatitis, systemic sclerosis and polymyositis and dermatomyositis.

[Q: 1989] OnExamination 2012 - Gastroenterology

With which of the following is non-alcoholic steatohepatitis associated?

- 1- A benign course in all cases
- 2- Alcohol abuse
- 3- Insulin resistance
- 4- Normal level of liver enzymes
- 5- Viral hepatitis

Answer & Comments

Answer: 3- Insulin resistance

Non-alcoholic steatohepatitis (NASH) is associated with insulin resistance, hyperlipidaemia and chronic moderately elevated liver enzymes.

The diagnosis is made only by histology of liver biopsy which shows lesions suggestive of

ethanol intake in a patient known to consume less than 40 g of alcohol per week.

It is not necessarily benign: cryptogenic cirrhosis in patients is a substantial number of probably end-stage NASH.

[Q: 1990] OnExamination 2012 - Gastroenterology

A 45-year-old gentleman presents with dyspepsia of five months duration and loss of weight.

Examination reveals mild pallor and slight epigastric tenderness. Gastroscopy reveals 5 mm posterior ulcer in the first part of duodenum and 2 cm mass on lesser curve of the stomach. Biopsy of the mass reveals mucosa-associated lymphoid tumour confined to gastric mucosa. He has tested positive for H. pylori infection.

Which of the following treatment options will be appropriate for him?

- 1- Chemotherapy
- 2- H. pylori eradication
- 3- Proton pump inhibitor
- 4- Radiotherapy
- 5- Surgery

Answer & Comments

Answer: 2- H. pylori eradication

Lymphomas restricted to the gastric mucosa usually disappear when H. pylori is eradicated.

These lesions are less likely to respond to H. pylori eradication alone if they extend beyond the gastric mucosa. Chemotherapy or surgical excision may then be indicated.

Duodenal ulcer will also disappear with H. pylori eradication.

[Q: 1991] OnExamination 2012 - Gastroenterology

A 50-year-old man who is well known to the casualty department attends inebriated.

He has an alcoholic encephalopathy with a Glasgow coma scale of 13. He is jaundiced, describes no symptoms, but is mildly short of breath.

You are presented with his blood results:

Haemoglobin 7.4 g/dl (12 - 16 g/dl)

White cell count $10.1 \times 10^9/L$ ($4 - 10 \times 10^9/L$)

Platelets $137 \times 10^9/L$ ($140-400 \times 10^9/L$)

Sodium 133 mmol/l (133 - 144 mmol/L)

Potassium 3.7 mmol/l ($3.5 - 5 \times 10^9/L$)

Urea 12 mmol/l ($3 - 8 \times 10^9/L$)

Creatinine 113 $\mu\text{mol/l}$ (50 - 100)

AST 124 U/L (5 - 40)

Alkaline Phosphatase 224 U/L (50 - 110)

Total Protein 54 g/l (60 - 80g/L)

Bilirubin 63 $\mu\text{mol/l}$ (3 - 18)

Cholesterol 15.3 mmol/l ($<5.5 \text{ mmol/L}$)

Triglycerides 7.2 mmol/l ($<2.2 \text{ mmol/L}$)

Blood film Profound spherocytosis

Which of the following is the most appropriate treatment for this patient?

- 1- IV steroids
- 2- MRI pancreas
- 3- Oesophago-gastro-duodenoscopy
- 4- Supportive therapy
- 5- Urgent laparotomy

Answer & Comments

Answer: 4- Supportive therapy

A combination of jaundice, alcoholic hepatitis, hyperlipidaemia, and haemolysis is known as Zieve's syndrome.

There is no specific treatment for Zieve's syndrome, but supportive therapy is indicated which includes:

Correction of clotting abnormalities

Treatment of haemolysis

Treating alcohol withdrawal

Preventing further alcohol intake and

Adequate nutrition.

The spherocytosis is the result of the haemolysis.

Pancreatitis is a possible differential diagnosis here, but in the first instance one would request an amylase rather than a magnetic resonance imaging (MRI) of the pancreas.

[Q: 1992] OnExamination 2012 - Gastroenterology

A 49-year-old woman presents with a six month history of pruritus.

Examination reveals jaundice, xanthelasma, scratch marks, vitiligo and 3 cm hepatomegaly. She was afebrile. Liver function tests reveal raised bilirubin, alkaline phosphatase, gamma glutamyl transferase and mildly elevated alanine transaminase and aspartate transaminase.

Which of the following conditions will most likely be found in this woman?

- 1- Constipation
- 2- Haemolysis
- 3- Lymphadenopathy
- 4- Vitamin A deficiency
- 5- Vitamin B complex deficiency

Answer & Comments

Answer: 4- Vitamin A deficiency

The most likely diagnosis is primary biliary cirrhosis as evidenced by pruritus, hypercholesterolaemia, jaundice, raised

alkaline phosphatase (ALP) and gamma glutamyl transferase (γ -GT).

Malsorption of fat-soluble vitamins (A, D, K) is common.

[Q: 1993] OnExamination 2012 - Gastroenterology

A group of construction workers presented to the emergency department with diarrhoea, flushing, sweating and a hot mouth. They fell ill minutes after eating lunch in the staff canteen. They admitted that they had eaten tuna fish.

What is the likely cause of food poisoning?

- 1- Clostridium perfringens
- 2- Heavy metal
- 3- Mushroom
- 4- Scrombotoxin
- 5- Staphylococcus aureus

Answer & Comments

Answer: 4- Scrombotoxin

Scrombotoxin food poisoning is caused by the ingestion of foods that contain high levels of histamine and possibly other vasoactive amines and compounds.

Histamine and other amines are formed by the growth of certain bacteria and the subsequent action of their decarboxylase enzymes on histidine and other amino acids in food, by spoilage of foods such as fishery products, particularly tuna or mahi mahi.

Incubation period is 10-60 minutes.

[Q: 1994] OnExamination 2012 - Gastroenterology

A 45-year-old female develops profuse watery diarrhoea with lower abdominal pain seven days after undergoing laparoscopic cholecystectomy.

What is the most likely diagnosis?

- 1- Abdominal sepsis
- 2- Bile acid diarrhoea
- 3- Campylobacter gastroenteritis
- 4- Pseudomembranous colitis
- 5- Pseudo-obstruction

Answer & Comments

Answer: 4- Pseudomembranous colitis

Prophylactic antibiotics are frequently given in both laparoscopic and open cholecystectomy.

Typically broad spectrum antibiotics are administered with a consequent risk of pseudomembranous colitis. However, it must also be remembered that *Clostridium difficile* may also be contracted on the wards.

Bile acid diarrhoea may affect 10% of patients following cholecystectomy. Typically it is post-prandial; the bile, with no gall bladder to store it, is excreted directly into the gut.

[Q: 1995] OnExamination 2012 - Gastroenterology

Which of the following is most likely to be reversible following venesection in a 45-year-old male with haemochromatosis?

- 1- Arthropathy
- 2- Cardiomyopathy
- 3- Cirrhosis
- 4- Diabetes mellitus
- 5- Hypopituitarism

Answer & Comments

Answer: 2- Cardiomyopathy

Disorders that are potentially reversible in haemochromatosis include the dermal pigmentation and cardiomyopathy.

Similarly there are improvements in liver function tests.

However, diabetes, cirrhosis, hypogonadism and arthropathy are usually irreversible.

[Q: 1996] OnExamination 2012 - Gastroenterology

A 17-year-old student returns from a backpacking trip to Nepal with a two week history of offensive diarrhoea and weight loss.

What is the most likely infective organism?

- 1- *Escherichia coli* 0157
- 2- *Giardia intestinalis* (G.lamblia)
- 3- *Salmonella typhi*
- 4- *Shigella flexneri*
- 5- *Yersinia enterocolitica*

Answer & Comments

Answer: 2- *Giardia intestinalis* (G.lamblia)

The history of diarrhoea over a couple of weeks makes giardiasis the most likely diagnosis here.

Giardia lamblia is a protozoan which can cause traveller's diarrhoea. It is transmitted by cysts from faecally contaminated water, or between people. The incubation period is 3 days to 3 weeks, and the symptoms can persist for several weeks. Diarrhoea tends to be the presenting symptom, and classically has a highly offensive smell. This is often followed by nausea, cramps, abdominal pain and bloating. The diarrhoea can become persistent, and lead to malabsorption and weight loss. Unlike other infective causes of chronic diarrhoea, giardia readily affects immunocompetent hosts as well as the immunocompromised.

Giardia is diagnosed by visualising cysts in stool, or trophozoites in small bowel mucosal biopsy. It is treated with tinidazole (2g single dose), or metronidazole (3-10 days). Metronidazole has been shown to cure over 90% of patients, and is often better tolerated than tinidazole. Paraomycin can be used in

pregnancy, as there is no systemic absorption. Resistant infection can often be cured with a combination of metronidazole and quinacrine.

Escherichia coli 0157 is a rare cause of infectious gastroenteritis. It usually causes bloody diarrhoea, which lasts less than a week. It can be complicated by haemolytic uraemic syndrome. *Shigella* and *Yersinia* also usually cause dysentery.

Salmonella typhi causes typhoid fever, which typically presents as a systemic illness with intermittent diarrhoea.

[Q: 1997] OnExamination 2012 - Gastroenterology

A 75-year-old male presents with a two month history of dyspnoea, weight loss and generalised lethargy. His medical history included a previous left-sided hemiparesis due to stroke for which he took aspirin and perindopril.

Examination revealed residual left sided hemiparesis together with a pale and slightly jaundiced appearance.

Investigations show:

Haemoglobin 5 g/dL (13.0-18.0)

MCV 109 fL (80-96)

White cell count $2 \times 10^9/L$ (4-11)

Platelets $45 \times 10^9/L$ (150-400)

Urinalysis: Increased urobilinogen.

What is the next most appropriate investigation?

- 1- Bone marrow aspirate
- 2- Direct antiglobulin test
- 3- Endoscopy
- 4- Serum haptoglobins
- 5- Vitamin B₁₂ concentration

Answer & Comments

Answer: 5- Vitamin B₁₂ concentration

In this situation, serum B12 estimation is the correct choice. With a pancytopenic picture and raised mean corpuscular volume (MCV), the most appropriate step is to check the B12 and folate.

The other choices are considered only after the basic assays.

Haemolysis does not explain the low WCC, nor the thrombocytopenia.

A haptoglobin only adds weight to a diagnosis of haemolysis, and a RBC-labelled scan would add greater sensitivity to the diagnosis of haemolysis.

The mild jaundice is typical of megaloblastic anaemia (Vitamin B₁₂ or folate deficiency) because of increased destruction of red cell precursors in the bone marrow.

[Q: 1998] OnExamination 2012 - Gastroenterology

A 70-year-old woman presented with a history of pancreatitis and persistent diarrhoea.

She also gave a history of osteoporosis and had had a deep vein thrombosis.

Which one of the following drugs will become less effective after she starts taking cholestyramine to relieve intolerable itching?

- 1- Aspirin
- 2- Folic acid
- 3- Thiamine
- 4- Vitamin D
- 5- Warfarin

Answer & Comments

Answer: 4- Vitamin D

Cholestyramine is an anion exchange resin, and will interfere with the absorption of fat-soluble vitamins.

Thus vitamin D absorption will be reduced, making treatment with this drug less effective when given along with cholestyramine.

Cholestyramine may enhance or reduce the anticoagulant effect of warfarin (see BNF).

[Q: 1999] OnExamination 2012 - Gastroenterology

A 19-year-old student presents with weight loss and blood loss per rectum. You organise a flexible sigmoidoscopy.

Which of the following histological features would favour a diagnosis of Crohn's disease and not ulcerative colitis?

- 1- Caseating granulomata
- 2- Crypt abscesses
- 3- Goblet cell mucus depletion
- 4- Lymphocyte infiltrate of the lamina propria
- 5- Metaplastic polyp formation

Answer & Comments

Answer: 4- Lymphocyte infiltrate of the lamina propria

Ulcerative colitis is characterised by mucosal inflammation with

General inflammatory cell infiltration

Goblet-cell mucus depletion

Crypt abscesses

Crypt shortening

Branching.

There is continuous inflammation, worsening from caecum to rectum.

In contrast, Crohn's disease is characterised by transmural inflammation, with

Neutrophil infiltrates and lymphoid aggregates

Fissures

Preservation of crypt architecture

Non-caseating granulomata.

There is patchy inflammation from mouth to anus.

[Q: 2000] OnExamination 2012 - Gastroenterology

An asymptomatic 40-year-old female underwent an abdominal ultrasound scan as part of a clinical trial and was noted to have gallstones but entirely normal liver function tests.

Which one of the following is the most appropriate management?

- 1- Chenodeoxycholic acid
- 2- Laparoscopic cholecystectomy
- 3- Lithotripsy
- 4- Observation
- 5- Ursodeoxycholic acid

Answer & Comments

Answer: 4- Observation

This patient is asymptomatic and does not require any treatment at present. 'If it ain't broke don't fix it' is the general rule.

There is no proven role for the use of oral drugs to try to reduce the formation of gallstones.

The only definitive treatment would be a cholecystectomy but that is not generally offered for asymptomatic gallstones.

[Q: 2001] OnExamination 2012 - Gastroenterology

A 42-year-old man being investigated for diabetes and impotence is noted to have the following results:

Alanine aminotransferase 30 U/l (5-35)

Aspartate aminotransferase 22 U/l (1-31)

Fasting plasma glucose 7.4 mmol/l (3.0-6.0)

Ferritin 500 µg/l (15-300)

Which one of the following would be the next most appropriate investigation?

- 1- Bone marrow smear and iron stain
- 2- Liver biopsy
- 3- Red cell protoporphyrins
- 4- Serum transferrin receptors
- 5- Transferrin saturation

Answer & Comments

Answer: 5- Transferrin saturation

This patient has a suspected diagnosis of haemochromatosis as suggested by the presentation and laboratory investigations including elevated ferritin.

The next investigation would be measurement of transferrin saturation, and then, if elevated (above 45%), genotyping (homozygosity for C282y mutations) would next be considered and would be expected to clinch the diagnosis.

In the event of rarer mutations confirmation with liver biopsy may be required.

[Q: 2002] OnExamination 2012 - Gastroenterology

Which of the following statements concerning transferrin is correct?

- 1- In the absence of anaemia transferrin is 80% saturated with iron
- 2- Levels are elevated in haemochromatosis
- 3- Levels are elevated in patients on the oral contraceptive pill
- 4- Transferrin binds ferrous iron
- 5- Transferrin levels fall during pregnancy

Answer & Comments

Answer: 3- Levels are elevated in patients on the oral contraceptive pill

Pregnancy and the oral contraceptive pill (OCP) both increase transferrin levels. Iron is carried in the blood bound to transferrin. Fe²⁺ (ferrous iron) is oxidised to Fe³⁺ (ferric iron) by caeruloplasmin to bind to transferrin which is about one third saturated with iron.

The saturation of transferrin (plasma iron concentration/TIBC x 100) is used as a measure of iron stores. A value below 16% is indicative of iron deficiency.

The transferrin level and the TIBC rise in iron deficiency. Pregnancy and the OCP both increase transferrin levels; whereas transferrin and TIBC fall in iron overload, percentage saturation is increased in haemochromatosis.

[Q: 2003] OnExamination 2012 - Gastroenterology

An 80-year-old woman presents with confusion associated with a chest infection.

She received standard treatment, and four days later she developed green, then bloody diarrhoea.

Which of the following organisms is most likely to be responsible for her diarrhoea?

- 1- Campylobacter jejuni
- 2- Clostridium difficile
- 3- Escherichia coli 0157
- 4- Methicillin-resistant Staphylococcus aureus
- 5- Vancomycin-resistant Enterococcus

Answer & Comments

Answer: 2- Clostridium difficile

This is typical of Clostridium infection with pseudomembranous colitis induced by prior treatment with broad spectrum antibiotics such as cefuroxime, Augmentin and the macrolides.

It is treated with oral vancomycin/metronidazole.

[Q: 2004] OnExamination 2012 -
Gastroenterology

Which of the following statements concerning iron metabolism is correct?

- 1- Approximately 0.1% of body iron circulates in the plasma
- 2- Approximately 90% of dietary iron is absorbed in the intestine
- 3- The main route of excretion is the liver
- 4- The serum ferritin concentration is reduced characteristically following surgery
- 5- The transferrin content of intestinal mucosal cells is high when body iron stores are high

Answer & Comments

Answer: 1- Approximately 0.1% of body iron circulates in the plasma

Approximately 4 mg of iron circulate within the plasma with a total body iron store of 3-4 g (2500 mg in the RBCs, 500 mg in liver, 500 mg in macrophages and about 500 mg in muscle).

From an intake of approximately 6 mg/1000 kcal of dietary iron only 15% is bioavailable.

The majority of iron contained within the RBCs is metabolised and re-utilised but 1 mg per day is lost through the gut.

Ferritin, the plasma protein responsible for binding iron, is an acute phase reactant protein and increases in inflammatory conditions following surgery.

Transferrin is a glycoprotein responsible for internal iron exchange and the content within mucosal cells is naturally low in haemochromatosis with high saturation.

[Q: 2005] OnExamination 2012 -
Gastroenterology

An 81-year-old frail man admitted with a stroke becomes increasingly drowsy after

receiving nasogastric (NG) feeding for five days.

Which biochemical abnormality is the most likely cause of his drowsiness?

- 1- Hyperglycaemia
- 2- Hypermagnesaemia
- 3- Hypernatraemia
- 4- Hypocalcaemia
- 5- Hypophosphataemia

Answer & Comments

Answer: 5- Hypophosphataemia

The chronology of his presentation five days after receiving NG feeds suggests hypophosphataemia associated with the re-feeding syndrome.

This is well described in elderly frail subjects who may have prior poor nutrition.

However, other electrolyte abnormalities are also described in association with NG feeds, for example, hypernatraemia.

But with this briefest of histories and the five days it is likely that the examiner is looking for hypophosphataemia.

[Q: 2006] OnExamination 2012 -
Gastroenterology

Which one of the following organs is in direct contact with the anterior surface of the left kidney, without being separated from it by peritoneum?

- 1- Duodenum
- 2- Jejunum
- 3- Pancreas
- 4- Spleen
- 5- Stomach

Answer & Comments

Answer: 3- Pancreas

This is a basic anatomy question.

The only entirely retroperitoneal structure listed in the question is the pancreas, the body of which is in direct approximation to the anterior surface of the left kidney. The duodenum (with the exception of the first part) is also retroperitoneal but not in direct approximation to the left kidney. The following mnemonic lists the retroperitoneal structures:

S uprarenal Glands (Adrenals)

A orta/IVC

D uodenum (except first part)

P ancreas (Tail is intraperitoneal)

U reters

C olon (Ascending and Descending only)

K idneys

E sophagus

R ectum

The spleen and stomach, though in contact, are covered in peritoneum.

[Q: 2007] OnExamination 2012 - Gastroenterology

A 28-year-old lady develops abdominal pain, jaundice and ascites worsening over a week.

She drinks ten units of alcohol each week and takes the oral contraceptive pill.

Which of the following findings would make a diagnosis of hepatic vein thrombosis (Budd-Chiari syndrome [BCS]) most likely?

- 1- Acute liver failure
- 2- Alanine aminotransferase (ALT) of 345 U/L (5 - 35)
- 3- Ankle oedema
- 4- Ascites fluid protein of 38 g/L
- 5- Tender enlarged liver

Answer & Comments

Answer: 5- Tender enlarged liver

The most common causes of an acute severe liver injury in a young woman are:

Viruses (including hepatitis A virus [HAV], hepatitis B virus [HBV])

Drugs (particularly paracetamol overdose)

Autoimmune hepatitis and

Hepatic vein thrombosis (often precipitated by pregnancy or oral contraceptive pill [OCP] use).

The presence of liver failure, ankle oedema, and an exudative ascites do not help differentiate between these aetiologies.

The ALT of 345 is moderately elevated and compatible with BCS. With viral or drug related hepatitis the peak ALT is usually much higher than this; the ALT may already be on the way down if she has had symptoms for a week.

Tender hepatomegaly is one of the hallmarks of BCS.

In acute severe viral, autoimmune or drug / toxin related liver disease the necrotic liver decreases in size.

[Q: 2008] OnExamination 2012 - Gastroenterology

Which of the following is true of spontaneous bacterial peritonitis (SBP)?

- 1- A survival rate of over 50% is expected at one year
- 2- Gentamicin is the treatment of choice
- 3- Is characteristically caused by aerobic bacteria
- 4- Is diagnosed by culture of ascitic fluid
- 5- Is due to intestinal perforation

Answer & Comments

Answer: 3- Is characteristically caused by aerobic bacteria

SBP is a frequent complication of the ascites of cirrhosis. It is diagnosed by ascitic fluid examination which reveals a PMN count of >250/ml.

SBP has poor prognostic significance with a one year survival after a diagnosis of between 30-50%.

It is, as the name suggests, a spontaneous event that is not a consequence of intestinal perforation. It is speculated that the infective organism may leak into the ascitic fluid via the blood or from intestinal overgrowth.

Organisms should be cultured by directly collecting into blood culture bottles.

It is typically caused by aerobic Gram negative bacteria. Hence cefotaxime is regarded as the drug of choice for treatment.

[Q: 2009] OnExamination 2012 - Gastroenterology

Which clinical feature is consistent with a diagnosis of VIPoma?

- 1- Alkalosis
- 2- Hypoglycaemia
- 3- Hypokalaemia
- 4- Increased gastric acid secretion
- 5- Provocation of VIP release by somatostatin

Answer & Comments

Answer: 3- Hypokalaemia

A VIPoma is a tumour secreting vasoactive intestinal polypeptide. They are mostly located in the pancreas but occasionally involve the sympathetic chain or adrenal cortex.

In health, VIP promotes electrolyte, water and hormone secretion from the pancreas and gut,

stimulates lipolysis, glycolysis and bile flow, and inhibits gastric acid secretion.

Symptoms:

Secretory diarrhoea ('pancreatic cholera')

Weight loss

Dehydration

Abdominal pain

Cutaneous flushing due to peripheral vasodilatation.

Biochemical features:

Hypokalaemic acidosis due to loss of alkaline secretions

Glucose may be elevated

VIP can be measured in plasma and is high

Achlorhydria with reduced gastric acid secretion.

[Q: 2010] OnExamination 2012 - Gastroenterology

A 36-year-old man presented with a three day history of bloody diarrhoea.

He was afebrile and mildly icteric.

Investigations revealed:

Haemoglobin 10.5 g/dL (13.0-18.0)

White cell count $19 \times 10^9/L$ ($4-11 \times 10^9$)

Platelets $70 \times 10^9/L$ ($150-400 \times 10^9$)

Serum urea 12.5 mmol/L (2.5-7.5)

Serum aspartate aminotransferase 90 U/L (1-31)

Prothrombin time 12s (11.5-15.5)

Blood film: Fragmented red cells

What is the most likely cause of his illness?

- 1- Escherichia coli O157 colitis
- 2- Ischaemic colitis
- 3- Leptospirosis
- 4- Salmonella enterocolitis

5- Ulcerative colitis

Answer & Comments

Answer: 1- Escherichia coli 0157 colitis

The combination of:

Bloody diarrhoea

Haemolytic anaemia

Thrombocytopenia but normal clotting and

Renal impairment

suggests haemolytic-uraemic syndrome.

This is associated with E coli 0157 toxin most commonly.

[Q: 2011] OnExamination 2012 - Gastroenterology

A 24-year-old woman was referred with tiredness and intermittent bloody diarrhoea and a past history of cerebral venous thrombosis.

On examination the sclera of the right eye was inflamed and multiple mouth ulcers were noted. At the colonoscopy, which confirmed colitis, two large vulval ulcers were noted.

Which is the most likely diagnosis?

- 1- Behcet's disease.
- 2- Crohn's disease.
- 3- HIV infection
- 4- Syphilis
- 5- Ulcerative colitis.

Answer & Comments

Answer: 1- Behcet's disease.

This is a classical description of the presentation of Behcet's, with oral and genital ulceration, colitis and scleritis.

[Q: 2012] OnExamination 2012 - Gastroenterology

A 24-year-old woman had ulcerative colitis (UC) for seven years and was prescribed mesalazine 1.5 g per day.

She smoked 20 cigarettes per day and was 10 weeks pregnant. She complained of worsening symptoms with six bloody stools per day.

Which one of the following statements is correct?

- 1- Azathioprine is relatively contraindicated.
- 2- Initiation of an elemental diet risks fetal malnutrition.
- 3- Oral corticosteroids are contraindicated.
- 4- Oral mesalazine therapy should be withdrawn.
- 5- Termination of the pregnancy is advisable.

Answer & Comments

Answer: 1- Azathioprine is relatively contraindicated.

The effect of pregnancy on UC is variable.

Oral corticosteroids and mesalazine are not contraindicated.

In general, the health of a mother with UC is the best predictor of the outcome of the pregnancy. Hence drug treatment is preferred to leaving active disease untreated.

The BNF states that azathioprine should not generally be started during pregnancy, but it is only relatively contraindicated. However, azathioprine is concentrated in breastfeeding.

In the context of pregnancy, an elemental diet does not risk maternal and/or fetal malnutrition.

[Q: 2013] OnExamination 2012 - Gastroenterology

A 48-year-old woman complains of pruritis, steatorrhoea and bruising.

On examination, she is jaundiced, pigmented with spider naevi and hepatosplenomegaly.

What is the most likely underlying diagnosis?

- 1- Alcoholic liver disease
- 2- Alpha-1 antitrypsin deficiency
- 3- Autoimmune hepatitis
- 4- Primary biliary cirrhosis
- 5- Wilson's disease

Answer & Comments

Answer: 4- Primary biliary cirrhosis

She has clinical evidence of chronic liver disease and portal hypertension.

The two main conditions causing pigmentation and chronic liver disease are primary biliary cirrhosis (PBC) and haemochromatosis.

PBC is a chronic cholestatic inflammatory liver disease, the aetiology of which is probably autoimmune. It most commonly affects middle-aged women.

There is jaundice with skin pigmentation, risk of developing oesophageal varices and fat malabsorption, leading to deficiency of the vitamins A, D, E, K (hence osteomalacia and also bruising).

Serum antimitochondrial antibody is positive in 95-99% cases.

[Q: 2014] OnExamination 2012 - Gastroenterology

A 26-year-old presents in the first trimester of her first pregnancy (six weeks gestation) for an antenatal check; she feels well.

Blood tests show a bilirubin of 40 $\mu\text{mol/L}$ (1-22); the other LFTs are completely normal.

Which of the following is the most likely diagnosis?

- 1- Cholestasis of pregnancy
- 2- Dubin-Johnson syndrome (DJS)

- 3- Gilbert's syndrome
- 4- Primary biliary cirrhosis (PBC)
- 5- Primary sclerosing cholangitis (PSC)

Answer & Comments

Answer: 3- Gilbert's syndrome

Gilbert's is the most common condition causing mild isolated hyperbilirubinaemia.

PBC and PSC are much less common conditions and are almost always associated with a rise in the other liver function tests (particularly alkaline phosphatase [ALP] and gammaglutamyltransferase [GGT]).

DJS is much less common than Gilbert's.

Intrahepatic cholestasis of pregnancy is relatively common but usually occurs in the second or third trimester; ALP is usually high, risk increases with multiparity.

[Q: 2015] OnExamination 2012 - Gastroenterology

A 20-year-old man was found to have iron deficiency anaemia when he went to donate blood. The Blood Transfusion Service contacted his general practitioner, who referred the patient to the outpatient clinic for further investigation.

Generally, the patient was very well. He had a good appetite, his weight was steady and he ate a normal diet. He had a normal bowel habit and had never passed any blood, mucus or diarrhoea in his stools. The patient denied knowledge of any overt blood loss from any other source.

His general practitioner had organised an open access endoscopy which was normal; duodenal biopsies were unremarkable. He had a limited knowledge of his family history as his mother had died in childbirth and as a result he was an only child. His father had died of what he thought was secondary liver and lung cancer but he was unsure.

On general physical examination he was fit and athletic. The skin and mucosal membranes were unremarkable. Pulse was 70 beats per minute and regular with a blood pressure of 132/78 mmHg. Heart sounds were normal and the chest was clear. His abdomen was soft and non-tender with no palpable masses or organs. Rectal examination was normal. On viewing the rectal mucosa through a rigid sigmoidoscope the colonic mucosa was covered in innumerable polyps.

What specific genetic abnormality is responsible for this appearance?

- 1- Germline mutation of the STK11 gene on chromosome 19
- 2- Heterozygous mutation of the MYH gene
- 3- Loss of the APC gene on chromosome 5
- 4- Mutations in mismatch repair genes (for example, MSH2)
- 5- Mutation of the p53 tumour suppressor gene

Answer & Comments

Answer: 3- Loss of the APC gene on chromosome 5

The patient will need a full colonoscopy and biopsy but the information presented is highly suggestive of familial adenomatous polyposis (FAP), caused by the loss of the APC gene on the short arm of chromosome 5.

Peutz-Jegher's syndrome (PJS) is an autosomal dominant inherited disorder caused by a germline mutation of the STK11 (serine threonine kinase 11) gene, usually located on the long arm of chromosome 19. Peutz-Jegher's syndrome is associated with intestinal hamartomatous polyps, but is usually (90%) associated with peri-oral pigmentation.

Hereditary nonpolyposis colon cancer (HNPCC) and MYC polyposis do not cause multiple polyps as suggested in this case. In HNPCC, affected individuals inherit a mutation in one of several genes involved in DNA

mismatch repair, including MSH2, MLH1, and PMS2.

Homozygous mutations in the MYH gene have been associated with a phenotype of multiple colorectal adenomas with or without cancer. This accounts for a proportion of FAP patients without a pathogenic APC mutation.

Mutations in the p53 tumour suppressor gene are found in many different cancers. While mutations in p53 are seen in cases of colon cancer, the question asks for the specific mutation associated with polyposis coli.

The main differential in this question is between FAP and PJS but the lack of perioral pigmentation favours FAP as the diagnosis.

[Q: 2016] OnExamination 2012 - Gastroenterology

You review an 84-year-old lady in the gastroenterology clinic.

She has been referred by her GP with a three month history of change in bowel habit and weight loss. Recently she has noticed PR bleeding with blood in the stool. There is a history of ischaemic heart disease with a previous myocardial infarction three years ago. She suffers from stable angina and congestive cardiac failure.

Which of the following investigations would be most appropriate to make the diagnosis?

- 1- Barium enema
- 2- Colonoscopy
- 3- CT abdomen
- 4- CT colonography
- 5- Flexible sigmoidoscopy

Answer & Comments

Answer: 5- Flexible sigmoidoscopy

Colorectal carcinoma needs to be excluded in this case. This is the third most common cancer in the UK, after breast and lung. Three

quarters of cases occur in people aged over 65y. Around 50% survive for over 5 years following diagnosis, but it remains the second most common cause of cancer death in the UK. The UK now has a national screening programme for those over 60y, which uses faecal occult blood testing.

With regard to the investigation of colorectal carcinoma, colonoscopy should be offered to patients without major co-morbidity. If a lesion suspicious of cancer is detected, a biopsy should be performed to obtain a histological diagnosis.

If the colonoscopy is incomplete, it should be repeated or CT colonography or barium enema should be performed.

Flexible sigmoidoscopy then barium enema should be offered for patients with major co-morbidity. CT colonography is an alternative if the local radiology service is competent in this technique. A small dose of oral contrast is administered 24 hours prior to the procedure and then the colon is imaged using helical CT scanning. Most CT colonography protocols require the use of bowel cleansing agents. The advantages over colonoscopy include no requirement for sedation, smaller risk of perforation, and extra-colonic pathology can also be demonstrated.

If a lesion suspicious of cancer is detected on CT colonography, a colonoscopy and biopsy should be offered (unless there are absolute contraindications).

CT chest, abdomen, pelvis should be offered after the diagnosis is made to estimate the stage of the disease. Patients with a rectal tumour should also undergo MRI to assess local disease. Endorectal ultrasound can then be offered if MRI shows disease amenable to local excision (or if MRI is contraindicated). Digital rectal examination is not part of the staging investigations.

In this case, the presence of congestive cardiac failure is a major co-morbidity. A

flexible sigmoidoscopy should therefore be first line (especially as she complains of fresh red bleeding, increasing the chance that this is a left-sided lesion). This would allow biopsy if a lesion is seen. If the flexible sigmoidoscopy is normal, a barium enema or CT colonography would be done.

[Q: 2017] OnExamination 2012 - Gastroenterology

Which of the following drugs does not undergo extensive hepatic first-pass metabolism?

- 1- Budesonide
- 2- Glyceryl trinitrate
- 3- Ketoconazole
- 4- Salbutamol
- 5- Warfarin

Answer & Comments

Answer: 5- Warfarin

The correct answer is warfarin.

The remaining listed drugs all undergo extensive hepatic first-pass metabolism.

reference:

Tofield C, Milson A, Chatu S. The hands-on guide to clinical pharmacology. Blackwell Publishing 2005.

[Q: 2018] OnExamination 2012 - Gastroenterology

Which of the following genotypes is associated with the lowest levels of alpha-1-antitrypsin (AAT)?

- 1- PiMM
- 2- PiMS
- 3- PiMZ
- 4- PiSZ
- 5- PiZZ

Answer & Comments

Answer: 5- PiZZ

PiMM is the normal phenotype.

The null phenotype (not in the list of options) is the least common but the most severe form of the disease where there is no detectable AAT in the serum.

[Q: 2019] OnExamination 2012 - Gastroenterology

Which of the following is an inhibitor of gastric acid secretion?

- 1- Acetylcholine
- 2- Histamine
- 3- Prostaglandins
- 4- Stomach distension
- 5- Swallowing

Answer & Comments

Answer: 3- Prostaglandins

The correct answer is prostaglandins.

The remaining listed options all stimulate the release of gastric acid.

[Q: 2020] OnExamination 2012 - Gastroenterology

A 61-year-old Caucasian patient presents to the gastroenterology clinic following a three month history of malaise with no other specific symptoms.

She had a hysterectomy in her 40s for symptomatic fibroids following completion of her family, and developed pre-eclampsia in both of her pregnancies. She is a current and lifelong smoker, takes no alcohol and previously worked as a secretary.

Present medication consists of Premarin 300 mcg OD, salbutamol PRN, Seretide BD and amlodipine 5 mg OD.

On examination the patient is pale with normal capillary refill time. The heart rate is 72, sinus rhythm. Blood pressure is 168/95 mmHg. Chest auscultation revealed neither crackles nor wheeze. Examination is otherwise unremarkable, with normal fundoscopy, urine dip and ECG.

Iron deficiency anaemia is seen on full blood count, and outpatient endoscopy is organised.

Which of the following is not a risk factor for the patient's pre-existent hypertension?

- 1- Hormone replacement therapy
- 2- Multiparity
- 3- Obstructive airway disease
- 4- Prior pre-eclampsia
- 5- Smoking

Answer & Comments

Answer: 3- Obstructive airway disease

This patient with iron deficiency anaemia presents with incidental hypertension, which may be multifactorial. Hypertension has classically been described in a male population, though relevant risk factors have been more recently identified in women.

These include

Multiple previous pregnancies

Menopause

Hysterectomy and

Hormone replacement therapy.

Though obstructive airway disease can cause pulmonary hypertension, and smoking is a well-recognised risk factor for arterial hypertension, in isolation it is not a cause of systemic hypertension.

Obstructive airway disease induced by familial α -1 antitrypsin deficiency is not associated with systemic hypertension.

Pre-eclampsia is a risk factor for consequent hypertension. Interestingly active smokers appear to have a lower incidence of pre-eclampsia.

Note that this patient takes unopposed oestrogen, which is safe in her case following hysterectomy though inadvisable in patients with an intact uterus due to the risk of endometrial carcinoma.

Reference:

NICE Clinical Guideline 34: Hypertension. National Institute for Health and Clinical Excellence, London (2006).

Wilson B et al. *BMJ* 2003; 326: 845 - 52: article on non-classical risk factors for hypertension.

[Q: 2021] OnExamination 2012 - Gastroenterology

A 71-year-old man presents to the Emergency department with acute severe abdominal pain and diarrhoea. He describes the pain as a dull ache across his abdomen.

He apparently underwent a bowel resection some four months earlier, and he has a history of ischaemic heart disease and two previous myocardial infarctions. He reports intermittent abdominal pain leading up to this latest event, which seemed to be worse if he had eaten a heavy meal.

On examination his BP is 100/55 mmHg, his pulse is 105 in atrial fibrillation (AF). His abdomen is generally tender, with sparse bowel sounds.

Investigations show

Hb 11.0 g/dl(13.5-18)

WCC $14.5 \times 10^9/L$ (4-11)

PLT $207 \times 10^9/L$ (150-400)

Na 139 mmol/l (135-146)

K 5.4 mmol/l (3.5-5)

Cr 172 mmol/l (79-118)

Amylase 450 U/l (60-180)

Lactate 4.2 mmol/l (0.5-2.2)

A plain abdominal film is unremarkable.

Which of the following is the most likely diagnosis?

- 1- Acute pancreatitis
- 2- Inflammatory colitis
- 3- Irritable bowel syndrome
- 4- Mesenteric ischaemia
- 5- Small bowel obstruction

Answer & Comments

Answer: 4- Mesenteric ischaemia

The history of ischaemic heart disease and presence of AF is suspicious for mesenteric ischaemia. Abdominal pain in the presence of a relatively normal x ray, diarrhoea, and a raised serum lactate add significantly to the suspicion.

CT scanning has become the imaging modality of choice for confirming the diagnosis, with a sensitivity and specificity for mesenteric ischaemia of over 90%.

Angiography is still used where the diagnosis is in doubt.

[Q: 2022] OnExamination 2012 - Gastroenterology

A 24-year-old man has returned a few days earlier from a Nile cruise.

He has begun suffering from profuse bloody diarrhoea. He opens his bowels several times per day, and there is blood and mucus mixed in with the motion each time. He is also complaining of dull abdominal pain.

There is no past medical history of note. On further questioning he admits to buying fruit from local stalls at the river side. On examination he is pyrexial 37.8°C, and has generalised lower abdominal tenderness.

Investigations show

Haemoglobin 12.1 g/dl(13.5-8)

White cell count $11.4 \times 10^9/L$ (4-10)

Platelets $204 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 125 $\mu\text{mol/l}$ (60-120)

Stool Blood

White cells ++

Trophozoites

Which of the following is the most appropriate initial therapy?

- 1- IV cefotaxime
- 2- Oral ciprofloxacin
- 3- Oral diloxanide
- 4- Oral metronidazole
- 5- Supportive therapy only with fluid resuscitation

Answer & Comments

Answer: 4- Oral metronidazole

This man has amoebic dysentery which occurs around seven days after exposure to *Entamoeba histolytica*.

Acute amoebic dysentery is managed with a course of oral metronidazole or tinidazole, to be followed by a ten day course of diloxanide to eradicate colonisation of the gut.

With appropriate diagnosis and treatment, mortality from amoebiasis is less than 1%.

Amoebic liver abscess may appear at any time from eight weeks after infection, and presents with night sweats, anorexia and right upper quadrant pain.

[Q: 2023] OnExamination 2012 - Gastroenterology

A 20-year-old woman was referred for investigation of iron deficiency anaemia.

Her mother died aged 28 years from colonic carcinoma complicating Peutz-Jegher syndrome.

Which is the most likely mode of inheritance of Peutz-Jegher syndrome?

- 1- Autosomal dominant
- 2- Autosomal recessive
- 3- Mitochondrial
- 4- Polygenic
- 5- X linked dominant

Answer & Comments

Answer: 1- Autosomal dominant

Peutz-Jegher syndrome is a condition characterised by perioral pigmentation and numerous hamartomas of the bowel.

Originally it was assumed that these did not predispose to malignancy but studies now suggest the contrary.

The condition is autosomal dominant.

[Q: 2024] OnExamination 2012 - Gastroenterology

A 60-year-old lady has a six month history of abdominal discomfort, bloating and altered frequency in stools.

Her symptoms seem to be worse following a large meal where she also feels nausea. Clinical examination is normal. She is suspected of fulfilling the criteria for irritable bowel syndrome.

Which of the following investigations should be undertaken to exclude other diagnoses?

- 1- Anti-tissue transglutaminase (TTG) antibodies
- 2- Faecal occult blood
- 3- Faecal ova/parasite tests
- 4- Sigmoidoscopy
- 5- Thyroid function test

Answer & Comments

Answer: 1- Anti-tissue transglutaminase (TTG) antibodies

Patients who fulfil the diagnostic criteria for irritable bowel syndrome should be screened for other conditions with full blood count (FBC):

Erythrocyte sedimentation rate (ESR) (or plasma viscosity)

C reactive protein (CRP)

Anti-endomysial antibodies (EMA)

Tissue transglutaminase (TTG) antibodies.

The British Society of Gastroenterology (BSG) guidelines list other investigations that are not required:

Ultrasound

Rigid/flexible sigmoidoscopy

Colonoscopy

Barium enema

Thyroid function tests (TFTs)

Faecal ova/parasite tests

Faecal occult blood

Hydrogen breath test.

[Q: 2025] OnExamination 2012 - Gastroenterology

A 58-year-old man presents with a history of abdominal discomfort that is relieved by passing stool.

In the past month his stools have been looser in nature and he has had a feeling of urgency and incomplete evacuation. His symptoms seem to be worse with eating. He has also noticed that he has passed mucus per rectum.

He is overweight with a BMI of 28 kg/m². His weight has fallen. He says that he has adjusted his diet in the last six months.

Which of the following is the most appropriate diagnosis?

1- Colo-rectal carcinoma

2- Diverticulitis

3- Inflammatory bowel disease

4- Irritable bowel syndrome

5- Malabsorption

Answer & Comments

Answer: 1- Colo-rectal carcinoma

Weight loss, tenesmus and a recent change in bowel habit all point towards an underlying diagnosis of colorectal cancer. Onset of symptoms in later life and a relatively short duration (that is, weeks rather than years) also point towards a 'biological' cause rather than irritable bowel syndrome.

The passage of mucus per rectum is a normal physiological function and not indicative of underlying pathology.

The symptoms are not suggestive of malabsorption.

Diverticulitis and inflammatory bowel disease are both potential diagnoses but given the duration of symptoms less likely than a colonic neoplasm.

[Q: 2026] OnExamination 2012 - Gastroenterology

A 52-year-old male is admitted with vomiting and acute epigastric abdominal pain which radiates through to his back. Investigations confirm severe acute pancreatitis.

Which of the following figures most accurately reflect the mortality associated with severe acute pancreatitis?

1- Less than 5%

2- Approximately 10%

3- Approximately 20%

4- Approximately 30%

5- Approximately 40%

Answer & Comments

Answer: 3- Approximately 20%

Mortality in acute pancreatitis varies according to age, co-morbidities and severity and is scored through the Ranson scoring system.

However, average mortality has remained pretty much unchanged over the last two decades with severe disease and is approximately 20%.

[Q: 2027] OnExamination 2012 - Gastroenterology

A 50-year-old woman is seen in the clinic because of deranged liver function tests (LFTs).

She drinks at most 4 units of alcohol weekly.

On examination she is obese with a BMI of 45 kg/m² and her LFTs show:

ALT 140 U/L(5-40)

AST150 U/L(10-40)

Alkaline phosphatase 250 U/L(45-105)

Which of the following is the most likely cause of this derangement?

- 1- Diabetes mellitus
- 2- Drug induced
- 3- Hyperparathyroidism
- 4- Hypertension
- 5- Hypothyroidism

Answer & Comments

Answer: 1- Diabetes mellitus

Diabetes mellitus associated with obesity is the most likely cause of non-alcoholic fatty liver disease (NAFLD) in this patient. It is caused by fatty accumulation in the liver leading to inflammation.

Other causes of hepatitis need to be excluded before making this diagnosis.

Patients who are obese and diabetic are advised to lose weight and control their diabetes.

Usually, a low fat, low calorie diet is recommended alongside treatment to lower HbA1c.

Patients with NAFLD should avoid alcohol or other substances that could be harmful to the liver.

[Q: 2028] OnExamination 2012 - Gastroenterology

A 35-year-old obese Afro-Caribbean lady presents with mild jaundice. She claims to be a teetotaler and her BMI is 30 kg/m².

Investigations reveal the following results.

Haemoglobin 14 g/dL (11.5-16.5)

U+Es Normal

Bilirubin 25 µmol/L (1-22)

Aspartate transaminase 140 U/L (1-31)

Alanine transaminase 155 U/L (5-35)

Alkaline phosphatase 160 U/L (60-110)

Random blood glucose 11.2 mmol/L (3.0-6.0)

Hepatitis A IgG Positive

Hepatitis B and C screening Negative

Anti-nuclear antibodies 1:16 titre

Ultrasound abdomen reveals hyperechogenic hepatic parenchyma.

Liver biopsy reveals lesions suggestive of alcoholic liver disease.

On review of her notes, liver function tests performed six months previously showed similar values.

Which of the following is the most likely diagnosis?

- 1- Alcoholic liver disease
- 2- Autoimmune hepatitis

- 3- Non-alcoholic steatohepatitis
- 4- Primary biliary cirrhosis
- 5- Viral hepatitis

Answer & Comments

Answer: 3- Non-alcoholic steatohepatitis

This is a case of non-alcoholic steatohepatitis, the diagnosis of which is made only by histology of liver biopsy which shows lesions suggestive of ethanol intake in a patient known to consume less than 40g of alcohol per week.

The diagnosis is supported by the presence of obesity, hyperglycaemia and hyperechogenic hepatic parenchyma.

In alcoholic hepatitis, AST to ALT ratio is more than 1.

[Q: 2029] OnExamination 2012 - Gastroenterology

A 24-year-old woman has ingested an unknown quantity of paracetamol tablets four hours ago.

She now presents with nausea, vomiting, anorexia and right subchondral pain.

Which of the following features suggest that she should be transferred to the liver unit?

- 1- ALT 800 units/L
- 2- Blood glucose 5 mmol/L
- 3- Heart rate 120 BPM
- 4- pH 7.25
- 5- Systolic BP 100 mmHg

Answer & Comments

Answer: 4- pH 7.25

A pH of less than 7.3 is a poor prognostic factor for this patient.

The criteria for transfer to a specialist unit are:

Encephalopathy

INR >2.0 at <48h or >3.5 at <72h

Serum creatinine >200 mol/L

Blood pH <7.3

Systolic BP <80 mmHg.

[Q: 2030] OnExamination 2012 - Gastroenterology

A vegetarian woman had lunch at a Chinese buffet restaurant.

In the evening she presented with diarrhoea and vomiting. There was no fever.

Which of the following is the likely cause of food poisoning in her case?

- 1- Bacillus cereus
- 2- Clostridium perfringens
- 3- Escherichia coli
- 4- Salmonella typhimurium
- 5- Yersinia enterocolitica

Answer & Comments

Answer: 1- Bacillus cereus

Bacillus cereus food poisoning is the general description although two recognised types of illness are caused by two distinct metabolites. The diarrhoeal type of illness is caused by a large molecular weight protein, while the vomiting (emetic) type of illness is believed to be caused by a low molecular weight, heat-stable peptide.

The onset of watery diarrhoea, abdominal cramps, and pain occurs six to 15 hours after consumption of contaminated food. Symptoms usually persist for 24 hours.

The emetic type of food poisoning is characterised by nausea and vomiting within 0.5 to six hours after consumption of contaminated foods. Occasionally, abdominal cramps and/or diarrhoea may also occur. Duration of symptoms is generally less than 24 hours.

A wide variety of foods including meats, milk, vegetables, and fish have been associated with the diarrhoeal type food poisoning. The vomiting-type outbreaks have generally been associated with reheated rice in restaurants.

Clostridium perfringens is associated with meat and *Yersinia enterocolitica* with milk. *Salmonella* infection is associated with dairy, poultry and meat products.

[Q: 2031] OnExamination 2012 - Gastroenterology

A 55-year-old woman is referred by her GP with abnormal liver function tests.

She is overweight but otherwise well.

Liver biopsy is reported as showing evidence of non-alcoholic steatotic hepatitis (NASH).

Which of the following statements is correct concerning NASH?

- 1- Commoner in males than females
- 2- Has not shown improvement with pioglitazone
- 3- Is associated with insulin resistance
- 4- Is treated with urso-deoxycholic acid
- 5- The majority of patients will develop cirrhosis

Answer & Comments

Answer: 3- Is associated with insulin resistance

NASH is associated with increased prevalence of insulin resistance/type 2 diabetes.

Approximately 20% develop cirrhosis

It is more common in obese females and the treatment is weight reduction.

Data from small clinical trials using pioglitazone have shown modest improvement in liver biopsy appearance over one year.

Reference:

Seminars in Liver Disease 2001;21(1):17-26.

[Q: 2032] OnExamination 2012 - Gastroenterology

A 55-year-old male presents with dysphagia, retrosternal discomfort and weight loss. Studies reveal achalasia.

Which of the following is most likely to provide symptomatic relief?

- 1- Buscopan
- 2- Diazepam
- 3- Nifedipine
- 4- Omeprazole
- 5- Surgical cardiomyotomy

Answer & Comments

Answer: 5- Surgical cardiomyotomy

Both calcium channel blockers (nifedipine) and nitrates relax the lower oesophageal sphincter however the effect on symptoms is variable, short-lived and usually suboptimal. Use is frequently limited by adverse effects. Consequently medical therapy is typically limited to those patients too frail or unwilling to undergo definitive treatment or other therapies. Studies looking at the efficacy of medical therapies are typically small and uncontrolled which will tend to overestimate the benefit of an intervention. Study estimates of symptom improvement with medical therapy vary between 53-87% however none claim to achieve full symptom improvement. On the other hand pooled results from 5 studies of surgical procedures (Heller myotomy) show good to excellent symptom response in 82% of patients. Other studies of surgical techniques typically show symptom response rates of 84-100%. Benefit seems to persist for at least 16 months beyond this there may be some recurrence. Reflux is the most common side effect and a concomitant anti-reflux procedure (Nissen's fundoplication) may be performed. Botox applied to the lower oesophageal sphincter is a recent new therapy with good efficacy however its effects are

short lived (typically less than six months) and use is generally recommended to be restricted to the frail or elderly in whom more aggressive therapy poses high risk.

None of other choices help the symptoms.

Oesophageal dilatation is usually attempted before laparoscopic surgical myotomy.

[Q: 2033] OnExamination 2012 - Gastroenterology

A 25-year-old female presents with red crusted lesions around the mouth and finger pulps, three months after having had small bowel resection for Crohn's disease.

What is the most likely cause of her skin condition?

- 1- Nicotinamide deficiency
- 2- Pyridoxine deficiency
- 3- Thiamine deficiency
- 4- Vitamin B₁₂ deficiency
- 5- Zinc deficiency

Answer & Comments

Answer: 5- Zinc deficiency

Zinc deficiency can lead to acrodermatitis which presents with perioral dermatitis, acral involvement and sometimes alopecia.

The features of this patient who had bowel resection suggest zinc deficiency.

[Q: 2034] OnExamination 2012 - Gastroenterology

A 36-year-old man presents with a 16 week history of indigestion.

Five years previously he had been treated for a duodenal ulcer.

Investigations reveal:

Fasting gastrin 120 pmol/l (<55)

Which one of the following statements regarding gastrin is correct?

- 1- It acts upon the G cells of the stomach
- 2- It inhibits the secretion of pancreatic bicarbonate
- 3- It is produced by the alpha cells of the pancreatic islets
- 4- It is produced by the parietal cells of the stomach
- 5- Its release is stimulated by gastric luminal peptides

Answer & Comments

Answer: 5- Its release is stimulated by gastric luminal peptides

Gastrin is mainly produced in two forms by the G cells of the gastric antrum.

It stimulates the parietal cells to produce hydrochloric acid and its production is stimulated by neural reflex pathways and also by the direct effect of digested peptides on the G cells themselves.

It also stimulates the production of bicarbonate.

[Q: 2035] OnExamination 2012 - Gastroenterology

A 65-year-old male presents with a four month history of diarrhoea with pale stools and weight loss.

Relevant results show:

Calcium 1.8 mmol/L (2.2-2.6)

Alkaline phosphatase 350 U/L (45-105)

What is the most likely diagnosis?

- 1- Coeliac disease
- 2- Giardia lamblia infection
- 3- Pancreatic carcinoma
- 4- Small intestinal bacterial overgrowth
- 5- Whipple's disease

Answer & Comments

Answer: 3- Pancreatic carcinoma

The patient has a marked hypocalcaemia associated with malabsorption. The raised alkaline phosphatase may represent osteomalacia, pancreatic carcinoma in its own right, metastases or even biliary obstruction/disease.

In this age pancreatic carcinoma is the most probable diagnosis.

Coeliac disease very seldom causes such an increased alkaline phosphatase and is more likely to present with iron deficiency anaemia.

The villous atrophy caused by Giardia is very transient.

Whipple's is extremely rare, found in middle aged men and caused by a bacillus, *Tropheryma whippelii*.

[Q: 2036] OnExamination 2012 - Gastroenterology

A 23-year-old woman with type 1 diabetes (T1DM) of three years duration, presents for annual review with weight loss.

She had normal menstrual cycles and bowel habit was unchanged.

On examination her BMI was 23 kg/m² and investigations revealed a haemoglobin of 7 g/dL (11.5-16.5) and a MCV of 69 fL (80-96).

Which of the following is the most likely diagnosis?

- 1- Anorexia nervosa
- 2- Bacterial overgrowth
- 3- Beta-thalassaemia minor
- 4- Coeliac disease
- 5- Crohn's disease

Answer & Comments

Answer: 4- Coeliac disease

Coeliac disease is the likely option as this patient has autoimmune disease (T1DM), an iron deficiency anaemia and little in the way of symptoms.

Bacterial overgrowth is associated with profuse diarrhoea and a macrocytosis due to vitamin B₁₂ consumption.

Crohn's disease would be expected to be symptomatic.

[Q: 2037] OnExamination 2012 - Gastroenterology

With respect to liver cirrhosis, which of the following statements is correct?

- 1- Endothelin causes dilatation of the sinusoids, thus decreasing portal hypertension
- 2- In end-stage cirrhosis, liver transplantation is associated with 20% five year survival
- 3- The final common pathway of hepatic fibrosis is mediated by the hepatic stellate cell
- 4- Transforming growth factor is a potent promoter of the fibrogenic response by hepatocytes
- 5- Tumour necrosis factor is an anti-inflammatory effector in fibrotic liver injury

Answer & Comments

Answer: 3- The final common pathway of hepatic fibrosis is mediated by the hepatic stellate cell

The hepatic stellate cells, which reside in the space of Disse are central to the process of fibrosis within the liver.

Tumour necrosis factor-A is a pro-inflammatory effector in fibrotic liver injury, through activation of the stellate cells. These cells then secrete the fibrillar collagen, constituting the defining features of hepatic fibrosis.

Interleukin-10 is thought to exert anti-inflammatory effects on the stellate cell.

Endothelin is a vasoconstrictor in the hepatic sinusoids (similarly in the endothelium of the systemic circulation), and functions by causing contraction of the hepatic stellate cells, thus increasing intrahepatic sinusoidal resistance, and promoting portal hypertension.

Nitric oxide antagonises the effects of endothelin in the liver.

Five year survival after liver transplantation is now 75%.

Reference:

BMJ 2003;327:143-7.

[Q: 2038] OnExamination 2012 - Gastroenterology

A 52-year-old male is admitted with haematemesis and melaena.

Examination reveals that he is icteric, confused with a flapping tremor, has signs of chronic liver disease, a pulse rate of 110 bpm and blood pressure of 100/70 mmHg. Abdominal examination reveals ascites.

An urgent endoscopy reveals small oesophageal varices without evidence of bleeding, but an oozing portal hypertensive gastropathy.

Which of the following measures would be the most appropriate treatment for this patient?

- 1- Endoscopic banding
- 2- Endoscopic injection of adrenaline
- 3- Endoscopic injection of ethanolamine
- 4- Intravenous vitamin K
- 5- Oral propranolol

Answer & Comments

Answer: 2- Endoscopic injection of adrenaline

The endoscopy shows small varices with no evidence of bleeding but diffuse oozing of

blood. Hence endoscopic measures like banding for small varices will not be useful.

There is probably no evidence that vitamin K is helpful, as the coagulation is already likely to be deranged.

Oral propranolol is useful as a later prophylaxis of variceal bleed.

[Q: 2039] OnExamination 2012 - Gastroenterology

A 55-year-old woman presents with lethargy, diarrhoea together with joint pains and intermittent fever. These symptoms have developed over the last six months during which time she has lost 6 kg in weight.

Supraclavicular lymphadenopathy is noted.

What is the most likely diagnosis?

- 1- Bacillary dysentery
- 2- Campylobacter infection
- 3- Coeliac disease
- 4- Giardiasis
- 5- Whipple's disease

Answer & Comments

Answer: 5- Whipple's disease

Whipple's disease is caused by *Tropheryma whippelii* and symptoms include:

Chronic diarrhoea

Arthralgia

Pyrexia

Lymphadenopathy.

Diagnosis is by microscopy of jejunal biopsy specimen which shows macrophages with p-aminosalicylic acid (PAS) positive granules.

Treatment is co-trimoxazole.

Bacillary dysentery and *Campylobacter jejuni* infection are characterised by bloody diarrhoea and are not chronic.

Coeliac disease and giardiasis have no lymph involvement.

[Q: 2040] OnExamination 2012 - Gastroenterology

A 26-year-old woman is referred with intermittent diarrhoea present for a couple of years.

She states that her weight has been steady but describes watery motions up to six stools per day and has also noted abdominal discomfort with bloating. She has not been aware of any blood in the motions or melaena.

She describes no other medical history and denies taking any medication.

Investigations show:

Full blood count Normal

Urea and electrolytes Normal

Albumin 39 g/L(37-49)

Corrected Calcium 2.2 mmol/L(2.2-2.6)

Alkaline phosphatase 94 U/L(45-105)

C-reactive protein 6 mg/L(<10)

Prothrombin time 12 s(11.5-15.5)

What is the most likely diagnosis?

- 1- Crohn's disease
- 2- Intestinal tuberculosis
- 3- Small bowel bacterial overgrowth
- 4- Laxative abuse
- 5- Microscopic colitis

Answer & Comments

Answer: 4- Laxative abuse

The normal albumin and C-reactive protein level count against a diagnosis of inflammatory bowel disease (Crohn's or microscopic colitis) or an infection pathology such as intestinal tuberculosis. Whilst small bowel bacterial overgrowth does not typically produce a raised C-reactive protein level it is

very unusual in patients without risk factors for the condition (previous bowel surgery, Crohn's disease, motility disorders such as scleroderma).

This leaves laxative abuse as the most likely diagnosis. Laxative abuse, where not a function of chronic constipation, is usually closely linked to eating disorders (Bulimia and Anorexia) and as such is typically over-represented in young, female patients. Patients may well present to medical services and be referred on to secondary care with symptoms relating to overuse of laxative agents. They may well also deny abusing any medications on initial questioning.

[Q: 2041] OnExamination 2012 - Gastroenterology

A 60-year-old man presents with a five day history of lower abdominal pain and diarrhoea.

He has a history of chronic obstructive airways disease (COAD) and has had numerous acute infective exacerbations over the last three months.

On examination he was dehydrated, with a temperature of 38.6°C, a blood pressure of 102/72 mmHg and has a distended, tender abdomen.

Which of the following is the most appropriate investigation for this patient?

- 1- Chest x ray
- 2- Plain abdominal x ray
- 3- Sigmoidoscopy and biopsy
- 4- Stool microscopy
- 5- Ultrasound scan of the abdomen

Answer & Comments

Answer: 2- Plain abdominal x ray

This is pseudomembranous colitis due to *Clostridium difficile* secondary to antibiotic usage for his COAD.

Plain AXR is useful for diagnosing toxic dilatation and would be the investigation of choice here due to his abdominal distension, so toxic dilatation should be excluded prior to sigmoidoscopy. However it does not establish the diagnosis.

Stool microscopy has no value but stool toxin assay is useful.

A patient with diarrhoea normally has involvement of the distal colon and rectum, and sigmoidoscopy with biopsy is helpful for rapid diagnosis but should not be performed if toxic dilatation is suspected.

Patients with involvement of right colon usually have little or no diarrhoea.

[Q: 2042] OnExamination 2012 - Gastroenterology

A 47-year-old man presents with confusion and drowsiness.

A diagnosis of hepatic encephalopathy is suspected and treatment with lactulose is begun.

Which of the following concerning lactulose is true?

- 1- Absorbed from the gut
- 2- Causes hypermagnesaemia
- 3- Contraindicated in diabetes mellitus
- 4- Inhibits proliferation of ammonia-forming organisms in the gut
- 5- Reduces absorption of spironolactone

Answer & Comments

Answer: 4- Inhibits proliferation of ammonia-forming organisms in the gut

Lactulose, an osmotic laxative which causes hypomagnesaemia associated with diarrhoea, is not absorbed, does not affect the absorption of spironolactone and may be used in diabetics.

In the management of hepatic encephalopathy lactulose has a number of actions to help reduce gut ammonia 'production' and absorption, production of a more acidic colonic pH is key in this. These mechanisms are:

1. Conversion of lactulose of lactic acid acidifies the gut the lumen, this favours oxidation of NH_4^+ to NH_3 and the passage of NH_3 from tissues into the lumen (NH_4^+ moves into the lumen where it is oxidised to NH_3 and is trapped as it is not absorbable, further NH_4^+ then diffuses across) - that is, inhibiting absorption as NH_3 is not absorbable;
2. The acidic pH inhibits the proliferation of ammonia producing microbes and promotes colonisation by non-ammonia producing bacteria such as lactobacilli;
3. The laxative effect leads to an overall reduction in colonic bacterial load and reduction in the protein load absorbed from the gut.

[Q: 2043] OnExamination 2012 - Gastroenterology

A 42-year-old female presents with tiredness.

Her investigations reveal:

Haemoglobin 7.8 g/dL (11.5-16.5)

MCV 72 fL (80-96)

White cell count $7.6 \times 10^9/\text{L}$ (4-11 $\times 10^9$)

Platelet count $350 \times 10^9/\text{L}$ (150-400 $\times 10^9$)

Serum ferritin 8 $\mu\text{g}/\text{L}$ (15-300)

She was commenced on oral iron therapy and one month later her haemoglobin concentration was 8.0 g/dL (11.5-16.5).

What is the most likely cause of the failure of her haemoglobin to respond to this treatment?

- 1- Coeliac disease
- 2- Folate deficiency
- 3- Inadequate dosage of iron

4- Poor compliance with therapy

5- Haemolytic anaemia

Answer & Comments

Answer: 4- Poor compliance with therapy

The most likely explanation for the failure of an iron deficiency anaemia to respond to iron therapy in a menstruant female is poor compliance. Oral iron commonly causes gastrointestinal side effects which can limit adherence to therapy.

It is likely that the dose that this patient is prescribed would be adequate and if not some response would still be expected.

Folate deficiency and coeliac disease can give a megaloblastic anaemia with a raised mean corpuscular volume (MCV).

Similarly, haemolytic anaemia typically causes a raised MCV, due to reticulocyte formation.

[Q: 2044] OnExamination 2012 - Gastroenterology

A 65-year-old woman presented with a malabsorption syndrome.

She had a past history of radiotherapy for cervical cancer.

Small intestine biopsy reveals

Villous atrophy and crypt hypertrophy

Chronic inflammatory cell infiltrate of the lamina propria

together with Increase in intraepithelial lymphocytes.

What is the most likely diagnosis?

- 1- Bacterial overgrowth
- 2- Coeliac disease
- 3- Crohn's disease
- 4- Mesenteric ischaemia
- 5- Radiation enteropathy

Answer & Comments

Answer: 2- Coeliac disease

Do not be put off by the description of the case; these histological features are typical of coeliac disease with

Villous atrophy

Crypt hyperplasia/hypertrophy

Inflammatory infiltrate of the lamina propria and

Intra-epithelial lymphocytes.

Useful serology includes anti-TTG antibodies which would be expected in over 90% of cases.

Treatment of this case would therefore entail gluten-free diet.

[Q: 2045] OnExamination 2012 - Gastroenterology

A 65-year-old man is referred with abnormal liver function and undergoes a liver biopsy.

Which of the following count against hepatic cirrhosis?

- 1- Fibrous septa formation
- 2- Granuloma formation
- 3- Liver cell necrosis
- 4- Nodular regeneration
- 5- Subendothelial fibrosis

Answer & Comments

Answer: 2- Granuloma formation

Granuloma formation is not classically seen in cirrhosis, which can be micro- or macronodular in type.

In the micronodular form, the nodules are less than 3 mm across with uniform liver involvement - seen in alcohol or biliary disease.

In the macronodular form, there are larger nodules, classically seen in chronic viral hepatitis.

[Q: 2046] OnExamination 2012 - Gastroenterology

Which of the following cell types are linked with the substance they synthesise?

- 1- Gastric chief cells - intrinsic factor
- 2- Islet A cells - somatostatin
- 3- Islet B cells - amylin
- 4- Islet D cells - pancreatic polypeptide
- 5- Islet F cells - glucagon

Answer & Comments

Answer: 3- Islet B cells - amylin

Islet beta cells produce insulin and amylin, as well as C peptide, pro-insulin and gamma-aminobutyric acid (GABA).

Islet D cells produce somatostatin

F cells produce pancreatic polypeptide and

A cells produce glucagon

Gastric chief cells produce pepsinogen whilst

Gastric parietal cells produce acid and intrinsic factor.

[Q: 2047] OnExamination 2012 - Gastroenterology

A 58-year-old man with a longstanding history of alcohol excess has had an enlarging abdomen for several months.

On physical examination he has a non-tender abdomen with no masses palpable, but there is a fluid thrill. An abdominal ultrasound scan shows a large abdominal fluid collection with a small cirrhotic liver.

A chest x ray shows a globally enlarged heart.

Which of the following conditions is most likely to be present?

- 1- Dilated cardiomyopathy
- 2- Lymphocytic myocarditis
- 3- Myocardial amyloid deposition
- 4- Non-bacterial thrombotic endocarditis
- 5- Severe occlusive coronary atherosclerosis

Answer & Comments

Answer: 1- Dilated cardiomyopathy

This man has alcoholic liver cirrhosis with ascites.

The cardiomyopathy of alcoholism is a dilated or congestive form.

[Q: 2048] OnExamination 2012 - Gastroenterology

In the diarrhoea associated with cholera toxin, there is activation of which of the following enzyme systems?

- 1- Adenosine triphosphate (ATP).
- 2- Adenylate cyclase.
- 3- Guanylate cyclase.
- 4- Na-glucose co-transporter.
- 5- Na⁺/K⁺ ATPase pump.

Answer & Comments

Answer: 2- Adenylate cyclase.

Cholera toxin has two parts, A and B.

B binds while A activates G protein, which activates adenylate cyclase.

Elevated cyclic adenosine monophosphate (cAMP) results in unrestricted chloride secretion from villous crypts.

[Q: 2049] OnExamination 2012 - Gastroenterology

A 70-year-old man was admitted with pallor, light-headedness and loss of energy.

On the day prior to admission he had reported loose dark stools.

Examination revealed a pulse of 110 per minute and a blood pressure of 106/70 mmHg.

Investigations revealed:

Haemoglobin 7.2 g/dl(14-18)

MCV 72 fl(80-96)

White cell count $11.3 \times 10^9/L$ (4-11)

Platelet count $480 \times 10^9/L$ (150-400)

What is the most appropriate next step in his management?

- 1- Barium meal
- 2- Blood transfusion
- 3- Endoscopy
- 4- Parenteral iron infusion
- 5- Proton pump inhibitor therapy

Answer & Comments

Answer: 2- Blood transfusion

There is only one answer here and that is blood transfusion.

He has clearly had a major gastrointestinal (GI) bleed since he presents with symptoms of shock with a high resting heart rate and lowish blood pressure the day after what sounds like melaena. What is more he has a significant microcytic anaemia.

He should be resuscitated with blood transfusion and then sent for upper GI endoscopy.

A barium meal will not help a bleeding vessel.

Parenteral iron is for chronic anaemia not acute bleeds and proton pump inhibitors, although widely used, have no supportive evidence and are nowhere near as important as giving blood to this man.

[Q: 2050] OnExamination 2012 - Gastroenterology

A 40-year-old man has a history of left-sided Crohn's colitis.

Though previously treated with steroids and mesalazine, he has had several relapses in the past year. The last relapse, treated with high doses of steroids, was complicated by gastric bleeding.

Investigations show:

Haemoglobin 10.8 g/dL(13.0-18.0)

MCV 76 fL(80-96)

MCH 24 pg(28-32)

White cell count $10 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $400 \times 10^9/L$ (150-400 $\times 10^9$)

Serum total protein 70 g/L(61-76)

Serum albumin 30 g/L(37-49)

Serum CRP 30 mg/L(<10)

Abdominal x ray is normal.

Which of the following is the most appropriate management?

- 1- A trial of oral metronidazole for three months.
- 2- Total colectomy with ileostomy construction.
- 3- Total colectomy with pouch construction.
- 4- Treatment with azathioprine.
- 5- Treatment with oral budesonide.

Answer & Comments

Answer: 4- Treatment with azathioprine.

This patient has all the hallmarks of active Crohn's colitis that is failing to settle with first-line medical therapy.

The next step is a trial of azathioprine, which is used as a steroid-sparing agent. This is particularly relevant to this particular patient, as he has had a serious side-effect from previous steroid treatment.

Metronidazole is rarely effective in the treatment of active Crohn's colitis.

Given that Crohn's disease can recur following surgery, an operation should not be embarked upon without first a trial of the second-line medical therapies such as azathioprine, its metabolite 5-mercaptopurine, or infliximab.

[Q: 2051] OnExamination 2012 - Gastroenterology

A 55-year-old man on no current treatment for his quiescent ulcerative colitis (UC) is found to have an ESR of 95 mm/hr (0-20mm/1st hour).

Investigations show:

Haemoglobin 13.2g/dL(13.0-18.0)

WCC $4.5 \times 10^9/L$ (4-11)

Platelets $160 \times 10^9/L$ (150-400)

Corrected Calcium 2.58 mmol/L(2.2-2.6)

IgG 25g/L(6-13)

IgA 1.8g/L(0.8-3.0)

IgM 1.6g/L(0.4-2.2)

What is the most appropriate next investigation?

- 1- Bone marrow trephine and aspiration.
- 2- Isotope bone scan.
- 3- Plasma immunoelectrophoresis.
- 4- Rectal biopsy.
- 5- x Ray skeletal survey.

Answer & Comments

Answer: 3- Plasma immunoelectrophoresis.

The erythrocyte sedimentation rate (ESR) is not raised in quiescent UC. Hence there must be another reason in this case.

The only abnormal result given is a raised IgG. This suggests that myeloma is the diagnosis.

Plasma immunoelectrophoresis to look for an M band is the most appropriate next investigation.

A bone marrow trephine is the definitive investigation but is traumatic and painful to the patient and so is not the next investigation of choice.

[Q: 2052] OnExamination 2012 - Gastroenterology

A 40-year-old single man returned from holiday in Europe with mild bloody diarrhoea which had lasted for two weeks.

He had lost 2.5 kg in weight, had occasional lower abdominal cramping discomfort and a painful swelling of his left knee.

What is the most likely diagnosis?

- 1- Amoebiasis
- 2- Campylobacter infection
- 3- Crohn's disease
- 4- Gonococcal septicaemia
- 5- Ulcerative colitis

Answer & Comments

Answer: 2- Campylobacter infection

Campylobacter infection is one of the commonest causes of inflammatory diarrhoea. Abdominal pain is often a prominent feature of the illness frequently localising to the right iliac fossa. Diarrhoea may be mild or very severe often with passage of blood. Symptoms may last a week or longer.

Reactive arthritis and Reiter's syndrome can develop following infection with a number of enteric pathogens including Shigella, Salmonella, Campylobacter and Yersinia.

[Q: 2053] OnExamination 2012 - Gastroenterology

A 58-year-old man complains of tiredness, fever, weight loss, arthralgia and diarrhoea.

Jejunal biopsy reveals flattened mucosa containing periodic acid-Schiff (PAS) positive macrophages.

What is the most likely diagnosis?

- 1- Coeliac disease
- 2- Parasitic infection
- 3- Tropical sprue
- 4- Tuberculosis
- 5- Whipple's disease

Answer & Comments

Answer: 5- Whipple's disease

Whipple's disease is rare and affects most commonly middle-aged males.

It can affect any organ, but dominated by involvement of small bowel, causing malabsorption.

The organism (*Tropheryma whippelii*) can be identified both between and within abnormal macrophages which stain magenta with PAS.

Treatment is with prolonged antibiotics, for example, parenteral penicillin and streptomycin for two weeks, followed by one year of doxycycline.

[Q: 2054] OnExamination 2012 - Gastroenterology

A 32-year-old man develops profuse diarrhoea with mucus and blood.

Biopsies from the flexible sigmoidoscopy shows evidence of ulcerative colitis.

Which of the following is true of the condition?

- 1- Colectomy may worsen gall bladder disease
- 2- Goblet cells are unaffected in the mucosa
- 3- Mesalazine therapy is associated with infertility in males
- 4- Pseudopolyps on sigmoidoscopic examination have premalignant potential

- 5- Topical 5-aminosalicylic acid is less effective than topical steroids in proctitis

Answer & Comments

Answer: 1- Colectomy may worsen gall bladder disease

Mesalazine is 5-aminosalicylic acid.

Sulphasalazine is the combination of 5-ASA and sulphapyridine, the latter being a sulphonamide and causing oligospermia.

Pseudopolyps are not premalignant and may occasionally regress.

Topical 5-aminosalicylic acid is as effective as topical steroids in proctitis.

Goblet cells are depleted in the mucosa.

[Q: 2055] OnExamination 2012 - Gastroenterology

A 35-year-old man is referred to the gastroenterology clinic with persistent pain in the rectum. The patient reports recurrent painful oral ulcers.

On direct questioning he admits to red and painful eyes. He also reports he has recently noticed an ulcer over his scrotum.

On examination there is evidence of oral aphthous ulceration; abdominal examination reveals tenderness in the right iliac fossa and a bruit on auscultation of the abdomen. Rectal examination demonstrates perianal ulceration.

What is the most likely diagnosis?

- 1- Behçet's syndrome
- 2- Crohn's disease
- 3- HIV infection
- 4- Syphilis
- 5- Tuberculosis

Answer & Comments

Answer: 1- Behçet's syndrome

Behçet's syndrome is a vasculitis of unknown pathophysiology.

Onset of disease is typically in the third and fourth decades. It is more common in men in the Middle East and women in the Far East.

Diagnostic criteria include oral aphthous ulcers which are painful, recurrent and non-scarring and two of:

Genital ulceration

Uveitis

Pustular vasculitis and synovitis

Meningoencephalitis

And the exclusion of inflammatory bowel disease, systemic lupus erythematosus, Reiter's syndrome and Herpes.

Aphthoid ulcers can occur anywhere in the gastrointestinal tract but are most commonly found in the ileo-caecal region, right colon and oesophagus.⁵

The presence of genital ulcers and the absence of significant bowel symptoms both go against a diagnosis of Crohn's disease, rather than the presence of an abdominal bruit which is a rare finding in vasculitis.⁶

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

Travis SPL, Ahmad T, Collier J, Steinhart AH. Pocket Consultant Gastroenterology. Blackwell Publishing 2005.

[Q: 2056] OnExamination 2012 - Gastroenterology

A 21-year-old woman is referred from the Emergency department with a paracetamol overdose.

Which of the following is an indication for liver transplantation in acute liver failure as a result of paracetamol overdose?

1- Arterial pH < 7.35

2- Bilirubin > 200 micromol/L

3- Creatinine > 250 micromol/L

4- Grade I encephalopathy

5- Prothrombin time > 100 seconds (INR > 6.7)

Answer & Comments

Answer: 5- Prothrombin time > 100 seconds (INR > 6.7)

Prothrombin time > 100 seconds in acute liver failure with paracetamol poisoning is one of the selection criteria for liver transplantation.⁵

The remainder of the selection criteria for liver transplantation in acute liver failure with paracetamol overdose are as follows:

Arterial pH < 7.3 (this needs to be interpreted with caution as pH may improve with N-acetylcysteine and rehydration)

Creatinine > 300 micromol/L

Grade III or grade IV encephalopathy.

Serum bilirubin > 300 micromol/L is part of the selection criteria for liver transplantation in non-paracetamol induced acute liver failure.⁵

There are a variety of complications with liver transplantation such as

Immunological rejection

Effects of immunosuppressive drugs used

Infection and

Disease recurrence.⁵

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 2057] OnExamination 2012 -
Gastroenterology

A 28-year-old woman is referred by her GP to the gastroenterology clinic after a recent gastroscopy with duodenal biopsies confirmed the diagnosis of coeliac disease.

What is the prevalence of coeliac disease in Europe?

- 1- 1:10
- 2- 1:30
- 3- 1:300
- 4- 1:1000
- 5- 1:3000

Answer & Comments

Answer: 3- 1:300

The prevalence of coeliac disease in Europe varies widely and is in the region of between 1:100 and 1:300. It is more common in the Celtic population⁵.

Coeliac disease is caused by a T cell mediated hypersensitivity reaction to gluten which causes intestinal inflammation and atrophy. It presents at any age but in adults the commonest age of presentation is 20s and 30s. Women are slightly more commonly affected.⁵

Patients usually have diarrhoea and steatorrhoea may be present. There is often a mild macrocytic anaemia with low folate. Classically iron or folate deficiency is seen.⁵

Ten per cent to 15% of patients have abnormal liver function tests. Patients may also have thrombocytosis. Low corrected calcium, vitamin D and zinc are also seen.⁵

IgA anti-endomysial and anti-tissue transglutaminase antibodies are useful serological tests. Anti-endomysial antibodies are 90% sensitive and almost 100% specific. Biopsies from the second part of the

duodenum are essential and demonstrate villous atrophy.⁵

Management includes a gluten-free diet - patients should avoid wheat, barley and rye.⁵

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 2058] OnExamination 2012 -
Gastroenterology

A 34-year-old woman is referred to the gastroenterology clinic. The GP referral letter states the patient has persistent lethargy and blood results have demonstrated iron deficiency anaemia.

Which of the following statements regarding iron deficiency anaemia is correct?

- 1- Endomysial antibody serology to investigate for coeliac disease should always be requested in addition to duodenal biopsies
- 2- Low serum iron with a low total iron-binding capacity confirms iron deficiency
- 3- Microcytosis may be absent where there is combined iron and folate deficiency
- 4- The presence of Howell-Jolly bodies on blood film would go against coeliac disease
- 5- Thrombocytosis indicates chronic blood loss

Answer & Comments

Answer: 3- Microcytosis may be absent where there is combined iron and folate deficiency

Distal duodenal (D2) biopsies should be taken in any patient with iron deficiency anaemia undergoing a gastroscopy as 2-3% of patients will have coeliac disease.⁶

Endomysial antibody serology can be useful to confirm that subtotal villous atrophy found at histology is not due to another cause.

Antibody titres help to determine whether or not the patient is adhering to a gluten free diet.

In the investigation of iron deficiency anaemia serology for coeliac disease would be performed prior to an OGD.

Low serum iron (< 10 pmol/L) with a high total iron-binding capacity (> 70 pmol/L) confirms iron deficiency⁶.

Howell-Jolly bodies on blood film indicate hyposplenism and are consistent with a diagnosis of coeliac disease⁶.

Thrombocytosis may occur in acute haemorrhage but is also found in a number of other situations such as inflammatory conditions⁶.

Travis SPL, Ahmad T, Collier J, Steinhart AH. *Pocket Consultant Gastroenterology*. Blackwell Publishing 2005.

[Q: 2059] OnExamination 2012 - Gastroenterology

A 48-year-old man presents with haematemesis and melaena. He admits to high alcohol intake.

On examination he is shocked, his heart rate is 110 beats per minute and blood pressure is 92/74 mmHg. There is evidence of leukonychia and abdominal examination reveals tenderness in the epigastrium.

What is the most likely underlying cause of the gastrointestinal haemorrhage?

- 1- Gastric antral vascular ectasia (GAVE)
- 2- Gastro-oesophageal varices
- 3- Mallory-Weiss tear
- 4- Peptic ulceration
- 5- Portal hypertensive gastropathy

Answer & Comments

Answer: 4- Peptic ulceration

Peptic ulceration is the commonest cause of acute upper gastrointestinal (GI) haemorrhage⁵.

Epigastric tenderness also points towards peptic ulcer disease. The history of high alcohol intake can be misleading in directing the candidate towards varices.

In this case the answer is the most common cause of an acute upper GI bleed which is peptic ulceration - 25-50% of cases of non-variceal upper GI bleeding and 5% of cases of upper GI haemorrhage are due to varices⁵.

Gastric antral vascular ectasia is a relatively uncommon condition. It typically presents as a cause of iron-deficiency anaemia as a result of chronic GI blood loss. Overt symptoms of upper GI haemorrhage may be precipitated by administration of anti-platelet agents or anti-coagulants. The mean age of diagnosis is around 70 and there is an association with scleroderma.

Portal hypertensive gastropathy is a poorly understood complication of portal hypertension (usually as a result of chronic liver disease). There is a typical mosaic or snakeskin like appearance to the gastric mucosa which, with increasing severity of the condition, can develop vascular ectasia and become very friable. Typical presentation is with chronic GI blood loss but acute haemorrhage may occur.

Reference:

Bloom S, Webster G, *Oxford Handbook of Gastroenterology and Hepatology*, Oxford University Press 2006.

[Q: 2060] OnExamination 2012 - Gastroenterology

A 71-year-old woman comes to the clinic for advice.

Over the course of the past year or two she has had increasing problems with regurgitation of rotten food, has lost weight and acquired a chronic cough. According to

her partner she has problems with halitosis which have not improved on multiple visits to the dentist.

On examination her BP is 145/82 mmHg, pulse is 70 and regular and her BMI is 27. She has a neck mass which appears to gurgle when she swallows.

Investigations show:

Haemoglobin 13.2 g/dl(11.5-16.0)

White cell count $7.3 \times 10^9/L$ (4-11)

Platelets $161 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 95 micromol/l (79-118)

Which of the following is the most likely diagnosis?

- 1- Achalasia
- 2- Gastro-oesophageal reflux disease (GORD)
- 3- Oesophageal carcinoma
- 4- Pharyngeal pouch
- 5- Plummer-Vinson's disease

Answer & Comments

Answer: 4- Pharyngeal pouch

The history of regurgitation of rotten food, coupled with chronic cough and a gurgling mass on examination fits best with a pharyngeal pouch. Aspiration of food from the pouch may lead in some cases to pneumonia. Management involves either diverticulectomy for larger lesions, or Dohlman's procedure for smaller pouches.

Whilst GORD is possible alternative diagnosis, a pouch would not be found on examination.

Achalasia is usually associated with progressive dysphagia to both liquids and solids, oesophageal carcinoma with progressive dysphagia first to solids then liquids.

Plummer-Vinson's disease is associated with progressive dysphagia due to oesophageal webs.

[Q: 2061] OnExamination 2012 - Gastroenterology

A 39-year-old man who is known to drink three bottles of wine per day presents to the Emergency department with dull abdominal pain. He tells you that he has suffered from increasing abdominal swelling over the past month.

On examination his BP is 105/72 mmHg, his pulse is 92 and regular. He is pyrexial 37.9°C. His abdomen is generally tender but there are bowel sounds on auscultation. He is penicillin allergic.

Investigations show:

Haemoglobin 10.5 g/dl(13.5-17.7)

White cell count $11.5 \times 10^9/L$ (4-11)

Platelets $125 \times 10^9/L$ (150-400)

Sodium 134 mmol/l (135-146)

Potassium 3.6 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

280 neutrophils / ml in ascitic fluid(<250)

Which of the following is the most appropriate treatment?

- 1- Ciprofloxacin and vancomycin
- 2- Co-amoxiclav
- 3- Erythromycin and ciprofloxacin
- 4- Erythromycin and metronidazole
- 5- Piperacillin and tazobactam

Answer & Comments

Answer: 1- Ciprofloxacin and vancomycin

The diagnosis here is spontaneous bacterial peritonitis - note the history of alcohol excess, gradually increasing abdominal girth and elevated neutrophil count in the ascitic fluid. Spontaneous bacterial peritonitis should be

managed aggressively, and whilst piperacillin and tazobactam are an appropriate choice in those who are not penicillin allergic, in this case ciprofloxacin and vancomycin are the default choice due to the presence of penicillin allergy. Oral continuation therapy is with ciprofloxacin alone or co-trimoxazole.

Co-amoxiclav is not appropriate due to the presence of penicillin allergy, nor is the piperacillin and tazobactam combination.

The two erythromycin combinations do not provide an adequate breadth of coverage.

[Q: 2062] OnExamination 2012 - Gastroenterology

Which of the following drugs is a recognised cause of pancreatitis?

- 1- Alendronic acid
- 2- Amiodarone
- 3- Amitriptyline
- 4- Atenolol
- 5- Azathioprine

Answer & Comments

Answer: 5- Azathioprine

The correct answer is azathioprine.

The remaining listed options are not known to cause pancreatitis.

Reference:

Tofield C, Milson A, Chatu S. *The hands-on guide to clinical pharmacology*. Blackwell Publishing 2005.

[Q: 2063] OnExamination 2012 - Gastroenterology

Which of the following is a cause of macroglossia?

- 1- Amyloidosis
- 2- Crohn's disease
- 3- Glossitis

4- Peutz-Jeghers syndrome

5- Tuberous sclerosis

Answer & Comments

Answer: 1- Amyloidosis

Crohn's disease can affect any part of the gastrointestinal tract from the mouth to the anus. Aphthous ulceration is common in active disease.⁹

Aphthous ulcers³ and glossitis² are both features of coeliac disease.

Patients with Peutz-Jeghers syndrome have characteristic mucocutaneous pigmentation², that is, perioral freckling.

Gingival fibromas are seen in tuberous sclerosis.

[Q: 2064] OnExamination 2012 - Gastroenterology

Which of the following is a cause of primary iron overload?

- 1- Alcoholic liver disease
- 2- Aplastic anaemia
- 3- Haemochromatosis
- 4- Insulin resistance syndrome
- 5- Repeated blood transfusions

Answer & Comments

Answer: 3- Haemochromatosis

Haemochromatosis is the correct answer.

The remaining options are all associated with secondary iron overload.

Iron overload secondary to repeated blood transfusion is a particular problem for patients with hereditary anaemia, and can be a major cause of morbidity.

The association between the metabolic syndrome (insulin resistance, obesity,

hyperlipidaemia) and the development of hepatic iron overload has been described on a number of occasions over the last couple of decades. These patients are usually middle-aged men with mild to moderate iron excess. It is thought compound heterozygosity for the HFE mutations (C282Y and H63D) may have a role, but the link is not yet fully understood.

Aplastic anaemia is often associated with chronic haemolysis, and repeated blood transfusions, both of which are linked with iron overload.

Following heavy alcohol intake, hepatocytes may lose their ability to compensate for inborn errors in iron metabolism, resulting in iron overload. The link between iron and alcohol is further demonstrated by the fact that alcohol increases the severity of liver damage in hereditary haemochromatosis.

Travis SPL, Ahmad T, Collier J, Steinhart AH. *Pocket Consultant Gastroenterology*. Blackwell Publishing 2005.

Review article: *alcoholic liver disease - pathophysiological aspects and risk factors*. Gramenzi A et al. *Aliment Pharmacol Ther* 24, 1151-116.

[Q: 2065] OnExamination 2012 - Gastroenterology

Which of the following drugs is a P450 hepatic enzyme inducer?

- 1- Ciprofloxacin
- 2- Erythromycin
- 3- Ketoconazole
- 4- Phenobarbitone
- 5- Sodium valproate

Answer & Comments

Answer: 4- Phenobarbitone

The correct answer is phenobarbitone.

The remainder of the listed options are all inhibitors of cytochrome P450.

Reference:

Tofield C, Milson A, Chatu S. *The hands-on guide to clinical pharmacology*. Blackwell Publishing 2005.

[Q: 2066] OnExamination 2012 - Gastroenterology

A 22-year-old man has been admitted with severe ulcerative colitis.

He has been on high-dose steroids intravenously for three days but there have been no signs of improvement.

The gastroenterology team have decided to commence ciclosporin.

Which of the following is a recognised adverse effect of ciclosporin?

- 1- Eczema
- 2- Hypertension
- 3- Nephrotic syndrome
- 4- Psoriasis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 2- Hypertension

The correct answer is hypertension.

The remainder are all indications for ciclosporin use - in cases of eczema, psoriasis and rheumatoid arthritis patients will have severe disease.

Cyclosporine also results in nephrotoxicity.

Gum hypertrophy, hirsutism and convulsions are rare adverse reactions.

Reference:

Tofield C, Milson A, Chatu S. *The hands-on guide to clinical pharmacology*. Blackwell Publishing 2005.

[Q: 2067] OnExamination 2012 -
Gastroenterology

Which of the following demonstrates autosomal dominant inheritance?

- 1- Acute intermittent porphyria
- 2- Cystic fibrosis
- 3- Dubin-Johnson syndrome
- 4- Haemochromatosis
- 5- Wilson's disease

Answer & Comments

Answer: 1- Acute intermittent porphyria

Cystic fibrosis is an autosomal recessive disease, where mutations in the gene for the CFTR (cystic fibrosis transmembrane conductance regulator) results in the production of dry protein-rich secretions leading to pulmonary and gastrointestinal complications.

Dubin-Johnson syndrome is a rare autosomal recessive disorder where there is conjugated hyperbilirubinaemia and impaired bilirubin excretion resulting in mild jaundice but normal liver function.

Haemochromatosis demonstrates autosomal recessive inheritance where iron overload can lead to cirrhosis. Other systems are also affected and patients may suffer from

Cardiomyopathy

Diabetes mellitus

Hypogonadism

Skin pigmentation ('bronze diabetes') and

Arthropathy.

Wilson's disease is an autosomal recessive disorder caused by copper retention and impaired incorporation of copper into caeruloplasmin. Patients may develop acute liver failure, and the disease is also a cause of cirrhosis. There may be neuropsychiatric

manifestations such as parkinsonism and cognitive impairment.

Reference:

Bloom S, Webster G, Oxford Handbook of Gastroenterology and Hepatology, Oxford University Press 2006.

[Q: 2068] OnExamination 2012 -
Gastroenterology

From where is the hormone somatostatin released?

- 1- Duodenum
- 2- Jejunum
- 3- Liver
- 4- Pancreas
- 5- Stomach

Answer & Comments

Answer: 4- Pancreas

Somatostatin is released from delta cells in the pancreas and is a strong inhibitor of insulin and glucagon secretion.

Reference:

Kelly C, Flatt PR, McClenaghan NH. Cell-to-cell communication and cellular environment alter the somatostatin status of delta cells.

[Q: 2069] OnExamination 2012 -
Gastroenterology

Which of the following features seen on barium studies is typical of both ulcerative colitis and Crohn's disease?

- 1- Cobblestone mucosa
- 2- Pseudopolyps
- 3- Rose-thorn ulcers
- 4- Skip lesions
- 5- Strictures

Answer & Comments

Answer: 2- Pseudopolyps

Pseudopolyps are seen in both ulcerative colitis and Crohn's disease.

The remainder of options listed tend to be features of Crohn's disease rather than ulcerative colitis.

Reference:

Travis SPL, Ahmad T, Collier J, Steinhart AH. *Pocket Consultant Gastroenterology*. Blackwell Publishing 2005.

[Q: 2070] OnExamination 2012 - Gastroenterology

A 21-year-old man was admitted with confusion.

He was noted to have Kayser-Fleischer rings and his liver function tests were consistent with acute hepatitis.

Which chromosome contains the gene for this disease?

- 1- Chromosome 6
- 2- Chromosome 13
- 3- Chromosome 15
- 4- Chromosome 17
- 5- Chromosome 22

Answer & Comments

Answer: 2- Chromosome 13

The gene involved in Wilson's disease is located on chromosome 13.

Wilson's disease is an autosomal recessive disorder which results in copper deposition in the liver and brain and impaired incorporation of copper into caeruloplasmin.

Wilson's disease is a cause of acute liver failure and can also lead to decompensated cirrhosis.

Patients with neurological disease often have Kayser-Fleischer rings.

In the majority of patients plasma caeruloplasmin is low (< 200 mg/L); serum

copper is < 11 µmol/L and in 65% of patients 24 hour urinary copper is elevated at > 3 µmol.

Liver biopsy will aid the diagnosis.

Treatment includes penicillamine which leads to urinary copper excretion.

Ninety per cent of cases of haemochromatosis are caused by the substitution of tyrosine for cysteine at position 282 of the HFE gene found on chromosome 6.

Marfan's syndrome is caused by defects in fibrillin; the gene responsible is located on chromosome 15.

Neurofibromatosis type 1 is due to a mutation or deletion of the NF1 gene located on chromosome 17.

Neurofibromatosis type 2 is the result of a mutation or deletion of the NF2 gene found on chromosome 22.

[Q: 2071] OnExamination 2012 - Gastroenterology

A 42-year-old man presents with a six month history of diarrhoea and abdominal cramps. On further questioning it appears he has also noticed facial flushing.

On examination there is wheeze on auscultation of his chest and abdominal examination reveals hepatomegaly.

Which of the following investigations would confirm the likely diagnosis?

- 1- 24-hour urinary 5-HIAA
- 2- 24-hour urinary copper
- 3- 24-hour urinary free cortisol
- 4- 24-hour urinary protein
- 5- 24-hour urinary VMA

Answer & Comments

Answer: 1- 24-hour urinary 5-HIAA

This patient has carcinoid syndrome. The diagnosis is made by 24-hour urine collection for 5-hydroxyindoleacetic acid (5-HIAA) - excretion is greater than 0.3 mmol.

Forty five per cent of carcinoid tumours arise in the appendix, 30% arise in the small bowel and 20% in the rectum.

Most patients with carcinoid syndrome have liver metastases.

5-HT, kinins, prostaglandins and other vasoactive substances are secreted.

Clinical features of carcinoid syndrome include diarrhoea and abdominal cramps in the majority of patients.

Flushing, which is often provoked by alcohol, bronchoconstriction and cardiac involvement with tricuspid or pulmonary incompetence are also features.

Diagnosis also includes chest x ray, abdominal ultrasound scan, small bowel radiology and echocardiography to establish the extent of disease. Surgical resection of the primary tumour is possible in some cases; octreotide is the treatment of choice.

In the majority of cases of Wilson's disease 24-hour urinary copper is greater than 3 µmol.

In Cushing's syndrome 24-hour urinary free cortisol is elevated.

Nephrotic syndrome is defined as proteinuria greater than 3.5 g/1.75 m² of body surface per 24 hours, hypoalbuminaemia and oedema.

Screening for pheochromocytoma can be performed by 24-hour urine collection for 4-OH-3-methoxymandelate (HMMA, VMA).

[Q: 2072] OnExamination 2012 - Gastroenterology

A 37-year-old woman gives an eight month history of bloody diarrhoea. On average she has six bowel motions per day with associated

urgency. She also reports weight loss of approximately 3 kg.

On examination she is dehydrated and tachycardic. There is evidence of pallor and abdominal examination reveals left-sided tenderness.

Which of the following pathological features would you expect to find given the likely underlying diagnosis?

- 1- Diffuse mucosal inflammation
- 2- Lymphoid aggregates
- 3- Normal crypt architecture
- 4- Presence of goblet cells
- 5- Transmural inflammation

Answer & Comments

Answer: 1- Diffuse mucosal inflammation

Chronic (particularly for this duration) bloody diarrhoea in a young patient is very suggestive of a diagnosis of ulcerative colitis. The time course is too long for an infective cause and whilst Crohn's may cause a colitis this is less frequent. Bloody diarrhoea occurs in 90-100% of cases of UC. Crohn's disease often presents with intermittent abdominal pain, diarrhoea is usually watery and in half of cases presentation is with perianal disease. Bloody diarrhoea may be a feature of Crohn's colitis but this is less common than UC. The predominant left sided symptoms (urgency and anatomical distribution of the tendency) should also point towards UC.

The answer here therefore is diffuse mucosal inflammation, all the remaining options are histological features of Crohn's disease. Mucosal inflammation is one of the histological findings in UC - transmural inflammation is seen in Crohn's disease.

Lymphocytes are seen in Crohn's disease, whereas neutrophils are found in UC.

Crypt abscesses and goblet cell depletion are also found in UC.

Reference:

Firth JD, Keshav SC, Atkinson RJ, Hirschfield GM, Leeds JS, Medical Masterclass Gastroenterology and Hepatology, Royal College of Physicians of London 2008.

Travis SPL, Ahmad T, Collier J, Steinhart AH. Pocket Consultant Gastroenterology. Blackwell Publishing 2005.

[Q: 2073] OnExamination 2012 - Gastroenterology

A 42-year-old man with a history of ulcerative colitis (UC) comes to the gastroenterology clinic. He currently takes mesalazine and has quiescent disease. He has had three episodes of severe disease, the last one some two years ago.

On examination he looks well, his BP is 115/72 mmHg, his pulse is 75 and regular, and his BMI is 23. His abdomen is soft and non-tender.

Investigations show:

Haemoglobin 13.0 g/dl(13.5-17.7)

White cells $7.8 \times 10^9/L$ (4-11)

Platelets $189 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

Albumin 40 g/l (35-50)

Alanine aminotransferase 35 U/l (5-40)

He asks questions about his UC and risk of colonic malignancy with respect to his UC.

Which of the following features would give you most cause for concern?

- 1- Disease confined to the rectum only
- 2- Disease duration of six years
- 3- Disease throughout the colon
- 4- No signs of primary sclerosing cholangitis
- 5- Three episodes of severe disease flare ups

Answer & Comments

Answer: 3- Disease throughout the colon

Out of these factors, pancolitis would give most cause for concern with respect to risk of colonic malignancy. The relative risk for colonic carcinoma versus the general population is 14.8 for pancolitis, versus 1.7 for distal disease only.

Other features of concern in patients with UC include:

Primary sclerosing cholangitis

Presence of dysplastic lesions within the colon

Prolonged disease (8-10 years after diagnosis or more).

High-grade dysplasia or carcinoma necessitates colectomy, while many also recommend colectomy in patients with low-grade dysplasia.

[Q: 2074] OnExamination 2012 - Gastroenterology

A 19-year-old woman returns from her gap year travels with chronic low grade fever, intermittent abdominal pain and diarrhoea. She has been feeling unwell for the past months and has returned to the UK because she has begun to lose weight. Her only medication is the combined oral contraceptive pill.

On examination she looks pale, her BP is 110/60 mmHg, pulse is 75, and her BMI is 18 kg/m². Her abdomen is soft, but she does complain of some right-sided abdominal pain.

Investigations show

Hb 11.0 g/dl(11.5-16.5)

WCC $9.8 \times 10^9/L$ (4-11)

PLT $187 \times 10^9/L$ (150-400)

CRP 67 mg/l (<10)

Na 139 mmol/l (135-146)

K 4.8 mmol/l (3.5-5)

Cr 120 $\mu\text{mol/l}$ (79-118)

Colonoscopy reveals areas of discrete ulceration identified, punctuated by normal mucosa. The biopsy reveals transmural non-caseating granulomata.

Which of the following is the most likely diagnosis?

- 1- Amoebiasis
- 2- Behçet's syndrome
- 3- Crohn's disease
- 4- Ulcerative colitis
- 5- Yersinia infection

Answer & Comments

Answer: 3- Crohn's disease

The presence of skipping and full thickness inflammation with granuloma formation is typical of Crohn's disease. Whilst an infectious agent is a possibility, it is less likely than inflammatory bowel disease here.

We are not given a history of significant oral or genital ulceration, which makes Behçet's less likely.

Corticosteroids and 5-ASA compounds are the mainstay of therapy for Crohn's.

[Q: 2075] OnExamination 2012 - Gastroenterology

A 27-year-old woman presents to the Emergency department very agitated, complaining of abdominal pain. This has been her third attendance over the past six months, and each time there have been no significant findings. Her only medication of note is the oral contraceptive pill.

On this occasion her BP is elevated 155/90 mmHg, her pulse is 92, and her temperature is 37.8°C. Her abdomen is generally tender but soft, and she has active bowel sounds. She complains of lower limb weakness, and she appears to have 4/5 power weakness below the knee.

Investigations show:

Hb 13.4 g/dl(13.5-18)

WCC $10.2 \times 10^9/L$ (4-10)

PLT $194 \times 10^9/L$ (150-400)

Na 132 mmol/l (134-143)

K 4.4 mmol/l (3.5-5)

Cr 110 $\mu\text{mol/l}$ (60-120)

Which of the following is the most likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Mesenteric adenitis
- 3- Münchausen's disease
- 4- Somatisation disorder
- 5- Variegate porphyria

Answer & Comments

Answer: 1- Acute intermittent porphyria

Acute intermittent porphyria (AIP) is associated with:

Hypertension

A mild increase in temperature

Non-specific abdominal pain

Hyponatraemia.

Patients feel normal between attacks, and the disease itself is due to accumulation of both porphobilinogen and amino-levulinic acid.

In general, drugs that lead to increased activity of the hepatic P450 system, such as phenobarbital, sulfonamides, oestrogens, and alcohol, are associated with increased risk of acute attacks.

The risk of other drugs is difficult to predict, and lists of agents thought to precipitate acute porphyria are available from the internet.

[Q: 2076] OnExamination 2012 -
Gastroenterology

A 21-year-old anorexic is admitted for parenteral nutrition and has a tunnelled line inserted.

A few days after parenteral feeding has begun you are asked to see her as she has begun complaining of diplopia, lethargy and muscle weakness. She also has paraesthesia affecting her hands and feet.

Examination confirms global muscle weakness and peripheral sensory loss.

Which of the following electrolyte abnormalities is the most likely to have occurred?

- 1- Hyperkalaemia
- 2- Hypermagnesaemia
- 3- Hyperphosphataemia
- 4- Hypocalcaemia
- 5- Hypophosphataemia

Answer & Comments

Answer: 5- Hypophosphataemia

This patient is suffering from re-feeding syndrome, where patients complain of a range of symptoms which can include

Muscle weakness

Peripheral neuropathy

Neurological impairment

Myocardial depression.

It is characterised by a fall in phosphate, magnesium, potassium and fluid accumulation, which in combination can lead to cardiac failure.

Patients at risk from re-feeding include those who are fed after a prolonged period of starvation, such as those with anorexia, and those with chronic alcoholism.

The key to avoiding re-feeding syndrome and hypophosphataemia is involvement of a specialist dietician who will be able to advise on adequate phosphate replacement during the initial stages of re-feeding.

[Q: 2077] OnExamination 2012 -
Gastroenterology

A 41-year-old woman comes to the gastroenterology clinic for review. She underwent extensive resection of her distal small bowel for Crohn's disease around three months earlier.

She is still suffering from diarrhoea and is worried that her Crohn's disease is still active. On examination her BP is 105/70 mmHg with a pulse of 80. Her abdomen is soft and non-tender.

Investigations show

Haemoglobin 10.4 g/dl(13.5-8)

White cell count $4.5 \times 10^9/L$ (4-10)

Platelets $195 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (134-143)

Potassium 3.4 mmol/l (3.5-5)

Creatinine 140 $\mu\text{mol/l}$ (60-120)

C reactive protein 9 mg/l (<10)

Which of the following is the most likely diagnosis?

- 1- Active Crohn's disease
- 2- Bacterial overgrowth syndrome
- 3- Bile acid diarrhoea
- 4- Ischaemic colitis
- 5- Short bowel syndrome

Answer & Comments

Answer: 3- Bile acid diarrhoea

We are told that this patient has undergone extensive distal small bowel resection, but she does not have an ileostomy. As such, it is most

likely that she has colonic bile acid irritation leading to diarrhoea.

Short bowel syndrome is usually associated with voluminous diarrhoea of up to 5 litres per day, normally through the ileostomy outlet.

There is no indication of active Crohn's disease, and bacterial overgrowth syndrome is usually associated with symptoms of abdominal bloating.

Cholestyramine may be effective for the treatment of bile acid diarrhoea.

[Q: 2078] OnExamination 2012 - Gastroenterology

A 58-year-old female with type 2 diabetes is admitted with diarrhoea and vomiting. She has noticed small amounts of blood in her stools. The vomiting had commenced one day after a meal of chicken and chips.

The patient's type 2 diabetes is treated with diet alone. Stool cultures taken by the GP reveal *Campylobacter jejuni*.

Which of the following is the most appropriate therapy?

- 1- Amoxicillin
- 2- Cefaclor
- 3- IV fluids
- 4- Metronidazole
- 5- Trimethoprim

Answer & Comments

Answer: 3- IV fluids

Campylobacter is a leading cause of diarrhoeal illness, often caused by ingestion of undercooked meat harbouring the pathogen. It is also a major cause of traveller's diarrhoea.

The use of antibiotic therapy for the management of *Campylobacter* infection in adults is controversial. Antibiotic of choice in this infection is erythromycin, though

ciprofloxacin and tetracycline may also be appropriate.

However, appropriate fluid replacement and anti-emetics are initially indicated - most units advocate no antibiotic treatment.

[Q: 2079] OnExamination 2012 - Gastroenterology

A patient presents with haematemesis.

An oesophagogastroduodenoscopy detects a bleed in the greater curvature of the stomach.

Which of the following arteries is most likely to be the source of the bleeding?

- 1- Cystic artery
- 2- Right gastric artery
- 3- Right hepatic artery
- 4- Splenic artery
- 5- Superior pancreaticoduodenal artery

Answer & Comments

Answer: 4- Splenic artery

The superior pancreaticoduodenal artery, a branch of the gastroduodenal artery, supplies the head of the pancreas and the upper duodenum and anastomoses with the inferior pancreaticoduodenal artery.

The right hepatic artery supplies the right lobe of the liver and part of the caudate lobe.

The right gastric artery is mainly found to supply the pylorus and the lesser curvature of the stomach.

The splenic artery sends branches to the greater curvature of the stomach, as well as supplying pancreas and spleen.

[Q: 2080] OnExamination 2012 - Gastroenterology

A patient presents with haematemesis. An oesophagogastroduodenoscopy detects a bleed in the lesser curvature of the stomach.

Which of the following arteries is most likely to be the cause of the bleeding?

- 1- Left gastro-omental artery
- 2- Pancreaticoduodenal artery
- 3- Right gastric artery
- 4- Right hepatic artery
- 5- Splenic artery

Answer & Comments

Answer: 3- Right gastric artery

The pancreaticoduodenal artery supplies mainly the upper and lower duodenum and the head of the pancreas.

The gastro-omental arteries supply the greater curvature of the stomach.

The right gastric artery arises from the hepatic artery or the left hepatic artery, supplies the pylorus and travels along the lesser curvature of the stomach, supplying it, and anastomosing with the left gastric artery.

[Q: 2081] OnExamination 2012 - Gastroenterology

A 51-year-old male labourer presents with a haematemesis.

Which of the following features confers the greatest risk of a poor outcome?

- 1- A blood pressure of 134/88 mmHg
- 2- A history of ischaemic heart disease (IHD)
- 3- A plasma glucose of 7.2 mmol/l
- 4- A pulse of 90 beats per minute
- 5- His age

Answer & Comments

Answer: 2- A history of ischaemic heart disease (IHD)

There are a number of available scoring systems which stratify subjects with GI bleed into high and low risk groups.

The Rockall scoring system is based on:

Age (the higher the age the worse the prognosis)

Comorbidities (IHD)

Presence of shock

Endoscopic abnormalities.

The Canadian Consensus Conference Statement utilises a similar system, incorporating endoscopic factors including:

Active bleeding

Major stigmata of recent haemorrhage

Ulcers greater than 2 cm in diameter

The location of ulcers in proximity to large arteries.

The Baylor Bleeding score attaches a score to pre- and post- endoscopic features.

The Blatchford score is based on clinical parameters alone:

Elevated blood urea nitrogen

Reduced haemoglobin

A drop in systolic blood pressure

Raised pulse rate

The presence of melaena or syncope

Evidence of hepatic or cardiac disease.

[Q: 2082] OnExamination 2012 - Gastroenterology

A study comparing contrast CT colonography with the reference technique of colonoscopy for large bowel carcinoma reveals the following data in 400 patients:

	CT Positive	CT Negative
Colonoscopy Positive	30	10
Colonoscopy negative	20	340

Which one of the following most accurately describes the performance of CT versus colonoscopy for the diagnosis of large bowel cancer?

- 1- There are 340 false negatives
- 2- There are 370 false negatives
- 3- There are 10 false positives
- 4- There are 20 false positives
- 5- There are 20 true negatives

Answer & Comments

Answer: 4- There are 20 false positives

In this question colonoscopy is the reference standard whilst CT colongraphy is the new test being evaluated.

There are 40 patients with bowel cancer as identified by colonoscopy. CT scanning correctly identifies 30 of these (true positives) but fails to identify 10 (false negatives). There are 360 patients without the disease with 20 identified as having cancer by CT (false positives), the remaining 340 are true negatives.

[Q: 2083] OnExamination 2012 - Gastroenterology

Which of the following gut hormones stimulates acid secretion in the stomach?

- 1- Cholecystokinin (CCK)
- 2- Gastrin
- 3- Polypeptide P
- 4- Secretin
- 5- Vasoactive intestinal peptide (VIP)

Answer & Comments

Answer: 2- Gastrin

Gastrin is secreted from the antrum of the stomach when stimulated by parasympathetic nerves and the presence of amino acids in the stomach.

It stimulates:

Gastric motility

Growth and acid secretion

Intestinal motility.

The secretion of gastrin is inhibited by acid in stomach and somatostatin.

[Q: 2084] OnExamination 2012 - Gastroenterology

A 64-year-old lady presents with symptoms suggestive of irritable bowel syndrome.

Which of the following would represent a 'red flag' indicator and prompt further investigation?

- 1- Abdominal pain
- 2- Bloating
- 3- Change in bowel habit for last two years
- 4- More frequent stools last two months
- 5- Weight gain

Answer & Comments

Answer: 4- More frequent stools last two months

The 'red flag' indicators are listed in the NICE guidelines as:

Unintentional and unintended weight loss

Rectal bleeding

A family history of bowel or ovarian cancer

A change in bowel habit to looser and / or more frequent stools persisting for more than six weeks in a person aged over 60 years.

Also on clinical examination the other 'red flag' indicators are:

Anaemia

Abdominal mass

Rectal mass

Inflammatory markers for inflammatory bowel disease.

[Q: 2085] OnExamination 2012 - Gastroenterology

A man is admitted with acute abdominal pain and vomiting. He is diagnosed and treated for acute pancreatitis.

Which of the following features is associated with a worse prognosis in acute pancreatitis?

- 1- Plasma glucose of 11.1 mmol/l (3.5-5.5)
- 2- Plasma sodium of 125 mmol/l (133-144)
- 3- Serum amylase of 1200 iu/l (24-100)
- 4- The patient is 50 years of age
- 5- White cell count of $13.9 \times 10^9/L$

Answer & Comments

Answer: 1- Plasma glucose of 11.1 mmol/l (3.5-5.5)

There are a number of criteria used in the Ranson's scoring system which reflect prognosis associated with acute pancreatitis.

Ranson's criteria on admission that signify a worse prognosis include:

Age more than 55 years

White cell count more than 16,000

Lactate dehydrogenase more than 600 U/l

Aspartate aminotransferase more than 120 U/l

Glucose more than 10 mmol/l.

[Q: 2086] OnExamination 2012 - Gastroenterology

A 70-year-old lady presented with dyspnoea and fever.

She has a history of weight loss which has been investigated with colonoscopy which found a tumour of the sigmoid colon and she is awaiting surgery.

On examination she has a systolic murmur and ECHO shows vegetations on the mitral valve. A diagnosis of infective endocarditis is made.

Which of the following organisms is associated with a high incidence of colorectal tumours?

- 1- Campylobacter jejuni
- 2- Enterococcus faecalis
- 3- Escherichia coli
- 4- Salmonella typhi
- 5- Streptococcus bovis

Answer & Comments

Answer: 5- Streptococcus bovis

Up to half of patients presenting with Streptococcus bovis endocarditis have colorectal tumours.

[Q: 2087] OnExamination 2012 - Gastroenterology

A 61-year-old man has a 2 cm adenoma removed from his sigmoid colon.

The biopsy results confirm an adenocarcinoma in situ with moderately differentiated dysplastic cells. The pathology report confirms total excision with clear resection margins.

What is the most appropriate follow up management for this patient?

- 1- Annual carcinoembryonic antigen (CEA)
- 2- Chemotherapy
- 3- No follow up
- 4- Regular follow up with colonoscopy
- 5- Regular follow up with no colonoscopy

Answer & Comments

Answer: 4- Regular follow up with colonoscopy

The first thing to note is the question is about planned management.

This patient has been picked up early and has had a tumour resected. His CEA would be normal and would not be expected to be elevated until the disease was quite established on the TNM scale.

However, this patient's prognosis would be excellent but he is by definition someone with increased risk.

Therefore, he should continue to be reviewed with colonoscopy annually for at least two years.

[Q: 2088] OnExamination 2012 - Gastroenterology

A 19-year-old student presents with a 15 week history of diarrhoea. He has lost 2 kg in weight, and has no recent travel abroad.

A smear of a duodenal biopsy reveals many trophozoites.

What is the best treatment option?

- 1- Ciprofloxacin
- 2- Gluten free diet
- 3- Metronidazole
- 4- Prednisolone
- 5- Quinine

Answer & Comments

Answer: 3- Metronidazole

The diagnosis here is giardiasis, caused by Giardia lamblia. Giardia has been reported as a cause of chronic diarrhoea.

Most patients respond to oral metronidazole 250-400 mg three times daily for five days.

[Q: 2089] OnExamination 2012 - Gastroenterology

A 69-year-old male is seen in the outpatients department. He reports weight loss of one stone over three months but his history is otherwise unremarkable.

On examination his abdomen is soft with no palpable masses. A PR examination is normal.

His blood tests show:

Haemoglobin 8.0 g/dL(12-16)

MCV 70 fL(80-96)

Which of the following is the most appropriate investigation for this patient?

- 1- Abdominal x ray and colonoscopy
- 2- CT scan of the abdomen and upper GI endoscopy
- 3- Sigmoidoscopy upper GI endoscopy
- 4- Ultrasound scan of abdomen and colonoscopy
- 5- Upper GI endoscopy and colonoscopy

Answer & Comments

Answer: 5- Upper GI endoscopy and colonoscopy

This man has weight loss and an unexplained microcytic anaemia.

The likely site of blood loss is from the gastrointestinal (GI) tract in absence of an alternative explanation.

This may be due to an occult GI malignancy and therefore the initial investigations of choice are upper and lower GI endoscopy.

[Q: 2090] OnExamination 2012 - Gastroenterology

A 40-year-old male presents with a six hour history of profuse vomiting and over the last two hours had developed left-sided chest pain and dyspnoea.

On examination he had a pulse of 110 beats per minute regular and a blood pressure of 168/90 mmHg.

On palpation, he had crepitus over the left supraclavicular region and neck, reduced heart sounds and left basal sided crackles, plus

some dullness to percussion over the right base of the chest.

What is the most likely diagnosis?

- 1- Aortic dissection
- 2- Aspiration pneumonia
- 3- Oesophageal rupture
- 4- Perforated peptic ulcer
- 5- Pneumothorax

Answer & Comments

Answer: 3- Oesophageal rupture

This man has a history of vomiting which then progressed to chest pain.

The most relevant finding on examination is the crepitus over the chest, indicating surgical emphysema. The most probable cause is therefore spontaneous rupture of the oesophagus.

Mackler's triad (vomiting, chest pain and surgical emphysema) is classical but absent in almost half the cases. The chest x ray (CXR) may reveal the surgical emphysema and a gastrografen swallow is diagnostic.

A CT scan should be performed if a gastrografen swallow is not possible or negative.

Lateral neck x rays may be useful in the early stages where the diagnosis is uncertain and surgical emphysema is not seen on a plain CXR.

Oesophagoscopy has a role in trauma but not in small mucosal tears as here.

[Q: 2091] OnExamination 2012 - Gastroenterology

Which of the following is most commonly associated with the development of pseudomembranous colitis?

- 1- Cefuroxime
- 2- Ciprofloxacin

- 3- Co-trimoxazole
- 4- Erythromycin
- 5- Flucloxacillin

Answer & Comments

Answer: 1- Cefuroxime

Clostridium difficile a Gram positive anaerobic bacterium is the cause of pseudomembranous colitis.

Studies show that when *C. difficile* colonise the gut they release two potent toxins, toxin A and toxin B, which bind to certain receptors in the lining of the colon and ultimately cause diarrhoea and inflammation of the large intestine or colon (colitis).

Commonly the disease is caused by broad spectrum antibiotics most commonly cephalosporins, broad spectrum penicillins and clindamycin. Less commonly, macrolides and quinolones have been reported to cause the disorder.

Appropriate treatment includes metronidazole and oral vancomycin.

[Q: 2092] OnExamination 2012 - Gastroenterology

A 45-year-old male with a long history of alcohol abuse presents with a two day history of deteriorating confusion.

On examination he is drowsy, has a temperature of 39°C, a pulse of 110 beats per minute, a small amount of ascites and has features of a left side hemiparesis.

What is the most likely diagnosis?

- 1- Cerebral abscess
- 2- Cerebro-vascular accident (CVA)
- 3- Hepatic encephalopathy
- 4- Subdural haematoma
- 5- Wernicke's encephalopathy

Answer & Comments

Answer: 1- Cerebral abscess

This man with chronic alcohol abuse now presents with a fever and left hemiparesis.

The most likely diagnosis would therefore be cerebral abscess.

The fever would not itself be explained by a subdural haematoma nor would a simple CVA explain this.

Similarly, delirium tremens or encephalopathy would not be associated with the hemiparesis.

[Q: 2093] OnExamination 2012 - Gastroenterology

Which of the following statements is correct concerning the relationship between type 2 diabetes and colonic cancer?

- 1- Increased concentrations of C peptide are a marker of increased colorectal cancer risk
- 2- Insulin treatment increases recurrence free survival after treatment of colonic cancer
- 3- The increased risk of colorectal cancer in diabetes is related to BMI
- 4- The increased risk of colorectal cancer in diabetes is related to total cholesterol
- 5- Type 1 diabetes has similar risks of colonic cancer as does type 2 diabetes

Answer & Comments

Answer: 1- Increased concentrations of C peptide are a marker of increased colorectal cancer risk

Type 2 diabetes is associated with a 40-60% increase in the risk of cancer of the large bowel. This increase is linked to changes in HbA1c.

Type 2 diabetes is associated with significantly higher rates of overall mortality and reduced disease free and recurrence free survivals after chemotherapy/radiotherapy, and insulin

has not been shown to have any effects on mortality.

No association has been found between colonic malignancy and type 1 diabetes, nor gestational diabetes.

A number of studies have independently linked high circulating concentrations of C-peptide, as a marker of insulin production, with increased colorectal cancer risk. The molecular basis has not been proven, but it may be reasonable to extrapolate it is linked to the growth stimulation effects of insulin. For a discussion see BMJ 2005;330:551-2.

[Q: 2094] OnExamination 2012 - Gastroenterology

A 43-year-old woman presents with abdominal pain and watery diarrhoea.

She is taking ibuprofen for joint pains and has been previously investigated for infertility. She was given a proton pump inhibitor (PPI) by her GP for six weeks with no relief of her symptoms.

Investigations show:

Haemoglobin 12.2 g/dL (11.5-16.5)

Calcium 2.86 mmol/L (2.2-2.6)

Albumin 42 g/L (37-49)

Phosphate 0.8 mmol/L (0.8-1.4)

CRP 10 mg/L (<10)

Endoscopy Multiple small duodenal ulcers

H. pylori Negative

What is the likely diagnosis?

- 1- Crohn's disease
- 2- Cushing's syndrome
- 3- NSAID induced PUD
- 4- Multiple endocrine neoplasia (MEN)
- 5- Small bowel lymphoma

Answer & Comments

Answer: 4- Multiple endocrine neoplasia (MEN)

The C reactive protein (CRP) is not raised making a diagnosis of Crohn's unlikely.

The duodenal ulcers (DUs) have persisted despite a lengthy treatment with PPIs.

Small bowel lymphoma is suggested by narrowing of the intestine lumen resulting in paraumbilical pain made worse by eating, with weight loss, vomiting and occasional intestinal obstruction. Small bowel lymphoma is diagnosed by contrast radiographs and intestinal biopsy.

The most likely diagnosis here is MEN, likely to be MEN1a (Wermer's syndrome).

Multiple DUs make a diagnosis of Zollinger-Ellison's syndrome likely, due to gastrinomas.

Hypergastrinaemia may be the cause of the diarrhoea.

There is also hypercalcaemia as a result of the parathyroid hyperplasia indicative of this condition.

There may not necessarily be a family history, sporadic cases make up 10% of new cases.

The infertility would fit with a prolactinoma.

[Q: 2095] OnExamination 2012 - Gastroenterology

A 50-year-old woman with a long history of alcohol abuse is prescribed phenytoin for epilepsy.

Examination was normal except for a liver edge.

Her full blood count reveals:

Haemoglobin 10.0 g/dL (11.5-16.5)

MCV 122 fL (80-96)

White cell count $2.2 \times 10^9/L$ ($4-11 \times 10^9$)

Platelet count $85 \times 10^9/L$ ($150-400 \times 10^9$)

What is the most likely explanation for these results?

1- Alcoholic liver disease

2- Aplastic anaemia

3- Folic acid deficiency

4- Hypothyroidism

5- Vitamin C deficiency

Answer & Comments

Answer: 3- Folic acid deficiency

Folic acid deficiency would give all these results. In addition she has good reason to be folate deficient - drinks a considerable amount and is on anticonvulsants.

Alcoholic liver disease on its own would not usually cause leucopenia. Where cirrhosis develops leading to portal hypertension and splenomegaly it may result in functional hypersplenism. This may result in pancytopenia. Alcohol itself is also a myelosuppressant. In this case the clinical examination does not support a diagnosis of cirrhosis and a toxic alcohol effect on the marrow is not an option in the answers.

Hypothyroidism would cause a raised mean corpuscular volume (MCV) but not the other parameters.

Scurvy does not cause this picture.

Aplastic anaemia could cause this haematological picture but the clinical scenario leads towards folic acid deficiency.

[Q: 2096] OnExamination 2012 - Gastroenterology

A 78-year-old woman with hip osteoarthritis presents with altered bowel habit.

She undergoes a sigmoidoscopy and rectal biopsy shows normal epithelium and pigment-laden macrophages in the lamina propria.

What is the most likely cause of these findings?

- 1- Diverticular disease
- 2- Laxative abuse
- 3- Mesenteric ischaemia
- 4- Non-steroidal anti-inflammatory drugs
- 5- Ulcerative colitis

Answer & Comments

Answer: 2- Laxative abuse

She has 'melanosis coli' as a result of prolonged laxative use.

Often the bowel mucosa looks dark and 'stained' during colonoscopy.

She may be predisposed to constipation due to immobility from her arthritis and/or use of constipating pain killers.

[Q: 2097] OnExamination 2012 - Gastroenterology

A 30-year-old man presents with acute, profuse, watery diarrhoea with some blood after returning from a holiday in Tanzania. He had been taking oral rehydration salts.

Which one of the following is the most appropriate treatment?

- 1- Ciprofloxacin
- 2- Loperamide
- 3- Metronidazole
- 4- Prednisolone
- 5- Vancomycin

Answer & Comments

Answer: 1- Ciprofloxacin

The most likely cause of such traveller's diarrhoea is *Escherichia coli* and hence ciprofloxacin is recommended for first line antibiotic therapy (when needed) before stool culture results are available.

Metronidazole would be suitable for *Giardia* infection but its course is usually more insidious.

[Q: 2098] OnExamination 2012 - Gastroenterology

A 33-year-old man with chronic hepatitis C is admitted with general deterioration, he has no specific symptoms.

He has missed many of his previous outpatient appointments and currently is not receiving any treatment.

On examination he is generally unwell with a temperature of 37.4°C, blood pressure of 130/72 mmHg and appears jaundiced with the presence of ascites.

His investigations reveal:

Serum Sodium 133 mmol/L (137-144)

Serum Potassium 4.3 mmol/L (3.5-4.9)

Serum Urea 21 mmol/L (2.5-7.5)

Serum Creatinine 336 µmol/L (60-110)

Bilirubin 78 µmol/L (1-22)

AST 92 U/L (5-35)

Alk Phosphatase 267 U/L (45-105)

Albumin 30 g/L (37-49)

Urine sodium 60 mmol/L

Urine dipstick - + blood, +++ protein, leukocytes trace, nitrites negative

Ascitic fluid analysis - RBCs 1,231/mm³, WBCs 190/mm³ (60% lymphocytes), albumin 12 g/L

What is the likely diagnosis?

- 1- Abdominal tuberculosis
- 2- Urinary tract infection
- 3- Hepatorenal syndrome
- 4- Mixed essential cryoglobulinaemia
- 5- Spontaneous bacterial peritonitis

Answer & Comments

Answer: 4- Mixed essential cryoglobulinaemia

This gentleman has renal failure with evidence of a primary renal pathology - significant proteinuria, relative hypertension. Hepatitis C infection is strongly associated with mixed essential cryoglobulinaemia which may produce mesangioproliferative glomerulonephritis. This condition is associated with renal impairment, systemic vasculitic manifestations (including neuropathy, skin manifestations) and arterial thrombosis.

Hepatorenal syndrome is a diagnosis of exclusion and requires correction of hypovolaemia, withdrawal of any diuretics, treatment of sepsis and exclusion of a primary renal pathology prior to diagnosis. In hepatorenal syndrome the kidneys are functionally normal and biopsy is normal, where patients in this situation receive liver transplantation the kidneys will almost always resume normal function. The urinary sodium and urine dipstick results given here indicate a primary renal pathology.

The ascitic tap results indicate that ascites is due to portal hypertension (serum albumin ascites gradient >11 g/L) and do not support the presence of infection within the ascitic fluid, counting against both abdominal tuberculosis and spontaneous bacterial peritonitis.

In the absence of symptoms a urine dipstick indicating a trace of leukocytes and negative nitrites is poorly predictive of the presence of a urinary tract infection, additionally this diagnosis does not adequately explain the degree of proteinuria or renal impairment.

[Q: 2099] OnExamination 2012 - Gastroenterology

With respect to gastric carcinoma, which of the following statements is true?

- 1- Aspirin use is a risk factor for gastric carcinoma

- 2- Early diagnosis of gastric carcinoma results in a five year survival rate of 20%
- 3- Endoscopic ultrasonography is superior to conventional CT scanning for local tumour staging
- 4- Helicobacter pylori infection is not associated with gastric carcinoma
- 5- Incidence of distal stomach tumours is increasing

Answer & Comments

Answer: 3- Endoscopic ultrasonography is superior to conventional CT scanning for local tumour staging

Incidence of distal stomach tumours is actually decreasing while the incidence of tumours in the proximal stomach is increasing.

Nonsteroidal anti-inflammatory drug (NSAID) use is associated with decreased risk of certain gastric tumours.

H. pylori infection has been associated in a number of studies with increased risk of gastric carcinoma.

Screening for gastric carcinoma in Japan detects up to 40% of gastric carcinomas at an early stage and in skilled hands five year survival can be upwards of 90%.

Computed tomography (CT) with gastric dilatation is a useful complementary investigation in the staging of gastric carcinoma, but endoscopic ultrasonography is superior to conventional CT scanning as it is able to assess depth of infiltration and lymphatic dissemination of tumour.

For a comprehensive review see Lancet 2003;362:305-15.

[Q: 2100] OnExamination 2012 - Gastroenterology

A 56-year-old female is noted to have hepatomegaly.

Six years ago she was diagnosed with diabetes mellitus and takes metformin 500 mg tds and gliclazide 80 mg bd. She drinks approximately 15 units of alcohol weekly and stopped smoking 10 years ago.

On examination she has a BMI of 36.2 kg/m², no stigmata of liver disease are evident but she has 6 cm hepatomegaly.

Investigations reveal:

Total Bilirubin 11 µmol/L(1-22)

Alkaline phosphatase 145 U/L(45-105)

AST 100 U/L(1-31)

ALT 150 U/L(5-35)

Albumin 40 g/L(37-49)

Ferritin 434 µg/L(15-300)

Ultrasound of the abdomen reveals an echobright appearance of the liver and gallstones in the gallbladder.

What is the most likely cause of her liver disease?

- 1- Alcoholic liver disease
- 2- Drug induced hepatitis
- 3- Gallstone disease
- 4- Haemochromatosis
- 5- Non-alcoholic steatohepatitis (NASH)

Answer & Comments

Answer: 5- Non-alcoholic steatohepatitis (NASH)

The patient has a hepatic picture in contrast to cholestasis.

Ferritin level is not too high to be considered for haemochromatosis and is an acute phase reactant being typically increased in any inflammatory process.

NASH is very common and is typically encountered in obese patients presenting with a hepatic picture with or without jaundice. Echobright liver suggests fatty change in the liver seen in NASH. It was

previously termed idiopathic decompensated hepatitis and if not treated in terms of lowering BMI and reducing fat intake can lead on to irreversible cirrhosis.

Gallstones are a distraction in this history.

[Q: 2101] OnExamination 2012 - Gastroenterology

A 52-year-old man presents with general deterioration.

He drinks approximately 25 units of alcohol each week and is a smoker of five cigarettes daily.

Examination reveals that he is jaundiced, has numerous spider naevi on his chest and he has a temperature of 37.2°C. Abdominal examination reveals hepato-splenomegaly.

Investigations reveal:

Bilirubin 100 micromol/L (1-22)

Alkaline phosphatase 310 iu/l (45 - 105)

ALT 198 iu/l (5 - 35)

AST 158 iu/l (1 - 31)

Albumin 25 g/L (37 - 49)

Hepatitis B virus surface antigen positive

Hepatitis B virus e antigen negative

Hepatitis B virus DNA awaited

What is the most likely diagnosis?

- 1- Alcoholic liver disease
- 2- Autoimmune chronic active hepatitis
- 3- Carcinoma of the pancreas
- 4- Chronic hepatitis B infection
- 5- Chronic hepatitis D (delta) infection

Answer & Comments

Answer: 4- Chronic hepatitis B infection

The most likely diagnosis is chronic hepatitis B infection given the positive HBV sAg test, multiple stigmata of chronic liver disease and the modest, ALT-predominant transaminitis.

A positive HBVsAg test indicates active hepatitis B infection. Two positive tests six months apart indicate chronic infection however a single positive test without any history of high-risk exposure in the last six months is suggestive.

Alcohol may be contributing to the degree of liver inflammation seen here however the overall amount of alcohol consumed is relatively low and alcohol-related liver disease is typically associated with an AST-predominant elevation in the liver function tests.

Autoimmune chronic active hepatitis would provide an explanation for abnormal liver function tests such as these however it would be unusual in a patient such as this and the positive HBVsAg points to an alternative cause.

Although the alkaline phosphatase level is raised when considered relative to the normal range the degree of elevation is not as significant as for the transaminases indicating that the jaundice is most likely hepatocellular rather than cholestatic (as would be seen in carcinoma of the pancreas obstructing the biliary system).

Additionally this diagnosis would not explain the florid stigmata of chronic liver disease. Infiltrative disease of the liver (for example, widespread metastases) tends to cause an isolated, sometimes profound, elevation of the alkaline phosphatase without any other abnormality on the liver function tests.

Hepatitis D (also known as the delta agent) may cause acute or chronic infection in the setting of hepatitis B infection. It may be a cause of acute hepatitis or decompensation of chronic liver disease. Those patients with super-added HDV infection and chronic hepatitis B tend to progress to cirrhosis and develop hepatocellular carcinoma more rapidly.

Overall HDV infection is rare, less prevalent than HBV infection and is uncommon in Europe with it being reported only in patients who have a history of high-risk behaviours such as injection drug abuse. High prevalence areas include South Italy, North Africa and the Middle East.

It would be unlikely in this individual given the information available.

[Q: 2102] OnExamination 2012 - Gastroenterology

A 40-year-old man is referred with gastro-oesophageal reflux disease (GORD).

Which of the following concerning GORD is correct?

- 1- Acid suppressant therapy should not be given continuously
- 2- Endoscopy is mandatory
- 3- In the presence of Barrett's oesophagus, the risk of future malignancy can be assessed endoscopically without biopsy
- 4- Oesophageal pH monitoring is a good guide to therapy
- 5- Symptoms do not correlate with mucosal status at endoscopy

Answer & Comments

Answer: 5- Symptoms do not correlate with mucosal status at endoscopy

Symptoms of GORD do not correlate with the mucosal appearances at endoscopy.

Although endoscopy should be performed in cases that are not clear cut or do not respond to proton pump inhibitors (PPIs), it is not mandatory.

The risk with Barrett's and hence the diagnosis of Barrett's can only be clarified with biopsy.

Monitoring of pH is not a good guide to therapy but symptomatic improvement is a good guide to the efficacy of therapy.

PPIs can be given continuously where the diagnosis has been satisfactorily proven and relapse of symptoms persist after withdrawal.

[Q: 2103] OnExamination 2012 - Gastroenterology

A 65-year-old man was investigated for weight loss and dyspepsia.

Endoscopic examination revealed an ulcerated lesion in the stomach and biopsy revealed the presence of a low grade mucosa-associated lymphoma with *Helicobacter pylori*.

Further investigation with CT of chest and abdomen were normal as were bone marrow aspirate and trephine.

What is the best treatment option for this patient?

- 1- Eradication therapy for *Helicobacter pylori*
- 2- IV chemotherapy
- 3- Oral chlorambucil
- 4- Partial gastric resection
- 5- Radiotherapy

Answer & Comments

Answer: 1- Eradication therapy for *Helicobacter pylori*

This is a gastric mucosal-associated lymphoid tissue (MALT) tumour.

These are usually marginal zone B cell lymphomas and associated with an excellent prognosis.

Low grade gastric MALT tumours associated with *Helicobacter pylori* infection respond in over 80% to *Helicobacter* eradication as the primary mode of treatment.

Radiotherapy is considered but is generally unnecessary.

[Q: 2104] OnExamination 2012 - Gastroenterology

A new diagnostic test for malabsorption has been analysed and the results have yielded the following 2x2 contingency table:

	Disease present	
	Yes	No
+ve test result	90	10
-ve test result	20	80

Applying this test to a case of chronic diarrhoea from a patient group where the prevalence of malabsorption is known to be 20% (probability = 0.2).

What is the probability of a patient having malabsorption if they have a positive test?

- 1- 0.16
- 2- 0.24
- 3- 0.48
- 4- 0.64
- 5- 0.8

Answer & Comments

Answer: 4- 0.64

This is tough but the College are putting more and more evidence based medicine questions into the examination. This question tests understanding of pre-test and post-test odds, likelihood ratios, sensitivity and specificity. Getting it right requires you to recognise that the prevalence of the condition is different in population from which the contingency table was produced (55%) as compared to the population from which the patient in question comes (20%).

You are being asked to calculate the positive posttest probability - ie the likelihood that a patient has the condition in question given a positive test. Where there is nothing to suggest that an individual's likelihood of having a particular condition is any different from the reference population then the

positive predictive value may be used as an estimate of the positive posttest probability however this is not the case here. As a result you are required to calculate likelihood ratios and take account of the prevalence of the condition within the new test population.

The calculation is as follows.

$$\text{Sensitivity} = A/(A+C) = 90/(90 + 20) = 0.818$$

$$\text{Specificity} = D/(B+D) = 80/(10 + 80) = 0.889$$

$$\text{Likelihood ratio for a positive test (LR+)} = \text{sensitivity}/(1 - \text{specificity}) = 0.818 / (1 - 0.889) = 7.2$$

$$\text{Pre-test odds} = \text{prevalence}/(1 - \text{prevalence}) = 0.2 / (1 - 0.2) = 0.25$$

$$\text{Post-test odds} = \text{pre-test odds} \times \text{LR+} = 0.25 \times 7.2 = 1.8$$

$$\text{Post-test probability} = \text{posttest odds}/(\text{posttest odds} + 1) = 1.8 / (1.8 + 1) = 0.64$$

Disease present

test result yes no

+ve true positive (A) false positive (B)

-ve false negative (C) true negative (D)

The following are formulas for calculating various common statistical values used in understanding the value of diagnostic tests:

$$\text{Sensitivity (how much a test is positive in disease)} = A / (A + C)$$

$$\text{Specificity (how much a test is negative in health)} = D / (B + D)$$

$$\text{Positive predictive value} = A / (A + B)$$

$$\text{Negative predictive value} = D / (C + D)$$

Pre-test odds = the odds of having the disease before you do the test (for example, your rule-of-thumb estimate or the prevalence of the disease in the population or based on clinical findings, etc.)

Post-test odds = the odds of having the disease after you did the test

$$\text{Systematic error} = (A + B) / (A + C)$$

Likelihood ratio (LR) = (the ratio of the chance of having a positive test if the disease is present to the chance of having a positive test if the disease is absent) = sensitivity / (1 - specificity)

$$\text{LR-} = (1 - \text{sensitivity}) / \text{specificity}$$

Likelihood ratios are good for

Directly calculating post-test odds

Tests with multiple levels (that is, not just +ve or -ve). Calculate the LR at each level by taking the ratio of true +ves to false +ves both expressed as percentages of the total number tested.

Diseases requiring multiple tests. The post-test odds after one test is the pre-test odds for the next.

[Q: 2105] OnExamination 2012 - Gastroenterology

A 56-year-old man from Thailand presented with abdominal pain and a mass in the right upper quadrant. He reported that he had been diagnosed with viral hepatitis several years previously.

Investigations showed:

Serum alpha-fetoprotein 13,500 IU/L (< 10)

What is the most likely underlying viral infection?

- 1- Hepatitis A virus
- 2- Hepatitis B virus
- 3- Hepatitis C virus
- 4- Hepatitis D virus
- 5- Hepatitis E virus

Answer & Comments

Answer: 2- Hepatitis B virus

The patient has chronic viral hepatitis and presents with a hepatoma.

The underlying cause must be either hepatitis B virus (HBV) or hepatitis C virus (HCV).

There is a higher prevalence of HBV in the Far East and since his country of origin is the only other detail that gives a clue to the cause of his hepatitis, the most likely viral agent is HBV.

[Q: 2106] OnExamination 2012 - Gastroenterology

Which one of the following statements is true of autoimmune hepatitis?

- 1- It is associated with hypogammaglobulinaemia
- 2- It may be associated with keratoconjunctivitis sicca
- 3- It rarely interferes with menstruation except in later stages
- 4- It rarely presents before 20 years of age
- 5- It usually presents as an acute hepatitis

Answer & Comments

Answer: 2- It may be associated with keratoconjunctivitis sicca

It occurs frequently in young (10-20 years) and middle-aged women.

Twenty five per cent present as acute hepatitis, but usually the onset is insidious.

Some may be asymptomatic for years and then are found to have signs of chronic liver disease.

Amenorrhoea is common.

It is associated with hyperglobulinaemia and other autoimmune disease.

Sixty per cent are associated with HLA-B8, DR3 and Dw3.

The sicca syndrome (xerostomia/dry eyes, keratoconjunctivitis sicca) may occur.

[Q: 2107] OnExamination 2012 - Gastroenterology

Which of the following is correct regarding infection with Salmonella typhi?

- 1- Children are particularly likely to become carriers
- 2- Most carriers are female
- 3- Faecal culture is almost always positive during the first week of illness
- 4- Relapse does not occur if antibiotics are taken for two weeks
- 5- Vaccinated individuals who develop the disease will have a mild illness

Answer & Comments

Answer: 2- Most carriers are female

Children are rarely chronic carriers of the organism although for some unknown reason females are more commonly long term carriers than males (remember Typhoid Mary).

C. Only 50% of cases.

E. Higher threshold but same disease.

[Q: 2108] OnExamination 2012 - Gastroenterology

A 28-year-old male presents with a four day history of profuse bloody diarrhoea after returning from a holiday in the Far East.

Which of the following regarding his illness is true?

- 1- A negative amoebic fluorescent antibody test excludes a diagnosis of acute amoebic dysentery
- 2- Cysts to *E. histolytica* in the stools confirms a diagnosis of acute amoebic dysentery
- 3- Cholera is a likely diagnosis
- 4- Giardiasis is a likely diagnosis
- 5- Shigellosis is a likely diagnosis

Answer & Comments

Answer: 5- Shigellosis is a likely diagnosis

Shigellosis is a possible cause of profuse bloody diarrhoea as cholera and giardiasis are associated with watery diarrhoea.

Trophozoites are seen in acute amoebic dysentery, and the test is not 100% sensitive.

[Q: 2109] OnExamination 2012 - Gastroenterology

A 44-year-old male with Child's grade C cirrhosis presented with haematemesis.

Which one of the following drugs, administered intravenously, would be the most appropriate immediate treatment?

- 1- Isosorbide dinitrate
- 2- Omeprazole
- 3- Propranolol
- 4- Somatostatin
- 5- Tranexamic acid

Answer & Comments

Answer: 4- Somatostatin

The suggestion is that this patient is at particularly high risk of oesophageal varices.

Child's classification of cirrhosis is a points scale, based upon ascites/bilirubin, etc, reflecting prognosis. The grades depend on the points scored from A-C, with C reflecting greatest risk.

Somatostatin acts to reduce portal pressures and has been demonstrated to be as effective as endoscopy at controlling variceal bleeding in the acute setting.

B-blockers can be used as oral prophylaxis for oesophageal varices.

Intravenous omeprazole has also been shown to be effective in reducing mortality in gastrointestinal haemorrhage of any cause

(NEJM 2002) but somatostatin may be expected to be superior for the above patient.

[Q: 2110] OnExamination 2012 - Gastroenterology

A 32-year-old woman with Crohn's disease has a history of a right hemicolectomy for ileo-colonic disease.

Since the operation she has had frequent diarrhoea but no blood in the stools.

Investigations show:

ESR 10mm (0-20mm/1st hour)

Platelets $240 \times 10^9/L$ (150-400 $\times 10^9$)

Serum CRP 7 mg/L (<10)

Which is the best treatment?

- 1- Cholestyramine
- 2- Mesalazine
- 3- Metronidazole
- 4- Omeprazole
- 5- Prednisolone

Answer & Comments

Answer: 1- Cholestyramine

The erythrocyte sedimentation rate (ESR), C reactive protein (CRP) and platelet counts are not raised indicating that this patient's symptoms are not due to active Crohn's. Also the diarrhoea is not bloody which goes against active Crohn's colitis.

Hence mesalazine or prednisolone would not be effective here.

Metronidazole is typically given for peri-anal disease.

The history includes a previous right hemicolectomy for ileo-colonic disease.

Loss of the terminal ileum frequently leads to bile salt malabsorption and treatment with the bile salt chelator cholestyramine quickly relieves the problem.

[Q: 2111] OnExamination 2012 -
Gastroenterology

A 52-year-old woman presented with history of worsening dysphagia over many years. Recently there had been episodes of ill-defined central chest discomfort and nocturnal cough.

What is the most likely diagnosis?

- 1- Achalasia
- 2- Barrett's oesophagus
- 3- Motor neurone disease (MND)
- 4- Oesophageal carcinoma
- 5- Pharyngeal pouch

Answer & Comments

Answer: 1- Achalasia

Achalasia presents most often in the third to fifth decade. Symptoms usually develop years before the patient presents. Vague chest discomfort is common. Thirty per cent have a nocturnal cough due to aspiration of oesophageal contents.

Barrett's oesophagus does not cause dysphagia.

MND causes dysphagia due to problems with chewing and initiating a swallow and would not cause chest discomfort.

Oesophageal carcinoma is very unlikely due to the duration of symptoms (years).

A pharyngeal pouch usually presents in the sixth to seventh decade with regurgitation and would not cause chest discomfort.

[Q: 2112] OnExamination 2012 -
Gastroenterology

Which of the following is the commonest cause of traveller's diarrhoea?

- 1- Entamoeba histolytica
- 2- Escherichia coli

- 3- Giardia lamblia
- 4- Shigella flexneri
- 5- Yersinia enterocolitica

Answer & Comments

Answer: 2- Escherichia coli

Enterotoxigenic E coli is the commonest cause of traveller's diarrhoea and is usually a self limiting condition.

Usually no treatment or investigation is required for this brief diarrhoeal illness.

Other causes that may be associated with prolonged diarrhoea include Giardia and amoebiasis.

Chronic diarrhoea merits investigation.

[Q: 2113] OnExamination 2012 -
Gastroenterology

Which of the following factors decrease large intestinal motility?

- 1- Anticholinergic agents
- 2- CCK-PZ
- 3- Gastric distension
- 4- Laxatives
- 5- Parasympathetic activity

Answer & Comments

Answer: 1- Anticholinergic agents

The other options and cholinergic agents increase large intestinal motility.

[Q: 2114] OnExamination 2012 -
Gastroenterology

A 30-year-old Caucasian male presents with a six month history of weight loss, abdominal pain, and diarrhoea. On examination you note finger clubbing.

Which of the following diagnoses is least likely.?

- 1- Coeliac disease
- 2- Crohn's disease
- 3- Ileo-caecal TB
- 4- Ulcerative colitis
- 5- Whipple's disease

Answer & Comments

Answer: 3- Ileo-caecal TB

Ileo-caecal TB is the only condition mentioned not associated with clubbing and would be very rare in a young Caucasian in the United Kingdom.

[Q: 2115] OnExamination 2012 -
Endocrinology

A 56-year-old man presented to the Emergency Department with an episode of collapse at home.

He had been feeling increasingly tired for the last two months and also reported a loss of libido. He had undergone a transsphenoidal surgery two years ago, followed by external beam radiation for a non-functional pituitary adenoma. He took ramipril 10 mg OD for hypertension.

On examination, pulse was 102 beats per minute and regular, BP measured 104/66 mmHg in the lying position, dropping to 80/40 mmHg on standing. Heart sounds were normal. There was no galactorrhoea to expression and testicular volume was normal.

Investigations showed:

Serum Sodium 129 mmol/L(137-144)

Serum Potassium 4.8 mmol/L(3.5-4.9)

Serum Urea 7.2 mmol/L(2.5-7.5)

Serum creatinine 88 µmol/L(60-110)

Serum testosterone 4.5 nmol/L(9-35)

Plasma LH 0.3 U/L(1-10)

Plasma thyroid-stimulating hormone 0.1 mU/L(0.4-5)

Plasma Free T₄ 7 pmol/L(10-22)

Insulin-like growth factor 15.2 nmol/L(5.6-23.3)

ECG Normal

Which is the next most appropriate investigation?

- 1- GHRH-arginine test
- 2- Insulin stress test
- 3- MRI scan of pituitary
- 4- Short Synacthen test
- 5- TRH test

Answer & Comments

Answer: 4- Short Synacthen test

The most appropriate investigation in this patient who has biochemistry suggestive of hypopituitarism and has hyponatraemia is to establish whether he has hypoadrenalism.

Thus the short Synacthen test is most appropriate and in view of the seriousness of undetected hypoadrenalism should be the first test.

[Q: 2116] OnExamination 2012 -
Endocrinology

A 48-year-old lady with Addison's disease presented in a small peripheral clinic. She says that she has run out of her hydrocortisone and she usually takes 20 mg in the morning and 10 mg in the evening.

No hydrocortisone is available at the clinic but you do have prednisolone which you would like to prescribe instead until a prescription of hydrocortisone can be dispensed.

What is the equivalent daily dose of prednisolone?

- 1- 2.5 mg
- 2- 5 mg
- 3- 7.5 mg
- 4- 10 mg
- 5- 20 mg

Answer & Comments

Answer: 3- 7.5 mg

1 mg is equivalent to 4 mg hydrocortisone so this lady should be given 7.5 mg.

If 2.5 mg tablets were not available (to go with a 5 mg tablet to make 7.5 mg tablet) then 10 mg would be fine.

It is better to overdose rather than underdose especially where there is stress or illness.

[Q: 2117] OnExamination 2012 - Endocrinology

A 39-year-old female presents with lethargy, nausea, and muscle cramps; and she has passed 450 ml of urine in the last 24 hours.

She was recently started on a new medication.

Investigations show:

Serum sodium 128 mmol/l (137-144)

Plasma osmolality 272 mosmol/l (275-290)

Urine osmolality 380 mosmol/l (350-1000)

Which of the following recently prescribed drugs accounts for the findings?

- 1- Aspirin
- 2- Fluoxetine
- 3- Furosemide
- 4- Lithium
- 5- Metoprolol

Answer & Comments

Answer: 2- Fluoxetine

This lady has:

Hyponatraemia

Hypotonicity (low serum osmolality) and

Inappropriately concentrated urine

which are consistent with syndrome of inappropriate antidiuretic hormone (ADH).

Of the drugs listed, fluoxetine is the most likely cause of syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

[Q: 2118] OnExamination 2012 - Endocrinology

A 57-year-old man attends the outpatient clinic. He has had type 2 diabetes for seven years having been diagnosed following an acute myocardial infarction at 50 years of age.

His diabetes was deteriorating with blood glucose readings of 9-12 at home despite following a diet and taking regular exercise.

Another practitioner commenced him on pioglitazone. His current treatment is metformin 850 tds, pioglitazone 30 mg, aspirin 75 mg/day, carvedilol 12.5 mg bd, ramipril 10 mg od, furosemide 80 mg daily, simvastatin 40 mg/day.

On examination he is overweight with a BMI of 29, his BP is 128/74 mmHg with pulse rate of 63 min⁻¹. He has no heart murmurs and there is some pitting oedema in the lower limbs. Auscultation reveals a clear chest with no evidence of pulmonary oedema. He is obese with no organomegaly.

His ECG shows sinus rhythm with poor r wave progression.

His HbA1c checked in the clinic is 8.5% (3.8-6.4).

What is the most appropriate way to treat his glycaemic control?

- 1- Add gliclazide 80 mg bd
- 2- Increase pioglitazone to 45 mg daily
- 3- Stop metformin and use Competact (combination of metformin and pioglitazone)
- 4- Substitute pioglitazone with gliclazide 80 mg bd
- 5- Add insulin to his regime

Answer & Comments

Answer: 4- Substitute pioglitazone with gliclazide 80 mg bd

This patient is likely to be insulin resistant; however there is evidence of heart failure and fluid overload, so use of pioglitazone is absolutely contraindicated. These drugs promote fluid retention by means of an action on the collecting ducts of the kidney so promoting sodium and water retention.

The only appropriate action therefore is to stop pioglitazone, substitute this with the insulin secretagogue gliclazide which will hopefully improve his glycaemic control, although progression to insulin may not be too far around the corner.

[Q: 2119] OnExamination 2012 - Endocrinology

A 42-year-old male presents with tiredness and central weight gain, two years after having undergone pituitary surgery for a non-functional pituitary tumour.

He has otherwise recovered from his pituitary surgery well, has been found to have complete anterior hypopituitarism and is receiving stable replacement therapy with testosterone monthly injections, thyroxine and hydrocortisone.

On examination there are no specific abnormalities, his vision is 6/9 in both eyes and he has no visual field defects. From his notes you see that he has gained 8 kg in weight over the last six months and his BMI is 31 kg/m². His blood pressure is 122/72 mmHg.

Thyroid function tests and testosterone concentrations have been normal. A post-operative MRI scan report shows that the pituitary tumour has been adequately cleared with no residual tissue.

Which of the following is the likely cause of his current symptoms?

- 1- Aldosterone deficiency
- 2- Depression
- 3- DDAVP deficiency
- 4- Growth hormone deficiency
- 5- Somatisation disorder

Answer & Comments

Answer: 4- Growth hormone deficiency

This patient presents with deteriorating tiredness and weight gain after having had

pituitary surgery for a non-functioning pituitary tumour. He has associated anterior hypopituitarism but is receiving appropriate and stable replacement therapy.

However, these symptoms are typical of an untreated adult growth hormone deficiency and reductions in quality of life, reduced energy and detrimental changes in body composition are well recognised. Recent evidence would suggest that GH replacement therapy in addition to his current replacement therapy does improve symptoms and quality of life and is endorsed by NICE guidance.

The renin-aldosterone system is independent of the hypothalamo-pituitary axis and therefore aldosterone is not necessary.

The patient does not have any symptoms of thirst or polyuria and therefore vasopressin deficiency is also an unlikely cause of his problems.

Whilst depression or somatisation are possibilities it is important to recognise that the symptoms of tiredness and the weight gain is more in keeping with GH deficiency and no other features of either of the former diagnoses are suggested.

[Q: 2120] OnExamination 2012 - Endocrinology

A 51-year-old man with type 2 diabetes and no previous history of CHD presents at annual review.

Currently he is taking metformin 500 mg bd, aspirin 75 mg od, perindopril 4 mg od and simvastatin 20 mg od.

On examination, his blood pressure is 140/72 mmHg, he has background diabetic retinopathy and has a peripheral sensory neuropathy to light touch in the feet.

Investigations reveal:

HbA1c 7.1 % or 54 mmol/mol (3.8-6.4 or 18-46)

Total cholesterol 3.9 mmol/L (<5.2)

Triglyceride 2.5 mmol/L(0.45-1.69)

HDL-cholesterol 0.8 mmol/L(>1.55)

LDL-cholesterol 2.1 mmol/L(<3.36)

Which treatment option will further improve this patient's dyslipidaemia?

- 1- Cholestyramine
- 2- Ezetimibe
- 3- Fenofibrate
- 4- No other treatment required
- 5- Rosuvastatin

Answer & Comments

Answer: 3- Fenofibrate

This patient's TC and LDL-C are at the currently advocated target levels.

Patients with T2DM commonly have low HDL-C and elevated triglycerides (TG). In some patients, TG may improve with stricter glycaemic control.

The role of HDL-C and triglycerides in cardiovascular risk remains unclear. Some authorities advocate desirable HDL-C levels > 1 mmol/l and plasma TG < 1.7 mmol/l in subjects at risk of cardiovascular disease (CVD).

The FIELD study assessed the effects of fenofibrate therapy on CV mortality in patients with type 2 diabetes. Although the primary end-point of CV mortality was not achieved partly due to high use of non-study lipid lowering therapies (statin use was much higher in placebo group 34% versus 18% in fenofibrate), the composite endpoint of major CVD events was significantly reduced with fenofibrate.

Furthermore, at any given LDL or TC level, reduced HDL-C is associated with an increased CHD risk.

Fenofibrate increases HDL-C by 10-15% and reduces plasma TG by 15-20%.

Concomitant fibrate-statin use is associated with an increased risk of myopathy so evaluation of combination therapy for safety and tolerability is important.

When evaluating a patient with hypertriglyceridaemia, secondary causes need to be considered. These include hypothyroidism and poorly controlled diabetes as well as excess alcohol intake.

[Q: 2121] OnExamination 2012 - Endocrinology

A 22-year-old female student presents acutely unwell with vomiting and dehydration. She has a two month history of weight loss and thirst.

Investigations confirm a diagnosis of diabetic ketoacidosis with a glucose of 29.3 mmol/L (3.0-6.0), a pH of 7.12 (7.36-7.44) on blood gas analysis and urinalysis reveals +++ ketones.

What percentage of type 1 diabetics are initially diagnosed following presentation with diabetic ketoacidosis?

- 1- 5%
- 2- 10%
- 3- 15%
- 4- 25%
- 5- 40%

Answer & Comments

Answer: 4- 25%

Approximately 25% of patients with type 1 diabetes will first present in diabetic ketoacidosis although often there are symptoms such as thirst, polyuria and weight loss which have been ignored.

[Q: 2122] OnExamination 2012 - Endocrinology

An 80-year-old woman with type 2 diabetes mellitus is referred with weakness.

She had been taking bendroflumethiazide, digoxin and tolbutamide.

On examination she had a temperature of 37.8°C, a pulse of 98 bpm in atrial fibrillation, and a blood pressure of 118/72 mmHg.

Investigations show:

Sodium 121 mmol/L (137-144)

Potassium 3.3 mmol/L (3.5-4.9)

Urea 4.8 mmol/L (2.5-7.5)

Creatinine 83 µmol/L (60-110)

Glucose 15.2 mmol/L (3.0-6.0)

Chest x ray Normal

What is the most likely cause for the hyponatraemia?

- 1- Addison's disease
- 2- Bendroflumethiazide
- 3- Hyperglycaemia
- 4- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- 5- Tolbutamide

Answer & Comments

Answer: 2- Bendroflumethiazide

This patient has hyponatraemia and hypokalaemia. This is probably due to the bendroflumethiazide which should be stopped.

It is unlikely to be SIADH, of which tolbutamide is a cause, as the hypokalaemia is not typically associated.

Her hyperglycaemia with an osmotic diuresis would cause dehydration.

Addison's disease would be associated with hyperkalaemia, hypotension and elevated urea.

[Q: 2123] OnExamination 2012 - Endocrinology

Which of the following is not a feature of zinc

deficiency?

- 1- Dwarfism
- 2- Geophagia
- 3- Hepatosplenomegaly
- 4- Hypertelorism
- 5- Hypogonadism

Answer & Comments

Answer: 4- Hypertelorism

Zinc deficiency is associated with:

Dwarfism

Hypogonadism

Hepatosplenomegaly

Rough and dry skin

Mental lethargy and

Geophagia.

Zinc supplementation has been shown to improve neuropsychological function in Chinese children.

Zinc deficiency is associated with adverse pregnancy outcomes.

[Q: 2124] OnExamination 2012 - Endocrinology

A 29-year-old female presents with headaches.

She is noted to be hypertensive with a blood pressure of 180/100 mmHg and initial investigations reveal a hypokalaemia of 2.9 mmol/L (3.5-4.9). On closer questioning she is found to consume a large quantity of liquorice.

Inhibition of which enzyme is responsible for the pseudohyperaldosteronism associated with liquorice?

- 1- 17 Alpha hydroxylase (17αOH)
- 2- 5 Alpha-reductase

- 3- 11 Beta hydroxylase (11 bOH)
 4- 11 Beta hydroxysteroid dehydrogenase (11 bHSD)
 5- 21 Hydroxylase

Answer & Comments

Answer: 4- 11 Beta hydroxysteroid dehydrogenase (11 bHSD)

11bHSD is responsible for the conversion of cortisol to the inactive cortisone, preventing activation of the mineralocorticoid receptor by cortisol but permitting activation by aldosterone.

Both liquorice and carbenoxolone inhibit 11bHSD and produce pseudohyperaldosteronism with hypertension and hypokalaemia yet appropriately low renin and aldosterone concentrations.

Much research is focused upon this enzyme of late.

[Q: 2125] OnExamination 2012 - Endocrinology

Useful therapy for improving fertility in polycystic ovarian syndrome (PCOS) includes which of the following?

- 1- Cyproterone acetate
 2- Ethinylloestradiol
 3- Glibenclamide
 4- Metformin
 5- Spironolactone

Answer & Comments

Answer: 4- Metformin

Metformin has been shown to increase the rate of conception in PCOs through improved insulin sensitivity.

Ethinylloestradiol and cyproterone acetate combine to form Dianette the oral contraceptive. Cyproterone acetate is also

used as an anti-androgen for hormonal treatment of prostatic carcinoma.

Spironolactone is used for hirsutism but is teratogenic.

Glibenclamide is not used in PCOs.

[Q: 2126] OnExamination 2012 - Endocrinology

A 32-year-old woman presents with a four month history of amenorrhoea.

She takes no specific therapy. She has two children and her husband has had a vasectomy.

Examination reveals an obese individual but no other abnormality.

Investigations show:

Serum oestradiol 100 pmol/L(130-500)

Serum LH 2.1 mU/L(3.0-6.6)

Serum FSH 2.2 mU/L(3.3-10.1)

Serum prolactin 800 mU/L(50-500)

Serum testosterone 2.1 pmol/L(<3.0)

Which investigation is the most appropriate?

- 1- 17 hydroxy-progesterone
 2- Insulin tolerance test
 3- Magnetic resonance imaging (MRI) of the pituitary
 4- Pregnancy test
 5- Urine free cortisol concentration

Answer & Comments

Answer: 3- Magnetic resonance imaging (MRI) of the pituitary

This patient has hypogonadotrophic hypogonadism as evidenced by suppressed luteinising hormone/follicle-stimulating hormone (LH/FSH) and a low oestradiol concentration.

This would exclude pregnancy as a cause and polycystic ovarian syndrome is also unlikely.

In the presence of a raised prolactin concentration, a microprolactinoma would be the most likely explanation for this patient's symptoms and results.

This may be demonstrated by a pituitary MRI scan.

An insulin tolerance test would usually be entirely normal in a microprolactinoma.

[Q: 2127] OnExamination 2012 - Endocrinology

An 18-year-old woman presents with hirsutism and oligomenorrhoea. She is concerned as this has provoked bullying at the college where she goes.

On examination her BP is 115/82 mmHg, pulse is 75 and regular, her BMI is 29. She has obvious male pattern facial hair, hair around her upper chest and areolae, and hair over her lower abdomen. She also has oily skin with evidence of facial acne.

Investigations show:

Haemoglobin 13.2 g/dl(11.5-16.0)

White cell count $6.0 \times 10^9/L$ (4-11)

Platelets $158 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

17-OH progesterone elevated

Which of the following is the most appropriate therapy for her?

- 1- Flutamide
- 2- Hydrocortisone
- 3- Metformin
- 4- Pioglitazone
- 5- Weight loss

Answer & Comments

Answer: 1- Flutamide

Hydrocortisone is not required in the treatment of non-classical congenital adrenal hyperplasia.

Metformin, pioglitazone and weight loss are all therapies which may increase insulin sensitivity in the context of polycystic ovarian syndrome.

Although this woman may benefit per se from weight loss, she is likely to derive most symptomatic benefit from an anti-androgen.

[Q: 2128] OnExamination 2012 - Endocrinology

A 29-year-old man comes to the endocrine clinic for review of his hypertension. He is currently taking ramipril and amlodipine but his BP is still elevated.

On examination his BP is 155/95 mmHg, pulse is 70 and regular, respiratory and abdominal examination is unremarkable.

Investigations show:

Haemoglobin 13.8 g/dl(13.5-17.7)

White cell count $6.9 \times 10^9/L$ (4-11)

Platelets $181 \times 10^9/L$ (150-400)

Sodium 143 mmol/l (135-146)

Potassium 3.1 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Ultrasoundleft adrenal mass

Which of the following is the most appropriate agent to help manage his blood pressure pre-operatively?

- 1- Amiloride
- 2- Furosemide
- 3- Indapamide
- 4- Spironolactone
- 5- Valsartan

Answer & Comments

Answer: 4- Spironolactone

Amiloride may be useful in treating hypokalaemia, but it is not a mineralocorticoid antagonist, as such it is not the correct choice here.

Indapamide may have utility as an anti-hypertensive agent, but it may worsen hypokalaemia.

Furosemide is a more effective treatment for heart failure than blood pressure.

Valsartan is less effective than spironolactone in reducing blood pressure in this situation.

[Q: 2129] OnExamination 2012 - Endocrinology

You are reviewing chemical pathology results which have come to your acute medicine inbox and are collecting a series from patients with chronic respiratory failure.

Which of the following would fit best with a compensated respiratory acidosis?

- 1- pH 7.41, pCO₂ 7.2kPa, pO₂ 9.2kPa
- 2- pH 7.1, pCO₂ 3.9kPa, pO₂ 8.8kPa
- 3- pH 7.54, pCO₂ 4.2 kPa, pO₂ 12.9kPa
- 4- pH 7.3, pCO₂ 3.8kPa, pO₂ 13.0kPa
- 5- pH 6.9, pCO₂ 3.4, pO₂ 8.2

Answer & Comments

Answer: 1- pH 7.41, pCO₂ 7.2kPa, pO₂ 9.2kPa

Option A is correct. For all of the other options the pH values are abnormal.

B, D and E are consistent with a metabolic acidosis, B and E also with significant hypoxia.

C is consistent with a metabolic alkalosis.

[Q: 2130] OnExamination 2012 - Endocrinology

A 45-year-old woman presents with chronic diarrhoea.

This has worsened over the past six months so that she is opening her bowels up to eight times per day with watery motions. The stool is normal smelling and tea coloured without blood or mucus. Her GP has been encouraging her to use codeine and loperamide to manage her symptoms.

On examination her BP is 110/70 mmHg, pulse is 65 and regular and her BMI is 21. General physical examination is unremarkable.

Investigations show:

Haemoglobin 11.0 g/dl(11.5-16.0)

White cell count 6.8 x 10⁹/L (4-11)

Platelets 203 x 10⁹/L (150-400)

Sodium 141 mmol/l (135-146)

Potassium 3.0 mmol/l (3.5-5)

Bicarbonate 15 mmol/l (22-30)

Creatinine 83 µmol/l (79-118)

Abdominal ultrasound Pancreatic mass

Which of the following is the most appropriate medical management of her diarrhoea?

- 1- Bromocriptine
- 2- Cholestyramine
- 3- Codeine
- 4- Somatostatin analogue
- 5- Somatotrophin analogue

Answer & Comments

Answer: 4- Somatostatin analogue

The most likely diagnosis here is VIPoma, therefore therapy should be targetted at this as the underlying cause, with somatostatin or an analogue the most appropriate option.

Bromocriptine is a dopamine agonist which can be used in the treatment of prolactinoma.

Cholestyramine is a bile acid sequestrant that can be used in the management of diarrhoea related to small bowel malabsorption or pancreatitis.

Codeine prolongs small bowel transit time and increases stool water absorption, it may be an adjunct in patients who do not adequately respond to somatostatin.

Somatotrophin is growth hormone, and has no place in managing the condition.

[Q: 2131] OnExamination 2012 - Endocrinology

A 62-year-old woman is admitted with progressive confusion and decreasing consciousness to the Emergency department.

On examination she is cold with a temperature of 35.2°C. Her BP is 100/60 mmHg and her pulse is 51. She has periorbital oedema on examination of her face; the most striking neurological abnormality is slow relaxing reflexes.

You notice on her laboratory records there is a TSH recorded at 11.2 some two months earlier. Her hospital notes record that she has recently started treatment for TB.

Which of the following agents is most likely to be responsible?

- 1- Ethambutol
- 2- Isoniazid
- 3- Pyrazinamide
- 4- Rifampicin
- 5- Streptomycin

Answer & Comments

Answer: 4- Rifampicin

Isoniazid

Pyrazinamide

Streptomycin and

Ethambutol

are not known to interfere with thyroxine absorption, and so cannot be the correct options here.

[Q: 2132] OnExamination 2012 - Endocrinology

You are trialling a new partial agonist of the vitamin D receptor and are hoping that it may share only some of the attributes of vitamin D3 itself.

Which of the following is a property of vitamin D?

- 1- Down regulates calbindin
- 2- Reduces intestinal calcium absorption
- 3- Reduces osteocalcin expression
- 4- Reduces phosphate absorption
- 5- Suppresses synthesis of type 1 collagen

Answer & Comments

Answer: 5- Suppresses synthesis of type 1 collagen

Calbindin is an intestinal transporter of calcium, and by upregulating calbindin expression, vitamin D leads to increased calcium absorption from the small intestine.

In addition to stimulating intestinal calcium absorption, vitamin D also stimulates absorption of magnesium and phosphate.

[Q: 2133] OnExamination 2012 - Endocrinology

A 25-year-old woman comes for a discussion about contraception some four weeks after she has given birth to her first child.

She complains that her hair seems to be falling out excessively when she brushes it. There is no medical history of note and she is coping well with caring for her baby.

On examination her BP is 105/70 mmHg, her BMI is 26.

Investigations show:

Haemoglobin 10.8 g/dl(11.5-16.0)

White cell count $6.9 \times 10^9/L$ (4-11)

Platelets $181 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 102 micromol/l (79-118)

Which of the following is the most appropriate initial management?

- 1- LH/FSH ratio
- 2- Reassurance
- 3- Testosterone
- 4- Thyroid hormone testing
- 5- Topical minoxidil

Answer & Comments

Answer: 2- Reassurance

The most likely explanation here is that an abnormal number of hairs have entered the telogen phase. This results in shedding of hair leading to loss of thickness. It occurs as a normal phenomenon one to three months after pregnancy. No treatment is required and hair thickness eventually recovers without further intervention.

Luteinising hormone/ follicle-stimulating hormone (LH/FSH) ratio and testosterone are both potential tests which could be considered if polycystic ovary syndrome (PCOS) or another condition leading to androgenic alopecia were considered. We are given no evidence of that in the scenario, accordingly they are not appropriate.

Equally, we are not told of weight gain or lethargy, hence thyroid function testing would not be a first choice.

Topical minoxidil is a therapy which promotes hair regrowth, but it is not required here.

[Q: 2134] OnExamination 2012 - Endocrinology

A 53-year-old woman comes to the clinic for review.

She is obese and has a history of hypertension which is managed with ramipril and amlodipine. Her blood pressure is 155/85 mmHg. Her BMI is 29.

Which of the following most accurately predicts her level of insulin resistance?

- 1- Blood pressure
- 2- BMI
- 3- HDL cholesterol
- 4- LDL cholesterol
- 5- Triglyceride / HDL ratio

Answer & Comments

Answer: 5- Triglyceride / HDL ratio

The answer is E, triglyceride / HDL ratio.

Cross-sectional studies across the Caucasian population have suggested that triglyceride/HDL ratio is most predictive of insulin resistance. As such TG/HDL can be used to stratify both future risk of the development of cardiovascular disease and future risk of diabetes mellitus.

Weight loss and exercise training is seen to impact on TG/HDL ratio; pioglitazone and metformin which impact on insulin resistance both lead to modest increases in HDL and a decrease in triglycerides in some patients.

[Q: 2135] OnExamination 2012 - Endocrinology

A 71-year-old man presents with chronic back and right hip pain which has been increasingly affecting him over the past few months. He finds it very difficult to mobilise in the mornings, and cannot dig his garden.

Clinical examination is unremarkable, apart from limitation of right hip flexion due to pain.

Investigations show

Haemoglobin 12.1 g/dl (13.5-17.7)

White cell count $8.2 \times 10^9/L$ (4-11)

Platelets $200 \times 10^9/L$ (150-400)
 C reactive protein 9 nmol/l (<10)
 ESR 15 mm/hr (<20)
 Sodium 140 mmol/l (135-146)
 Potassium 3.9 mmol/l (3.5-5)
 Creatinine 92 $\mu\text{mol/l}$ (79-118)
 Alanine aminotransferase 12 U/l (5-40)
 Alkaline phosphatase 724 U/l (39-117)
 Calcium 2.55 mmol/l (2.20-2.67)

Which of the following is the most likely diagnosis?

- 1- Chronic liver disease
- 2- Malignant melanoma
- 3- Osteoarthritis right hip
- 4- Osteoporotic collapse lumbar spine
- 5- Paget's disease

Answer & Comments

Answer: 5- Paget's disease

This man's markedly elevated alkaline phosphatase in the presence of normal liver enzymes, normal calcium and normal ESR, and his history of lumbar spine and right hip pain points towards Paget's disease as the most likely diagnosis.

x Ray examination of his lumbar spine and hip is likely to show areas of both osteolysis and new bone formation typical of the disease.

Pain relief with non-steroidals, and either oral or intermittent IV pulsed bisphosphonate therapy represents the treatment of choice.

[Q: 2136] OnExamination 2012 - Endocrinology

A 21-year-old man with known sickle cell anaemia comes to the Emergency department with increasing shortness of breath which is now so bad that he is unable to walk.

He says a few days earlier there were symptoms of a non-specific mild flu-like illness but nothing else of note.

On examination his BP is 124/72 mmHg, pulse is 95. He has severe left ventricular failure. Blood gas examination reveals an Hb of 6.4 g/dl.

Which of the following is most likely to be responsible?

- 1- Coxsackie B virus
- 2- Cytomegalovirus
- 3- Epstein-Barr virus
- 4- Influenza A
- 5- Parvovirus B19

Answer & Comments

Answer: 5- Parvovirus B19

Parvovirus B19 is known to be associated with aplastic crises in sickle cell anaemia which can precipitate severe anaemia and subsequent cardiac failure. Recovery may be spontaneous over the course of a few weeks, but transfusion, particularly when there is associated cardiac failure is usually required.

Whilst the other viruses listed may contribute to myocardial dysfunction and as such could precipitate cardiac failure, they are not associated with aplastic crisis in sickle cell.

Therefore it is parvovirus which is the only possible correct answer here.

[Q: 2137] OnExamination 2012 - Endocrinology

A 45-year-old man presents with an ulcer on his right foot.

He has a 20 year history of type 1 diabetes and currently uses mixed insulin twice daily.

On examination he has a small ulcer of approximately 2 cm diameter on the outer aspect of his right big toe.

His peripheral pulses are all palpable but he has a peripheral neuropathy to the mid shins.

The ulcer has an erythematous margin and is covered by pus.

What is the most likely infective organism?

- 1- Escherichia coli
- 2- MRSA
- 3- Pseudomonas aeruginosa
- 4- Staphylococcus aureus
- 5- Streptococcus pyogenes

Answer & Comments

Answer: 4- Staphylococcus aureus

Diabetic foot ulcers can be divided into:

Those in neuropathic feet and

Those in feet with ischaemia.

The neuropathic foot is warm and well perfused with palpable pulses, sweating is decreased and the skin may be dry and prone to fissures.

The ischaemic foot is cool and pulseless with thin, shiny skin which often lacks hair. There may also be atrophy of the subcutaneous tissues, but intermittent claudication and rest pain may be absent due to co-existent neuropathy.

Diabetic foot infections are common and always serious, and range in severity from superficial paronychia to deep infection and gangrene.

Other manifestations include:

Cellulitis

Myositis

Abscesses

Necrotising fasciitis

Septic arthritis

Tendonitis

Osteomyelitis.

All are associated with increased frequency and length of hospitalisation, and risk of lower extremity amputation.

Neuropathy, vascular insufficiency and reduced neutrophil function all mean that diabetics are more susceptible to foot ulceration.

Once skin ulceration occurs, the underlying tissues are exposed to colonisation by pathogenic organisms. The inflammatory response is often impaired, and therefore early signs of infection may be subtle. Local signs of wound infection are:

Granulation tissue that becomes increasingly friable

Yellow or grey moist tissue at the base of the ulcer

Purulent discharge and

An unpleasant odour.

The most common pathogens in acute, previously untreated superficial ulcers in diabetic patients are aerobic Gram positive bacteria (particularly Staphylococcus aureus and beta-haemolytic Streptococci).

In patients who have recently received antibiotics or who have deep tissue involvement, infection is usually caused by a mixture of aerobic Gram positive, Gram negative (for example, Escherichia coli, Proteus, Klebsiella) and anaerobic organisms (for example, Bacteroides, Clostridium).

Methicillin-resistant Staphylococcus aureus (MRSA) is more common in patients who have been previously hospitalised or who have received antibiotic therapy, although increasingly it is community acquired.

If infection is suspected, deep swab and tissue samples should be sent for culture and broad-spectrum antibiotics started. The presence of deep infection with abscess, cellulitis

gangrene or osteomyelitis is an indication for hospitalisation.

Indications for urgent surgical intervention are:

A large area of infected sloughy tissue

Localised fluctuance and expression of pus

Crepitus in the soft tissues on radiological examination

Purplish discolouration of the skin (which indicates subcutaneous necrosis).

Antibiotic treatment should subsequently be tailored according to the clinical response, culture results and sensitivity. If osteomyelitis is present, surgical resection should be considered and antibiotics continued for four to six weeks.

[Q: 2138] OnExamination 2012 - Endocrinology

A 26-year-old man with a past history of parathyroid surgery presented with galactorrhoea.

Investigations showed:

Plasma follicle-stimulating hormone 4.2 U/L (1-7)

Plasma luteinising hormone 5.6 U/L (1-10)

Plasma prolactin 1654 mU/L (<360)

Plasma thyroid-stimulating hormone 3.8 mU/L (0.4-5)

Insulin-like growth factor 133.4 nmol/L (7.5-37.3)

Which of the following is the most likely diagnosis?

- 1- MEN type 1
- 2- MEN type 2a
- 3- MEN type 2b
- 4- Polyglandular syndrome type 1
- 5- Polyglandular syndrome type 2

Answer & Comments

Answer: 1- MEN type 1

The story of galactorrhoea suggests hyperprolactinaemia and in the context of primary hyperparathyroidism suggests MEN type 1.

MEN type 1 is an autosomal dominant condition and is associated with hyperparathyroidism, pancreatic neuroendocrine tumours and pituitary tumours.

[Q: 2139] OnExamination 2012 - Endocrinology

A middle-aged woman presents with new onset palpitations. She also commented that she had lost weight recently despite an increased appetite.

Examination reveals a goitre and a degree of exophthalmos. During physical examination, she fell unconscious. Blood pressure was 70/40 mmHg. Electrocardiogram revealed atrial fibrillation (AF) with rapid ventricular response.

What is the appropriate immediate management?

- 1- Anticoagulation
- 2- Carbimazole
- 3- DC cardioversion
- 4- Intravenous amiodarone
- 5- Intravenous propranolol

Answer & Comments

Answer: 3- DC cardioversion

The patient is haemodynamically compromised due to AF.

The emergency management is DC cardioversion 200 J ? 360 J ? 360 J.

Adverse signs necessitating DC cardioversion are:

BP ?90 mmHg

Chest pain

Heart failure

Impaired consciousness

Heart rate ?200 bpm.

[Q: 2140] OnExamination 2012 - Endocrinology

A 24-year-old female presents with a two week history of polyuria and polydipsia together with frequent nocturia.

Investigations show

Serum Sodium 144 mmol/L (137-144)

Serum Potassium 3.3 mmol/L (3.5-4.9)

Serum Calcium 2.6 mmol/L (2.2-2.6)

Plasma glucose 6.8 mmol/L (3.0-6.0)

Serum osmolality 310 mOsmol/L (275-295)

What is the diagnosis?

- 1- Diabetes insipidus
- 2- Diabetes mellitus
- 3- Drug abuse
- 4- Primary hyperparathyroidism
- 5- Primary polydipsia

Answer & Comments

Answer: 3- Drug abuse

This patient has polyuria and polydipsia of relatively recent onset and has an elevated plasma osmolality with a high calcium and glucose concentration.

These features would be unlikely in DI and are more in keeping with thiazide diuretic abuse - high calcium, glucose and hypokalaemia.

Similarly, the serum osmolality would be low in association with primary polydipsia.

There may be plenty of variations purely by alteration of the biochemistry of this question in the examination.

[Q: 2141] OnExamination 2012 - Endocrinology

Maturity onset diabetes of the young (MODY) is due to which of the following?

- 1- BRCA1 and BRCA2 (breast cancer) gene products
- 2- Glucokinase mutations
- 3- HOX (homeobox) gene family
- 4- Leptin mutations
- 5- Stargardt's disease mutations

Answer & Comments

Answer: 2- Glucokinase mutations

MODY is an autosomal dominantly inherited form of diabetes and is due to glucokinase mutations.

Other causes of MODY include hepatocyte nuclear factor (HNF) gene mutations.

[Q: 2142] OnExamination 2012 - Endocrinology

A 17-year-old female who is 16 weeks pregnant reports that her elder brother has vitamin D resistant rickets.

What is the most likely mode of inheritance of this condition?

- 1- Autosomal dominant
- 2- Autosomal dominant with incomplete penetrance
- 3- Autosomal recessive
- 4- X linked dominant
- 5- X linked recessive

Answer & Comments

Answer: 4- X linked dominant

Vitamin D resistant rickets is inherited in an X linked dominant manner.

Therefore an affected female will transmit the disease to 50% of her sons and 50% of her daughters.

An affected male will transmit the condition to all of his daughters but none of his sons.

In this case the mother is unaffected, therefore there is no risk of the condition being passed to her unborn child.

[Q: 2143] OnExamination 2012 - Endocrinology

Which of the findings listed below is true of acromegaly?

- 1- A random growth hormone (GH) concentration may be diagnostically useful
- 2- Growth hormone concentrations are suppressed to normal by bromocriptine therapy
- 3- It is unusual for the pituitary fossa to be enlarged
- 4- Pituitary hormones other than growth hormone are rarely affected
- 5- The majority of patients demonstrate an abnormal glucose tolerance test (GTT)

Answer & Comments

Answer: 5- The majority of patients demonstrate an abnormal glucose tolerance test (GTT)

A Random GH concentrations are pretty useless in the diagnosis of acromegaly, which depends upon non-suppression of GH in the oral glucose tolerance test, in which approximately 50% have either impaired GTT or diabetes.

B GH concentrations seldom suppress to normal with bromocriptine but often respond far better with octreotide.

C Usually at presentation the fossa is enlarged (about 80%).

D This is awkward, but prolactin is often elevated (30%) although hypopituitarism would be unusual unless the tumour is particularly large.

[Q: 2144] OnExamination 2012 - Endocrinology

A 29-year-old woman presents with a one year history of irregular periods, deteriorating hirsutism and weight gain.

Investigations reveal:

Serum testosterone 4 mmol/L (0.5-3)

Serum dehydroepiandrosterone sulphate (DHEAS) 15 µmol/L (0.3-9.3)

Which one of the following statements is most probable for this patient?

- 1- Pituitary gonadotrophins are likely to become suppressed.
- 2- She has an increased risk of multiple pregnancies.
- 3- She is at increased risk of autoimmune disease.
- 4- She is at increased risk of ovarian carcinoma.
- 5- She is likely to develop acanthosis nigricans.

Answer & Comments

Answer: 5- She is likely to develop acanthosis nigricans.

This patient has oligomenorrhoea, weight gain and hirsutism.

The investigations show a modest elevation of androgens and support a diagnosis of polycystic ovarian syndrome.

This condition is associated with insulin resistance and acanthosis nigricans is a feature.

[Q: 2145] OnExamination 2012 - Endocrinology

A 60-year-old female was prescribed thyroxine 150 microgrammes daily for hypothyroidism.

She was clinically hypothyroid and no goitre was present.

She attends a follow up clinic and following are her results:

Serum total T₄ 68 nmol/L (55-145)

Serum total T₃ 0.5 nmol/L (0.9-2.5)

Serum TSH 70 mU/L (0.4-5)

Which of the following would be the next step in her management?

- 1- Investigation for TSH secreting pituitary tumour
- 2- Measurement of free thyroxine concentration
- 3- Questioning of the patient about compliance
- 4- She has sick euthyroid syndrome, no further investigation required
- 5- Thyroid ultrasound scan

Answer & Comments

Answer: 3- Questioning of the patient about compliance

Apart from by the RCP total thyroid hormone levels are now seldom measured.

This patient has a raised thyroid-stimulating hormone but normal total thyroxine (T₄) and a low tri-iodothyronine (T₃).

Either there is a block on the conversion of T₄ to T₃ or as seems more likely the patient has taken the T₄ just prior to coming to clinic.

The explanation is non-compliance.

[Q: 2146] OnExamination 2012 - Endocrinology

A 28-year-old female presents in the 24th week of pregnancy with profound tiredness and anxiety.

Examination reveals a tremor, a pulse of 100 beats per minute and a soft bruit heard over the thyroid gland.

Thyroid function tests show:

Free T₄ 32.9 pmol/L (10-22)

TSH 0.04 mU/L (0.4-5)

Which of the following treatments would you select for this patient?

- 1- Carbimazole
- 2- Lithium
- 3- Potassium perchlorate
- 4- Propranolol
- 5- Radioactive iodine therapy

Answer & Comments

Answer: 1- Carbimazole

This patient has Graves' disease and the most appropriate treatment for the thyrotoxicosis is carbimazole.

This she should receive in the lowest dose to maintain euthyroidism.

A block and replacement regime is not appropriate in pregnancy.

Radioactive iodine is contraindicated as it would also be taken up by the fetal thyroid.

Propranolol would ameliorate the symptoms but may impact upon the fetus.

Lithium is contraindicated in pregnancy as is potassium perchlorate.

Of course surgery may also be used in severe cases.

Both carbimazole and propylthiouracil may (and should) be used in pregnancy. Many

prefer propylthiouracil because there is some evidence that it may be less likely to be transferred across the placenta.

[Q: 2147] OnExamination 2012 - Endocrinology

A 29-year-old woman with a history of type 1 diabetes comes to the endocrine clinic for review. She is very concerned as she has begun to lose significant amounts of hair from a patch on her scalp over the course of the last few months.

On examination she has a circular area of hair loss with an area of normal looking skin in the middle of it. Skin scrapings taken by the GP have not produced any growth.

Which of the following is the most appropriate treatment?

- 1- Griseofulvin
- 2- Intra-lesional triamcinolone
- 3- Oral ciclosporin
- 4- Topical clotrimoxazole
- 5- Topical hydrocortisone

Answer & Comments

Answer: 2- Intra-lesional triamcinolone

Griseofulvin and topical clotrimoxazole are both anti-fungals. With a negative culture specimen and the lack of scarring this is highly unlikely to be due to fungal infection.

Topical hydrocortisone is likely to be ineffective in managing alopecia, and systemic treatment with oral ciclosporin is usually an option when disease is more extensive.

[Q: 2148] OnExamination 2012 - Endocrinology

Low uptake of ^{123}I on the thyroid uptake scan would be an expected finding in which of the following?

- 1- A multi-nodular toxic goitre

- 2- A solitary toxic nodule
- 3- Amiodarone induced thyrotoxicosis type 1
- 4- DeQuervain's thyroiditis
- 5- Graves' thyrotoxicosis

Answer & Comments

Answer: 4- DeQuervain's thyroiditis

DeQuervain's thyroiditis is classically associated with low or absent ^{123}I (or ^{131}I radioactive isotopes of iodine) uptake.

The others will have high or normal uptake.

In particular type 1 amiodarone induced thyrotoxicosis may be distinguished from the thyroiditis of type 2 by the normal or high uptake scan.

[Q: 2149] OnExamination 2012 - Endocrinology

A 35-year-old woman comes to the endocrine clinic for review. She has suffered a left Colle's fracture and attends for osteoporosis assessment.

Which of the following factors would put her at increased risk?

- 1- Early menarche
- 2- Europic ethnic origin
- 3- Family history of osteoporotic fracture
- 4- Five units / week alcohol consumption
- 5- Use of a thiazide

Answer & Comments

Answer: 3- Family history of osteoporotic fracture

Early menarche and late menopause are associated with reduced risk of fracture.

Europic ethnic origin is associated with a reduced risk of osteomalacia versus populations with increased skin pigmentation.

Alcoholism is associated with osteoporosis, whereas alcohol consumption within recommended limits is not.

Thiazide diuretics increase serum calcium and are not associated with risk of osteoporosis.

[Q: 2150] OnExamination 2012 - Endocrinology

A 72-year-old woman presents to the clinic with confusion.

She has a history of hypertension for which she takes bendroflumethiazide and amlodipine.

On examination her BP is 120/70 mmHg, with a postural drop of 10 mmHg and her pulse is 80 and regular. Her BMI is 22. There are no other abnormal findings.

Investigations show:

Haemoglobin 12.2 g/dl(11.5-16.0)

White cell count $7.0 \times 10^9/L$ (4-11)

Platelets $188 \times 10^9/L$ (150-400)

Sodium 124 mmol/l (135-146)

Potassium 3.4 mmol/l (3.5-5)

Creatinine 132 $\mu\text{mol/l}$ (79-118)

Urinary sodium 24 mmol/l (>20)

Which of the following is the most likely diagnosis?

- 1- Addison's disease
- 2- Chronic pyelonephritis
- 3- Hypovolaemia and diuretic use
- 4- Primary polydypsia
- 5- SIADH

Answer & Comments

Answer: 3- Hypovolaemia and diuretic use

Addison's disease is incorrect because relative hyperkalaemia and a longer history of deteriorating health would be expected.

Chronic pyelonephritis would be an alternative diagnosis in the absence of thiazide use.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and primary polydypsia would be associated with euvolaemia.

[Q: 2151] OnExamination 2012 - Endocrinology

A 56-year-old man with a history of type 2 diabetes comes to the clinic for review. He complains of bilateral burning pain and weakness in both thighs, worse on the left than the right, which is unbearable.

He takes metformin and a sulphonylurea to maximal doses for his diabetic control, and has a history of hypertension.

On examination his BP is 148/79 mmHg, pulse is 70 and regular, BMI is 31. There is bilateral loss of sensation in his feet. He has proximal muscle wasting of both lower limbs.

Investigations show:

Haemoglobin 13.5 g/dl(13.5-17.7)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 142 mmol/l (135-146)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 132 $\mu\text{mol/l}$ (79-118)

HbA1c 9.8%(<5.5)

Which of the following is the most appropriate way to manage the pain and muscle wasting in his thighs?

- 1- Add pioglitazone
- 2- Amitriptyline
- 3- Duloxetine
- 4- Physiotherapy
- 5- Transition to insulin

Answer & Comments

Answer: 5- Transition to insulin

Whilst duloxetine is first line therapy and amitriptyline second line therapy for peripheral diabetic neuropathy, it is improved glycaemic control which has most effect on diabetic amyotrophy, so these are not correct options.

Whilst pioglitazone would improve his diabetic control, his HbA1c is probably too elevated at 9.8% to enable him to reach target on triple oral therapy, therefore it is not the correct option.

Whilst physiotherapy may help regain muscle strength, it is improved glycaemic control which is the most important initial therapeutic intervention.

[Q: 2152] OnExamination 2012 - Endocrinology

A 26-year-old Chinese man is admitted on the acute emergency take. He became very unwell after a squash game, complaining of severe proximal limb weakness. Apparently, he has just begun carbimazole treatment for thyrotoxicosis.

On examination his BP is 125/80 mmHg, pulse is 85 and regular and he looks anxious. He is unable to get up off the bed due to proximal weakness.

Investigations show:

Haemoglobin 13.9 g/dl(13.5-17.7)

White cell count $4.8 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 2.8 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Guillain-Barre syndrome
- 2- Hyperkalaemic periodic paralysis

3- Hypokalaemic periodic paralysis

4- Myositis

5- Thyrotoxic hypokalaemic periodic paralysis

Answer & Comments

Answer: 5- Thyrotoxic hypokalaemic periodic paralysis

The history given is too acute to be either Guillain-Barre or myositis, with Guillain-Barre associated with weakness developing over a number of days, and myositis taking a more chronic course with muscle tenderness.

Without the presence of thyrotoxicosis, this picture would fit with hypokalaemic periodic paralysis.

[Q: 2153] OnExamination 2012 - Endocrinology

You are looking at a potential inhibitor of gastrin for the treatment of Zollinger-Ellison(ZE) syndrome.

When considering gastrin, which of the following correctly reflects its function or the pathophysiology associated with it?

- 1- Fasting gastrin $>1000 \text{ pg/ml}$ and gastric $\text{pH} < 2$ suggests ZE syndrome
- 2- Gastric mucosal atrophy is usually seen in ZE syndrome
- 3- Gastrin promotes small bowel mucosal growth
- 4- Gastrin receptors do not bind cholecystokinin
- 5- It is secreted by L cells

Answer & Comments

Answer: 1- Fasting gastrin $>1000 \text{ pg/ml}$ and gastric $\text{pH} < 2$ suggests ZE syndrome

Gastrin receptors also bind cholecystokinin and as such are also known as CCK-B receptors.

Gastrin promotes gastric mucosal growth and as such gastric mucosal hypertrophy is seen in the ZE syndrome.

Gastrin is synthesised in G cells which are found in gastric pits, primarily in the antrum of the stomach.

[Q: 2154] OnExamination 2012 - Endocrinology

A 32-year-old woman presents with symptoms of palpitations, anxiety and sleep intolerance. She had a flu-like illness some three weeks prior to presenting, and has tenderness over her neck.

On examination her BP is 145/80 mmHg, her pulse is 100 and regular. She has a fine tremor and tenderness over a smoothly enlarged thyroid gland on palpation. TSH is suppressed at <0.1.

Which of the following is true of her underlying condition?

- 1- There is an association with HLA-B27
- 2- There is an association with HLA-B35
- 3- There is an association with HLA-DR3
- 4- There is an association with HLA-DR4
- 5- There is an association with HLA-DR5

Answer & Comments

Answer: 2- There is an association with HLA-B35

This presentation is typical of that associated with sub-acute or De Quervain's thyroiditis, where flu-like illness is followed by transient hyperthyroidism, then hypothyroidism, then recovery. The gland is diffusely tender, although pain responds to non-steroidal anti-inflammatories. Anti-thyroid drugs have no value in the management of the condition. It is associated with HLA-B35 and it is thought that a viral antigen binds to HLA-B35 molecules on macrophages.

HLA-B27 is associated with inflammatory bowel disease and seronegative arthritis.

DR3 and DR4 are associated with increased risk of type 1 diabetes in particular.

HLA-DR5 is associated with clearance of hepatitis C infection and Hashimoto's thyroiditis.

[Q: 2155] OnExamination 2012 - Endocrinology

A 51-year-old woman with type 2 diabetes managed with BD mixed insulin and metformin comes to the clinic for review.

She is worried as a recent HbA1c has risen from 7.2 to 7.9%, and she has increased in weight by 6 kg.

On examination her BP is 156/88 mmHg, her BMI is 36. She is interested in bariatric surgery.

Which of the following features would most prompt you to refer her?

- 1- BMI in the 35-40 range without attempting conventional weightloss measures
- 2- Failure to lose weight even after intensive weight management intervention
- 3- Inferior MI in the past two months
- 4- Presence of hypertension
- 5- Presence of type 2 diabetes

Answer & Comments

Answer: 2- Failure to lose weight even after intensive weight management intervention

NICE guidelines from 2006 with respect to who should be referred for bariatric surgery indicate patients with a BMI over 40, or those with a BMI between 35 and 40 who have other significant disease such as hypertension or type 2 diabetes.

This is provided that:

All appropriate non-surgical measures have failed to achieve or maintain adequate clinically beneficial weight loss for at least six months

They are receiving or will receive intensive specialist management

They are generally fit for anaesthesia and surgery

They commit to the need for long term follow up.

BMI in the 35-40 range is incorrect because whilst it is a criterion for bariatric surgery, there is no indication she has failed conventional weight reduction measures first.

"Failure to lose weight even after intensive weight management intervention" is the correct answer because in this patient it is a requirement before progressing to bariatric surgery.

Inferior myocardial infarction in the past two months is incorrect because it would be a relative contraindication to anaesthetic.

Hypertension is incorrect because whilst it is a criterion for bariatric surgery patients must have failed to lose weight on other measures first.

Type 2 diabetes is incorrect because whilst it is a criterion for bariatric surgery, patients must have failed to lose weight on other measures first.

Obesity, NICE Clinical Guideline (2006); Obesity: the prevention, identification, assessment and management of overweight and obesity in adults and children. [Note the NICE guide is currently being reviewed]

[Q: 2156] OnExamination 2012 - Endocrinology

A 77-year-old woman comes to the clinic for review. She has suffered a previous Colles' fracture, and has a history of a previous left leg DVT.

She takes a range of medication including omeprazole for severe reflux oesophagitis. A T score was measured at -4.2, and she was unable to tolerate weekly alendronate due to symptoms of indigestion.

Which of the following is the most appropriate alternative for her?

- 1- Daily calcium and vitamin D
- 2- Daily strontium ranelate
- 3- Monthly ibandronate
- 4- Monthly risedronate
- 5- Six monthly denosumab

Answer & Comments

Answer: 5- Six monthly denosumab

This patient falls into the severe osteoporosis range and definitely requires therapy in excess of calcium and vitamin D.

Whilst bisphosphonates can be given monthly, they still cause oesophagitis and are not appropriate here.

Denosumab is a rank ligand inhibitor leading to inhibition of osteoclast activity. It is given by six monthly subcutaneous injection and is associated with a 40% reduction in the risk of hip fracture over three years. It is recommended in NICE guidance for this patient type.

A. Daily calcium and vitamin D are incorrect because they are less effective than bisphosphonates in the treatment of osteoporosis.

B. Strontium ranelate is incorrect because it is associated with increased risk of deep vein thrombosis.

C. Monthly ibandronate is incorrect because it is still associated with symptoms of oesophagitis.

D. Monthly risedronate is incorrect because it is still associated symptoms of oesophagitis.

E. Six monthly denosumab is correct because it is effective in managing osteoporosis in this patient type.

[Q: 2157] OnExamination 2012 - Endocrinology

A 32-year-old man who is overweight is screened for diabetes mellitus because he complains of excessive tiredness and nocturia.

On examination his BMI is 34, his BP is 155/90 mm/Hg.

Investigations show:

Haemoglobin 12.3 g/dl(13.5-18)

White cell count $6.1 \times 10^9/L$ (4-10)

Platelets $212 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (60-120)

Fasting glucose 12.9 mmol/l (<7.0)

According to the ADA/EASD consensus algorithm 2006, which of the following is the most appropriate management for him?

- 1- A period of six months diet and lifestyle measures then review
- 2- A period of three months diet and lifestyle measures then review
- 3- BD s/c exenatide injections with diet and lifestyle measures commenced concurrently
- 4- Metformin 500 mg BD commenced with diet and lifestyle measures
- 5- Pioglitazone 30 mg with diet and lifestyle measures commenced concurrently

Answer & Comments

Answer: 4- Metformin 500 mg BD commenced with diet and lifestyle measures

The authors state in their consensus document that over time diet and lifestyle

measures fail to maintain the desired degree of weight loss or glucose control.

For this reason they recommend commencing metformin concurrently with these interventions at the point of diagnosis.

They state the recommendation is made because of metformin's

Glucose-lowering effect without significant hypoglycaemia

Lack of weight gain

Generally high level of acceptance

Low cost.

In patients who cannot take metformin they recommend the use of either a sulphonylurea or insulin.

They do not recommend one of the newer agents such as a glitazone or dipeptidyl peptidase IV (DPPIV) inhibitor as a first line alternative.

Reference:

Nathan et al. 29 (8): 1963. (2006)

[Q: 2158] OnExamination 2012 - Endocrinology

A 29-year-old woman who is 31 weeks pregnant comes to the Emergency Department with severe headaches and palpitations.

She is found to have a blood pressure of 175/94 mmHg. There is no past medical history of note and general physical examination is unremarkable.

Investigations show:

Haemoglobin 11.0 g/dl(11.5-16.0)

White cell count $5.2 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 102 $\mu\text{mol/l}$ (79-118)

Abdominal ultrasound - Left adrenal mass

Raised urinary catecholamines

Which of the following is the most appropriate way to manage her?

- 1- Alpha block her then allow the pregnancy to continue to term
- 2- Alpha block her, remove the tumour and allow the pregnancy to continue
- 3- Beta block her, remove the tumour and allow the pregnancy to continue
- 4- Beta block her then allow the pregnancy to continue to term
- 5- Plan for lower segment caesarean section and later surgery for the tumour

Answer & Comments

Answer: 5- Plan for lower segment caesarean section and later surgery for the tumour

Unopposed beta blockade should not be used in the management of pheochromocytoma because of the risk of paradoxical increases in blood pressure, so those options listing beta blockade first are incorrect.

By the time she has reached the third trimester, initial removal of tumour is not an option for the pregnancy to continue, so those options are incorrect.

[Q: 2159] OnExamination 2012 - Endocrinology

A 48-year-old lady with hyperthyroidism was reviewed in the endocrine clinic.

She had initially presented to her general practitioner a month ago with flu-like symptoms and tremulousness. Her thyroid function tests at that time were consistent with hyperthyroidism and she was commenced on propranolol.

On examination, her pulse was 88 beats per minute and regular. She did not have any eye signs. She had a diffuse, tender goitre.

Investigations showed:

Plasma thyroid-stimulating hormone <0.01 mU/l (0.4-5)

Plasma Free T₄ 66 pmol/l (10-22)

Radioactive iodine (RAI) uptake scan revealed less than 2% uptake within the thyroid gland.

What is the most appropriate treatment?

- 1- Carbimazole
- 2- Lugol's iodine
- 3- Prednisolone
- 4- Propylthiouracil
- 5- Thyroidectomy

Answer & Comments

Answer: 3- Prednisolone

This patient is likely to have de Quervain's thyroiditis as suggested by the diffuse tender goitre, hyperthyroidism due to rapid release of pre-formed thyroid hormones and very low uptake on RAI uptake scan.

The most appropriate treatment of de Quervain's thyroiditis is symptomatic control.

B-blockers help control the tremor and anxiety associated with thyrotoxicosis and prednisolone or NSAIDs for the thyroiditis.

[Q: 2160] OnExamination 2012 - Endocrinology

A 64-year-old retired Caucasian solicitor attends the surgery.

He is overweight and takes little exercise. He has been treated for hypertension for five years and is controlled on 5 mg of ramipril. He also takes 20mg of simvastatin for hypercholesterolaemia.

A 75g oral glucose tolerance test was recently performed and gave a result consistent with impaired glucose tolerance (IGT) with a two hour plasma glucose concentration of 9.3 mmol/L (3.0-6.0).

The patient is keen to know what would be his risk of developing type 2 diabetes.

What do you tell him?

- 1- 6% over 6 years
- 2- 10% over 6 years
- 3- 33% over 6 years
- 4- 60% over 6 years
- 5- 100% over 6 years

Answer & Comments

Answer: 3- 33% over 6 years

Individuals with IGT are at significant risk of progression to type 2 diabetes.

A number of studies have looked at the absolute risk of progression from IGT to type 2 diabetes. The large and widely-quoted Hoorn study which looked at 1342 Caucasian non-diabetic subjects found that 33.8% progressed to type 2 diabetes over six years follow up. This increased to 64.5% if individuals had both IGT and impaired fasting glycaemia (IFG).

A similar rate of progression for individuals with IGT was Vaccaro who studied a Caucasian group in Italy.

Intensive lifestyle changes involving diet changes, regular exercise and weight loss have been shown to reduce the rate of progression to type 2 diabetes.

[Q: 2161] OnExamination 2012 - Endocrinology

A 55-year-old obese man with type 2 diabetes mellitus is uncontrolled on diet alone.

Which antidiabetic therapy would increase insulin sensitivity in this patient?

- 1- Acarbose
- 2- Gliclazide
- 3- Glimepiride
- 4- Pioglitazone

5- Repaglinide

Answer & Comments

Answer: 4- Pioglitazone

Of the drugs listed only pioglitazone would boost insulin sensitivity, as would metformin, but pioglitazone has more effect on peripheral insulin resistance.

Gliclazide, glimepiride and repaglinide are insulin secretagogues - they boost insulin secretion. Acarbose has a modest effect on the absorption of sugars from the gut, but its main effect is to cause flatulence.

Type 2 diabetes is due to two defects - insulin resistance and insulin deficiency. In 95% of patients it is insulin resistance that is the main cause of the diabetes. These patients are typically obese with features of the metabolic syndrome. The bulk of the insulin resistance appears to be in skeletal muscle.

The state of insulin resistance is associated with abnormal glucose metabolism (obviously) and excessive free fatty acids in the blood. Drugs and lifestyle modifications that increase insulin sensitivity (and thereby reduce insulin resistance) help to reverse these abnormalities.

[Q: 2162] OnExamination 2012 - Endocrinology

A 53-year-old man with a known history of Graves' disease presents to the Emergency department with palpitations, anxiety and fine tremor of both hands.

ECG shows rapid atrial fibrillation (AF) with ventricular rate of 160 to 180/min.

His blood pressure was 110/80 mmHg.

TSH 0.01 mU/l (0.4-5.0)

Free T₄ 60.3 pmol/l (10-22)

What is the immediate management for this patient?

- 1- Carbimazole
- 2- DC cardioversion
- 3- Digoxin
- 4- Propanolol
- 5- Warfarin

Answer & Comments

Answer: 4- Propanolol

AF occurs in 10% to 25% of patients with hyperthyroidism, more commonly in men and the elderly than in women or patients less than 75-years-old.

In a patient with hyperthyroidism and AF, initial therapy should focus on ventricular rate control with β -blockers, but conversion to sinus rhythm frequently occurs spontaneously with treatment of hyperthyroidism.

AF in thyrotoxicosis is characterised by rapid ventricular response, typically resistant to digoxin therapy.

Electric or pharmacologic cardioversion should be attempted only in euthyroid patients who are haemodynamically unstable.

If AF persists, consideration should be given to anticoagulation in patients who are at risk of embolic events.

[Q: 2163] OnExamination 2012 - Endocrinology

An 17-year-old female presented with a one year history of secondary amenorrhoea. She had been prescribed temazepam and dihydrocodeine previously.

On examination she had galactorrhoea to expression. Her prolactin concentration was 6000 mU/L (50-450). Pregnancy test was negative.

What is the most likely diagnosis?

- 1- Drug-induced hyperprolactinaemia
- 2- Non-functioning pituitary tumour

- 3- Pituitary microadenoma
- 4- Polycystic ovarian syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 3- Pituitary microadenoma

This patient presents with the classical signs of hyperprolactinaemia, confirmed with the finding of elevated serum levels of prolactin.

There are a number of different causes of hyperprolactinaemia, and it is useful to classify them as below:

1. Hypothalamic stimulation: primary hypothyroidism, adrenal insufficiency.
2. Medications: inhibit dopamine release, leading to reduced inhibition and therefore higher prolactin release.
 - Neuroleptics: phenothiazines, haloperidol
 - Antihypertensives: calcium-channel blockers, methyldopa
 - Psychotropic agents: tricyclic antidepressants
 - Anti-ulcer agents: H₂ antagonists
 - Opiates and opiate antagonists
3. Neurogenic: via autonomic nervous system.
 - Chest wall injury
 - Breast stimulation
 - Breast feeding
4. Physiological causes: via oestrogen stimulation.
 - Pregnancy, coitus
 - Exercise, sleep, stress
5. Increased prolactin production:
 - Ovarian: polycystic ovarian syndrome

- Pituitary tumours: adenomas, hypothalamic stalk interruption, hypophysitis

6. Reduced prolactin elimination:

- Renal failure
- Hepatic insufficiency

The grossly elevated prolactin concentration in this scenario is most suggestive of a microprolactinoma.

This is not polycystic ovarian syndrome as the hyperprolactinaemia is far too high.

The drugs that she is taking would not cause this level of hyperprolactinaemia.

If she were to have a non-functioning pituitary tumour, stalk compression would be expected to produce a prolactin concentration of less than 2000 mU/L.

Prolactin levels can be raised in Turner's syndrome, but you would expect some of the other classical features of the condition to be present.

[Q: 2164] OnExamination 2012 - Endocrinology

A 70-year-old woman presents with a six month history of frontal headaches and weight loss.

On examination a bitemporal hemianopia was noted.

Which of the following suggests the diagnosis of a pituitary tumour?

- 1- 9 am cortisol concentration of 350 nmol/L (200 - 700)
- 2- LH concentration of 44 uL (>30)
- 3- Prolactin concentration of 620 mU/L (50-550)
- 4- Random growth hormone (GH) concentration 1.2 mU/L (< 1 excludes acromegaly)
- 5- TSH concentration of 3.8 mU/L (0.5 - 4.5)

Answer & Comments

Answer: 3- Prolactin concentration of 620 mU/L (50-550)

All of these tests are appropriate in the assessment of a patient with a possible pituitary tumour.

However, the TSH and cortisol are in the reference range so add little to the diagnosis.

The LH is consistent with post-menopausal status in this patient.

As growth hormone exhibits a large degree of diurnal variation, this result also adds little new information. A better test for growth hormone status is often the insulin-like growth factor - 1 (IGF-1). This has much less diurnal variation and is more helpful in the diagnosis of acromegaly or GH deficiency than a random GH level.

Prolactin is elevated which is consistent with a diagnosis of a pituitary tumour. Prolactin can be released in two ways:

Prolactinoma - secreting large amounts of prolactin

Stalk compression - macroadenoma compresses stalk and prevents dopaminergic inhibition of prolactin secretion.

At a level of 620 mU/L, stalk compression is more likely than prolactinoma.

Other causes of elevated prolactin are:

Pregnancy and lactation

Antipsychotic, antidepressant and anticonvulsant medications

Hypothyroidism

After a seizure.

[Q: 2165] OnExamination 2012 - Endocrinology

A patient with type 1 diabetes displays typical symptoms of hypoglycaemic unawareness.

Which of the following statements regarding hypoglycaemic unawareness is correct?

- 1- Alcohol inhibits gluconeogenesis in patients with hypoglycaemia unawareness
- 2- Glucose sensing occurs in the locus caeruleus
- 3- Recurrent hypoglycaemia has no long term consequences on higher cerebral function
- 4- Recurrent hypoglycaemia is most commonly associated with poor diabetic control
- 5- Selective beta-blockers are an important cause of hypoglycaemia unawareness

Answer & Comments

Answer: 1- Alcohol inhibits gluconeogenesis in patients with hypoglycaemia unawareness

Alcohol

Inhibits gluconeogenesis

Decreases peripheral hypoglycaemic responses and

Impairs perception of symptoms of hypoglycaemia.

There is no evidence to suggest that β -blockers cause hypoglycaemic unawareness.

Glucose sensing occurs in the hypothalamus, and there is evidence to suggest that chronic, and recurrent hypoglycaemia may have deleterious effects on higher cerebral function.

[Q: 2166] OnExamination 2012 - Endocrinology

A diagnosis of diabetes mellitus is being considered in 32-year-old woman who is 16 weeks pregnant.

Her body mass index (BMI) was 22 kg/m² (18-25).

A 75 g oral glucose tolerance test (OGTT) was reported as follows:

TimePlasma glucose concentrationNormal range

0 hr 6.0 mmol/l (3.0-6.0)

2 hr 12.5 mmol/l (<11.1)

Which of the following is the most appropriate next step in the management of this patient?

- 1- Glipizide therapy
- 2- Insulin therapy
- 3- Low calorie diet
- 4- Metformin therapy
- 5- Repeat OGTT in four weeks

Answer & Comments

Answer: 4- Metformin therapy

The result confirms a diagnosis of gestational diabetes mellitus (GDM), with the two hour OGTT result above 11.1 mmol/l.

To minimise the fetal consequences of GDM (macrosomia, fetal malformations, still birth, IUGR etc.), the patient's glycaemia should be strictly controlled

A low calorie diet is inappropriate and glipizide is not licensed for use in pregnancy.

With respect to agents for glucose control, a very large trial suggested that metformin is an excellent initial option for therapy, with insulin added in later on top. This is supported by NICE guidance

There is no point in repeating the OGTT in four weeks as control is required now.

[Q: 2167] OnExamination 2012 - Endocrinology

In which of the following conditions would it be expected to find an elevated plasma total cortisol concentration?

- 1- Congenital adrenal hyperplasia
- 2- Patients on long term benzodiazepine therapy

- 3- Patients taking prednisolone
- 4- Pregnancy
- 5- Primary aldosteronism

Answer & Comments

Answer: 4- Pregnancy

Cortisol levels are increased in pregnancy, conditions of physical and emotional stress and drug therapy (oestrogens, oral contraceptives, amphetamines, cortisone, and spironolactone).

Treatment with other forms of steroid lead to decreased levels of cortisol.

[Q: 2168] OnExamination 2012 - Endocrinology

Which one of the following is a recognised feature of achondroplasia?

- 1- Autosomal recessive inheritance
- 2- Increased liability to pathological fractures
- 3- May be diagnosed radiologically at birth
- 4- Shortened spine
- 5- Subfertility

Answer & Comments

Answer: 3- May be diagnosed radiologically at birth

Achondroplasia an autosomal dominant condition and one of the commonest forms of short-limbed dwarfism. It is caused by an activated point-mutation of the fibroblast growth factor receptor 3 (at 4p16.3). The incidence increases with paternal age. Epiphyseal growth cartilage fails, but there is normal bone formation and repair. There is therefore no increased risk of fracture. The homozygous form is usually fatal.

Affected persons have short stature due to shortening of the limbs, but spinal length is maintained. In addition they have

characteristic facies with frontal bossing and mid-face hypoplasia, exaggerated lumbar lordosis, limited elbow extension and trident-like hands. The fingertips may only come down to the iliac crest, and the shortness of the limbs is often most marked proximally. The limbs appear broad with deep creases.

It may be diagnosed radiographically at birth, or becomes obvious within the first year with disparity between a large skull, normal trunk length and short limbs. X-rays show metaphyseal irregularity, flaring in the long bones, and late-appearing irregular epiphyses. The pelvis is narrow in anteroposterior diameter with deep sacroiliac notches and short iliac wings. The spine shows progressive narrowing of the interpedicular distance from top to bottom (reverse of normal).

Subfertility is not associated with achondroplasia.

[Q: 2169] OnExamination 2012 - Endocrinology

A 16-year-old woman presents to the clinic with primary amenorrhoea.

Her only past medical history of note is bilateral inguinal hernias repaired as a baby during a period when she lived abroad. No records are available from that time.

On examination she is 1.65 m in height. There is no evidence of acne or secondary sexual hair. Breasts and her external genitalia look normal.

Investigations show:

Haemoglobin 12.0 g/dl (11.5-16.0)

White cell count $5.3 \times 10^9/L$ (4-11)

Platelets $278 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 80 micromol/l (79-118)

Testosterone 9.1 nmol/l (<2.5)

Which of the following is the most likely diagnosis?

- 1- Androgen insensitivity syndrome
- 2- Autoimmune ovarian failure
- 3- Kallman's syndrome
- 4- Klinefelter's syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 1- Androgen insensitivity syndrome

The testosterone which is in the male range, the history of hernias as a baby and absence of acne or secondary sexual hair are all pointers towards androgen insensitivity syndrome.

The woman will in fact have a male XY karyotype although with breast development and normal external genitalia they appear female.

Cryptorchidism goes hand in hand with the condition, and often it is the testes which herniated through the abdominal wall.

Given the complete absence of menarche, autoimmune ovarian failure is extremely unlikely as it is usually a cause of secondary amenorrhoea. Additionally, the absence of secondary sexual hair counts against this diagnosis.

Klinefelter's is associated with a male phenotype.

Kallman's is associated with loss of sense of smell and failure of secondary sexual development, including breast growth.

Turner's, XO karyotype is associated with a number of other features such as short stature, webbing of the skin around the neck, hypertension and abnormalities of the aorta.

[Q: 2170] OnExamination 2012 - Endocrinology

A 32-year-old male physical education teacher has a three year history of type 1 diabetes.

At the last annual review his HbA1c was 6.8% but he complains of hypoglycaemic events particularly during exercise. He has been commenced on the insulin analogue, lispro insulin.

Compared with conventional short acting insulins what is the advantage of insulin analogue therapy?

- 1- Longer duration of action
- 2- Reduces post-prandial glucose concentrations
- 3- Reduces the incidence of hypoglycaemic events
- 4- Reduces the incidence of long term diabetic complications
- 5- Significant improvement in HbA1c

Answer & Comments

Answer: 2- Reduces post-prandial glucose concentrations

The short acting insulin analogue, lispro, has a rapid onset of action and a shorter duration of action than conventional short acting soluble insulins.

Consequently studies reveal reduced post-prandial glucose concentrations versus soluble insulin and potentially a reduced incidence of hypoglycaemia although the evidence for this is lacking.

[Q: 2171] OnExamination 2012 - Endocrinology

A 33-year-old woman presents to the GP with tiredness and anxiety during the third trimester of her second pregnancy.

Examination is unremarkable, with a BP of 110/70 mmHg and a pulse of 80. Her BMI is 24

and she has an abdomen consistent with a 31 week pregnancy.

The GP decides to check some thyroid function tests.

Which of the following would be considered normal?

- 1- Decreased TSH
- 2- Elevated TSH
- 3- Elevated free T3
- 4- Elevated free T4
- 5- Elevated total T4

Answer & Comments

Answer: 5- Elevated total T4

Decreased thyroid-stimulating hormone (TSH) may be an indicator of thyrotoxicosis or pituitary failure and so would be considered abnormal in this case.

Elevated TSH would be indicative of possible thyroid failure and hypothyroidism.

Elevated free tri-iodothyronine (T3) or thyroxine (T4) would be suggestive of thyrotoxicosis and as such are both abnormal.

Elevated total T4 is normal because of a rise in thyroid binding globulin

[Q: 2172] OnExamination 2012 - Endocrinology

A 29-year-old woman brings her 6-week-old child to the new baby clinic at the GP surgery.

She is concerned as the child has poor suckling and has been admitted to the Emergency department on two occasions with possible bowel obstruction but later discharged. She tells you there is a history in the family of a tumour 'syndrome', and one of her relatives died at a young age.

Which of the following is the most likely underlying diagnosis?

- 1- MEN-1

- 2- MEN-2a
- 3- MEN-2b
- 4- Peutz-Jegher's
- 5- Polycystic kidney disease

Answer & Comments

Answer: 3- MEN-2b

MEN-1 is not associated with mucosal neuromas but is associated with hyperparathyroidism and pancreatic endocrine tumours.

MEN-2a does not present as early as 2b because of the absence of neuromas.

Peutz-Jegher's, whilst being associated with gastrointestinal (GI) hamartomas, presents later in childhood with GI bleeding.

Polycystic kidney disease is associated with cerebral haemorrhage, but is not associated with GI tract pathology in infancy.

[Q: 2173] OnExamination 2012 - Endocrinology

You are planning to start a 72-year-old man who has chronic renal failure and secondary hyperparathyroidism on 1,25-OH vitamin D supplementation.

Which of the following correctly represents an action of 1,25-OH vitamin D supplementation?

- 1- Decreased calcium reabsorption in the kidney
- 2- Decreased IL6 production
- 3- Decreased intestinal reabsorption of calcium
- 4- Decreased mobilisation of calcium from bone
- 5- Decreased muscle strength

Answer & Comments

Answer: 2- Decreased IL6 production

With respect to calcium metabolism, the actions of vitamin D are to increase serum calcium.

This includes increased intestinal absorption of calcium, increased mobilisation of calcium from bone, and increased calcium reabsorption from the kidney.

[Q: 2174] OnExamination 2012 - Endocrinology

A 28-year-old man with type 1 diabetes comes to the clinic with his wife.

They want to know about the aetiology of type 1 diabetes (T1DM) and the chances of any offspring inheriting the disease.

Which of the following accurately represents one aspect of the pathogenesis of T1DM?

- 1- 50% of patients developing the disease have a positive family history
- 2- All patients are ZnT8 autoantibody positive
- 3- Enteroviruses may play a role in protection from and susceptibility to T1DM
- 4- The disease is primarily mediated by pathogenic B cells
- 5- There is 100% twin concordance

Answer & Comments

Answer: 3- Enteroviruses may play a role in protection from and susceptibility to T1DM

Type 1 diabetes is a primarily T cell mediated disorder. Whilst autoantibodies to beta cell antigens are measurable in patients with the disease, they are not thought to play direct role in its pathogenesis.

ZnT8 is found within the beta cell; whilst ZnT8 autoantibodies are often positive in patients with type 1 diabetes, it is not invariable.

Conventionally, anti-GAD and anti-IA2 antibodies are measured to support the diagnosis.

Only 10% of patients have a positive family history, and there is 30-50% twin concordance.

[Q: 2175] OnExamination 2012 - Endocrinology

You are developing a new long acting antidiuretic hormone antagonist for the treatment of SIADH.

Where would you expect to see binding of your antagonist occur?

- 1- Aquaporin 1 channels
- 2- Aquaporin 2 channels
- 3- Aquaporin 3 channels
- 4- V1 receptors
- 5- V2 receptors

Answer & Comments

Answer: 5- V2 receptors

V1 receptors are involved in mediating platelet aggregation and do not have a role in controlling water reabsorption.

There are multiple subtypes of aquaporin channels, some of which, such as aquaporin 3, are involved in passage of water through the skin.

[Q: 2176] OnExamination 2012 - Endocrinology

A 42-year-old man comes to the Emergency department with sudden onset severe retro-orbital headache, nausea and vomiting.

He tells you he has suffered from problems with his vision over the past few days and admits to feeling increasingly tired over the past few weeks.

On examination his BP is 100/60 mmHg, pulse is 90 and regular. He has a right third nerve palsy.

Investigations show:

Haemoglobin 12.9 g/dl(13.5-17.7)

White cell count $5.1 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 113 $\mu\text{mol/l}$ (79-118)

Prolactin 1400 mU/l (<400)

TSH 0.2 U/l (0.5-4.5)

Which of the following is the most likely diagnosis?

- 1- Cerebral infarct
- 2- Cluster headache
- 3- Pituitary adenoma
- 4- Pituitary apoplexy
- 5- Subarachnoid haemorrhage

Answer & Comments

Answer: 4- Pituitary apoplexy

The presentation with retro-orbital headache and normal blood pressure means that both cerebral infarction and subarchnoid haemorrhage are less likely.

The abnormal clinical and laboratory findings count against a diagnosis of cluster headache.

Finally, whilst a pituitary adenoma is likely to have pre-dated the presentation here, it is haemorrhage into the gland which has precipitated his attendance at the Emergency department.

[Q: 2177] OnExamination 2012 - Endocrinology

A 48-year-old woman presents with weight gain and lethargy.

She is finding it difficult to hold down her job and has taken sick leave for the past six weeks.

On examination her BP is 150/80 mmHg, her pulse is 52 and she has a BMI of 29. She has thinning hair.

Investigations show:

TSH 9 IU(0.5-4.5)

Free T₄ 10.2 nanomol/l (10-24)

Total cholesterol 6.2 mmol/l (<5.2)

Anti-TPO Antibody positive

Which of the following is the most appropriate treatment?

- 1- Atorvastatin 10 mg
- 2- Carbimazole 10 mg
- 3- Reassurance
- 4- Thyroxine 50 mcg
- 5- Thyroxine 100 mcg

Answer & Comments

Answer: 4- Thyroxine 50 mcg

This patient's symptoms are consistent with subclinical hypothyroidism. She is at significant risk of becoming clinically euthyroid with a thyroxine (T₄) below the lower limit of normal over the next few months.

Her weight gain and lethargy necessitate replacement with low dose thyroxine at this stage, aiming to titrate therapy until the thyroid-stimulating hormone (TSH) is within the normal range.

Atorvastatin is not an appropriate treatment because this patient's raised total cholesterol is likely to be related at least in part to her hypothyroidism which should be treated first.

Carbimazole has no value in the treatment of hypothyroidism.

Reassurance is not appropriate given this patient has symptoms.

100 mcg is too high an initial starting dose for thyroxine, given her T₄ is at the lower limit of the normal range.

[Q: 2178] OnExamination 2012 -
Endocrinology

A 39-year-old woman comes to the clinic complaining of excessive hairiness and problems with acne. She also reports increased libido over the past few months.

There is no medical history of note and she has two healthy children. On examination her BP is 131/82 mmHg, pulse is 75 and regular and her BMI is 25. She has androgenic alopecia and evidence of increased hair around her areolae, upper lip and lower abdomen.

Investigations show:

Haemoglobin 12.2 g/dl(11.5-16.0)

White cell count $4.9 \times 10^9/L$ (4-11)

Platelets $281 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 90 micromol/l (79-118)

Testosterone 8.9 nmol/l (<2.5)

Which of the following is the most likely underlying diagnosis?

- 1- Androgen secreting tumour
- 2- Cushing's disease
- 3- Normal individual
- 4- Obesity related testosterone excess
- 5- Polycystic ovarian syndrome

Answer & Comments

Answer: 1- Androgen secreting tumour

The key here is the testosterone level, which is more than three times the upper limit of normal. As such an androgen secreting tumour must be considered as a possible diagnosis. Abdominal ultrasound, CT or MRI would be follow-on investigations to elucidate whether an adrenal or ovarian tumour is the underlying cause.

This woman is of normal weight and has no features suggestive of Cushing's. Therefore this is not a likely diagnosis, although rarely Cushing's may be associated with hyperandrogenism.

Equally the possibility that she is a normal individual is ruled out by the testosterone level. Whilst obesity and PCOS may be associated with rises in testosterone, it is never to this degree.

[Q: 2179] OnExamination 2012 -
Endocrinology

A 63-year-old man comes to the clinic for review of his type 2 diabetes.

Current medication includes metformin 1 g BD and 30/70 mixed insulin 22U BD. He is also taking lisinopril, amlodipine, atorvastatin and indapamide.

On examination his BP is 147/84 mmHg, his pulse is 77 and regular, and his BMI is 29 kg/m².

Investigations show:

Haemoglobin 13.4 g/dl(13.5-17.7)

White cells $5.3 \times 10^9/l$ (4-11)

Platelet $233 \times 10^9/l$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 127 micromol/l (79-118)

HDL cholesterol 0.7 mmol/l (0.8-1.8)

LDL cholesterol 3.9 mmol/l (<4.0)

Triglycerides 3.6 mmol/l (0.7-2.1)

HbA1c 7.1% (<5.5) (54 mmol/mol (<36))

Which of the following represents the accepted target for fasting triglyceride levels in this patient?

- 1- 1.0 mmol/l
- 2- 1.2 mmol/l
- 3- 1.5 mmol/l
- 4- 1.7 mmol/l

5- 2.1 mmol/l

Answer & Comments

Answer: 4- 1.7 mmol/l

The answer is option D, 1.7 mmol/l.

Despite the fact that the upper limit of the normal range for triglycerides in men is considered to be 2.1, and in women it is 1.7, the JBS2 guidelines recommend a target of 1.7 mmol/l for both men and women. The reason for this is that epidemiological analyses suggest that triglycerides above 1.7 are associated with a 30% relative risk increase with respect to cardiovascular events.

With respect to patients with type 2 diabetes, risk calculators should not be used to estimate 10 year cardiovascular risk when making treatment choices, this is because type 2 diabetes is considered as a secondary prevention equivalent.

As such LDL should be treated to the secondary prevention target of < 2.0 mmol/l and triglycerides to the 1.7 mmol/l target.

[Q: 2180] OnExamination 2012 - Endocrinology

You are asked by your surgical colleagues to comment on current referrals for gynaecomastia at the hospital. They have seen a peak in GP referrals for men in the 60+ age group.

Which of the following underlying diagnoses is most likely to contribute to this peak?

- 1- Cirrhosis
- 2- Drug related gynaecomastia
- 3- Hyperthyroidism
- 4- Renal impairment
- 5- Secondary hypogonadism

Answer & Comments

Answer: 2- Drug related gynaecomastia

Drug related gynaecomastia is said to account for 10-25% of cases, with a number of agents known to cause gynaecomastia such as digoxin and spironolactone having increased use in this age group, this is therefore the most likely cause.

Cirrhosis is a less common cause of gynaecomastia, said to be responsible for around 8% of cases.

Hyperthyroidism is thought to be responsible for 1.5% of cases of gynaecomastia, renal failure around 1%, and secondary hypogonadism around 2% of cases of gynaecomastia.

[Q: 2181] OnExamination 2012 - Endocrinology

A 52-year-old woman with type 2 diabetes comes to the clinic. She has had type 2 diabetes for the past three years and is currently treated with metformin 850 mg twice daily.

On examination her BP is 152/85 mmHg and her BMI is 29.

Investigations show:

Haemoglobin 12.5 g/dl(13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $199 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 125 $\mu\text{mol/l}$ (60-120)

HbA1c 8.1%(<5.5)

You are planning to add a sulphonylurea to her regime.

Which of the following features, according to the consensus, is true regarding sulphonylurea therapy?

- 1- Delayed onset of glucose lowering effect
- 2- Increased cardiovascular risk
- 3- Low risk of hypoglycaemia

- 4- Synergistic effects when used with DPP-IV inhibitors
- 5- Weight gain

Answer & Comments

Answer: 5- Weight gain

The question of increased cardiovascular risk for sulphonylureas (SUs) was raised after the university group diabetes programme (UGDP) study conducted during the 1970s.

The consensus authors state, however, that the question has since been answered by the UK prospective diabetes study (UKPDS) and ADVANCE studies, where no cardiovascular risk signal was seen for SUs.

Whilst SUs are well known to have a rapid onset of glucose lowering effect, their side-effects of hypoglycaemia and weight gain are well known.

Any synergistic effect with DDP-IV inhibitors is widely debated.

[Q: 2182] OnExamination 2012 - Endocrinology

A study reports on the results of a large study of the primary prevention of stroke in a diabetic population using a new antiplatelet agent versus aspirin.

The results of the study reveal that over a five year period the incidence of stroke in the aspirin treated group is 3%, compared to a rate of 1.5% in the group treated with the new antiplatelet agent ($p < 0.001$).

What is the relative risk reduction in stroke associated with the new drug?

- 1- 1.5%
- 2- 15%
- 3- 30%
- 4- 40%
- 5- 50%

Answer & Comments

Answer: 5- 50%

The relative risk reduction is an important calculation for the interpretation of publications.

In this case there is an absolute risk reduction of 1.5% (3 - 1.5%) in stroke afforded by the new agent compared with aspirin yet the relative risk reduction is $1.5 / 3 = 50\%$.

That is 50% fewer strokes may be prevented by the use of the newer agent compared with aspirin although this would be the equivalent of 15 per 1000 patients treated (30 strokes expected / 1000 patients treated with aspirin but only 15 with the new drug).

[Q: 2183] OnExamination 2012 - Endocrinology

An elderly woman, a known case of longstanding diabetes, presents with right shoulder pain of several months duration. Pain sometimes interferes with sleep.

The shoulder is tender to palpation, and both active and passive movements are restricted. There are no sensory, motor, or reflex changes.

What is the most likely diagnosis?

- 1- Adhesive capsulitis
- 2- Referred pain from subdiaphragmatic irritation
- 3- Rotator cuff tear
- 4- Shoulder dislocation
- 5- Supraspinatus tendinitis

Answer & Comments

Answer: 1- Adhesive capsulitis

Adhesive capsulitis is a recognised musculoskeletal complication of diabetes.

Often referred to as 'frozen shoulder', adhesive capsulitis is characterised by pain

and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. Night pain is often present in the affected shoulder.

Adhesive capsulitis occurs more commonly in women after age 50. Pain and stiffness usually develop gradually over several months to a year but progress rapidly in some patients. Pain may interfere with sleep.

The shoulder is tender to palpation, and both active and passive movements are restricted.

Radiographs of the shoulder show osteopenia.

The diagnosis is confirmed by arthrography.

[Q: 2184] OnExamination 2012 - Endocrinology

A 45-year-old woman presents to the clinic with a three month history of sweats and weight gain of 7 kg. Her sweats tend to be worse in the morning and with exercise and she often feels light headed.

On examination she has a BMI of 30 kg/m² but no abnormality is noted. Urinalysis negative.

What is the likely diagnosis?

- 1- Acromegaly
- 2- Diabetes mellitus
- 3- Insulinoma
- 4- Pheochromocytoma
- 5- Primary ovarian failure

Answer & Comments

Answer: 3- Insulinoma

This patient has sweats and weight gain exacerbated by exercise or fasting (in the morning) and associated with lightheadedness. This information suggests the presence of an insulinoma.

Pheochromocytoma is unlikely as there is typically weight loss and there is no mention of hypertension.

If this were acromegaly the features should be described.

In diabetes mellitus per se, possibly urinalysis would be expected to show glycosuria.

Presenting features of insulinoma include:

Double vision

Tachycardia/palpitations

'Weakness'

Confusion

Memory loss

Seizures

Sweating

Hunger

Weight gain.

[Q: 2185] OnExamination 2012 - Endocrinology

A 51-year-old woman presented with nocturia and pruritus vulvae.

Investigations revealed:

Urine dipstick analysis glucose 2%

Which one of the following would most reliably confirm a diagnosis of diabetes mellitus?

- 1- 50 g oral glucose tolerance test
- 2- Elevated glycated haemoglobin concentration
- 3- Fasting plasma glucose of 6.7 mmol/L (3.0-6.0)
- 4- Random plasma glucose of 8.3 mmol/L
- 5- Two hour post-prandial plasma glucose of 12 mmol/L (<11.1)

Answer & Comments

Answer: 5- Two hour post-prandial plasma glucose of 12 mmol/L (<11.1)

The post-prandial glucose gives an equivalent to the 75 g glucose tolerance test which would be one of the investigations of choice in this patient.

None of the other results listed here formally confirm the diagnosis of type 2 diabetes.

The diagnosis of diabetes requires (WHO guidelines):

Fasting plasma glucose >7.0 mmol/l

Random plasma glucose >11.1 mmol/l.

75g OGTT 2-hr plasma glucose >11.1 mmol/l.

The American Diabetes Association have recently added another criterion:

HbA1c >6.5% or 48 mmol/mol.

Diagnosis should generally not be made on a single sample, especially if the patient was unwell as the stress response affects glucose homeostasis.

[Q: 2186] OnExamination 2012 - Endocrinology

A 73-year-old female is diagnosed with Cushing's disease.

Which of the following is correct?

- 1- Adrenalectomy would be the treatment of choice.
- 2- op-DDD is a treatment if unfit for surgery
- 3- Ketoconazole may be used as a treatment if unfit for surgery
- 4- Recurrence of Cushing's disease after transphenoidal surgery is less than 5%
- 5- Yttrium implantation is an effective treatment

Answer & Comments

Answer: 3- Ketoconazole may be used as a treatment if unfit for surgery

Transphenoidal hypophysectomy/adenomectomy would be the initial treatment of choice.

Laparoscopic adrenalectomy would be advised where pituitary surgery has failed.

Ketoconazole may be an effective treatment for patients unfit for surgery.

opDDD is used for adrenal carcinomas.

Yttrium implantation has been abandoned even for acromegaly as it is pretty useless.

The recurrence rate for Cushing's disease after surgery is of the order of 20-30% in most series and depends on the size of the tumour with macroadenomas having a higher rate of relapse.

[Q: 2187] OnExamination 2012 - Endocrinology

Which of the following is a characteristic feature of primary hyperaldosteronism?

- 1- Gross oedema
- 2- Hyponatraemia
- 3- Muscular weakness
- 4- Oliguria
- 5- Vitiligo

Answer & Comments

Answer: 3- Muscular weakness

Primary hyperaldosteronism or Conn's syndrome is characterised by hypokalaemic hypertension.

Patients can present with tetany (alkalosis) and muscle weakness (hypokalaemia).

Oedema and oliguria are more features of secondary hyperaldosteronism (cirrhosis); and vitiligo (suggesting auto-immunity) is not a feature.

[Q: 2188] OnExamination 2012 -

Endocrinology

A 16-year-old girl with obesity was referred with abdominal swelling and mild ankle oedema.

On examination the blood pressure was 140/90 mmHg.

Investigations revealed:

Haemoglobin 10.5 g/dl(11.5-16.5)

Serum biochemistry Normal

Serum albumin 34 g/l (37-49)

Urine dipstick Proteinuria +

Which is the most appropriate investigation that you would request next for this patient?

- 1- 24 hour urinary protein estimation
- 2- Abdominal ultrasound
- 3- Plasma protein electrophoresis
- 4- Urinary albumin: creatinine ratio
- 5- Urinary B-human chorionic gonadotrophin test (B-HCG)

Answer & Comments

Answer: 5- Urinary B-human chorionic gonadotrophin test (B-HCG)

This young girl has been 'gaining weight', has abdominal swelling and ankle oedema.

She is hypertensive and has a mild anaemia with proteinuria.

These signs should 'ring a bell' suggesting a concealed pregnancy with pre-eclampsia.

The most relevant investigation would be a pregnancy test - urinary B-HCG.

[Q: 2189] OnExamination 2012 - Endocrinology

You are consulted by a 52-year-old man with type 2 diabetes diagnosed for one year.

His blood pressure is 156/88 mmHg, his cholesterol is 5.3 mmol/L (<5.2), he has a BMI of 29 kg/m² and does not smoke. His HbA1c is

7.9% (3.8-6.4), he currently takes only metformin 500mg bd.

The single intervention most likely to reduce his overall risk of both microvascular and macrovascular events is:

- 1- Antihypertensive therapy
- 2- Aspirin therapy
- 3- Statin therapy
- 4- Sulphonylurea therapy
- 5- Weight reduction

Answer & Comments

Answer: 1- Antihypertensive therapy

Note this question asks about reducing both micro and macrovascular complications. The best evidence seems to be for multifactorial intensive therapy as in the Steno studies from Denmark. However, in this question, as worded, BP is the simplest answer.

Trials have shown that antihypertensive therapy reduces the risk of cardiovascular events and microvascular complications. The intensity of the treatment is currently of debate.

Lowering HbA1c only resulted in a significant reduction in microvascular events and, in some trials after a longer period, shows cardiovascular benefit. However, the trial showed an excess of deaths in the intensive glycaemic control arm perhaps because the intensification occurred later in the course of the disease when cardiovascular disease was present and may have put participants at increased risk from hypoglycaemia.

Lipid lowering therapy benefits patients with diabetes as much as those without diabetes in preventing macrovascular events in subgroup analyses but has no effect on microvascular events demonstrated so far. Adding fibrate may have an effect on retinopathy.

Aspirin is recommended to type 2 patients with one other cardiovascular risk factor but there is little trial evidence of efficacy.

Weight reduction may reduce progression to overt diabetes from states of impaired glucose tolerance but has not been demonstrated to reduce microvascular risk in diabetes.

[Q: 2190] OnExamination 2012 - Endocrinology

A 54-year-old female presented with a neck swelling which has been more noticeable over the previous four months.

Examination revealed a moderate goitre and clinically she appeared euthyroid.

Investigations revealed:

T₄ 13.1 pmol/L (10-22)

TSH 5.3 mU/L (0.4-5)

Anti -microsomal antibodies Positive

What is the most likely explanation of this patient's goitre?

- 1- Anaplastic thyroid carcinoma
- 2- DeQuervain's thyroiditis
- 3- Graves' disease
- 4- Hashimoto's thyroiditis
- 5- Multi-nodular goitre

Answer & Comments

Answer: 4- Hashimoto's thyroiditis

This patient has goitre with subclinical hypothyroidism, as reflected by elevated thyroid-stimulating hormone but normal thyroxine and elevated microsomal antibodies.

This suggests a diagnosis of Hashimoto's thyroiditis.

[Q: 2191] OnExamination 2012 - Endocrinology

A 58-year-old man who has a history of

hypertension and type 2 diabetes presents to the Emergency department complaining of central chest pain which is going down his left arm.

His medication includes ramipril, metformin, atorvastatin and gliclazide.

On examination his BP is 129/72 mmHg, and his pulse is 81. He has bibasal crackles on auscultation of his chest.

Investigations reveal:

Haemoglobin 13.8 g/dl(13.5-17.7)

White cell count $8.9 \times 10^9/L$ (4-11)

Platelet $197 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 123 $\mu\text{mol/l}$ (79-118)

Glucose 12.3 mmol/l (<7.0)

ECG - Anterolateral ST depression

He is given sublingual GTN.

Which of the following is the next most appropriate therapy?

- 1- Aspirin 300 mg and low molecular weight heparin
- 2- Aspirin 300 mg and clopidogrel 300 mg and low molecular weight heparin
- 3- Beta blockade
- 4- Clopidogrel 300 mg
- 5- IV GTN infusion

Answer & Comments

Answer: 2- Aspirin 300 mg and clopidogrel 300 mg and low molecular weight heparin

The answer is B, aspirin, clopidogrel and low molecular weight heparin.

This patient is high risk given his history of type 2 diabetes mellitus, and as such should be loaded with both aspirin and clopidogrel.

Further chest pain, or failure of his ECG signs to resolve may drive further intervention including progression to angiography.

If this patient does not progress to angiogram then screening for ischaemia should be considered prior to discharge.

[Q: 2192] OnExamination 2012 - Endocrinology

Which of the following is a glycoprotein hormone?

- 1- Cortisol
- 2- Growth hormone releasing hormone
- 3- Oxytocin
- 4- Thyrotropin (TSH)
- 5- Thyrotropin releasing hormone (TRH)

Answer & Comments

Answer: 4- Thyrotropin (TSH)

Thyrotropin is glycosylated, cortisol is a steroid hormone and the others are peptide hormones/neuropeptides which as a group are rarely glycosylated.

[Q: 2193] OnExamination 2012 - Endocrinology

A 72-year-old man is found by his home help in a collapsed state. According to neighbours who spoke to paramedics, he had not been seen outside for some days.

He has a history of hypertension and obesity and takes multiple medications.

On examination his BP is 135/72 mmHg, his pulse is 90 and regular and he is pyrexial 38.2°C. There are signs of a right lower lobe pneumonia.

Investigations show:

Haemoglobin 12.8 g/dl (13.5-17.7)

White cell count $12.9 \times 10^9/L$ (4-11)

Platelets $189 \times 10^9/L$ (150-400)

Sodium 149 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Bicarbonate 23 mmol/l (22-30)

Creatinine 172 $\mu\text{mol/l}$ (79-118)

Glucose 42 mmol/l (<7.0)

Which of the following represents the optimal rate at which his glucose should be reduced?

- 1- 1 mmol/hr
- 2- 3 mmol/hr
- 3- 5 mmol/hr
- 4- 7 mmol/hr
- 5- 10 mmol/hr

Answer & Comments

Answer: 2- 3 mmol/hr

Correction at 1 mmol/hr is too slow a correction of blood glucose, and 5 mmol/hr or greater correction of glucose is too rapid.

Individual hospitals usually give sliding scale guidance, but insulin replacement of 0.151 U/kg/hr is recommended as an initial guide.

Fluid management is essential, with replacement tailored to correct significant hyperosmolarity, whilst taking account of pre-existing comorbidities such as underlying cardiovascular disease.

[Q: 2194] OnExamination 2012 - Endocrinology

A 32-year-old woman presents to the endocrine clinic with a lump on the left side of her neck.

TFTs checked by her GP reveal that she is euthyroid. She has no medical history of note and takes the combined oral contraceptive pill.

On examination her BP is 110/70 mmHg, her pulse is 70 and regular, and she has a firm non-painful mass on the left side of her neck.

Investigations show:

Haemoglobin 12.9 g/dl(11.5-16.0)

White cell count $4.9 \times 10^9/L$ (4-11)

Platelets $205 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 99 $\mu\text{mol/l}$ (79-118)

TSH 1.5 IU/l (0.5-4.5)

Fine needle aspiration suggestive of papillary carcinoma

Activation of which of the following proto-oncogenes is most associated with papillary carcinoma of the thyroid?

1- BCL-2

2- BRCA

3- C-myc

4- P53

5- Trk

Answer & Comments

Answer: 5- Trk

BCL-2 is a chemo-attractant protein for human B lymphocytes.

BRCA-1 and 2 oncogene mutations are involved in the familial breast and ovarian cancer syndromes.

P53 mutations knock out a tumour suppressor, leading to cancers across a range of different tissues.

The c-myc protein is a regulator of transcription, therefore c-myc mutations also lead to development of a range of tumours.

[Q: 2195] OnExamination 2012 - Endocrinology

A 25-year-old woman presents to the endocrine clinic with recurrent episodes of collapse. During one of these episodes she is found to have hypoglycaemia with a venous blood glucose of 2.0 mmol/l, coupled with

raised insulin and C peptide. Sulphonylurea screen is negative.

Which of the following other pathologies is most likely to be found?

1- Medullary thyroid carcinoma

2- Neuromas

3- Parathyroid hyperplasia or adenomas

4- Pheochromocytoma

5- Prolactinoma

Answer & Comments

Answer: 3- Parathyroid hyperplasia or adenomas

This patient has an insulinoma, which should lead you to suspect she has multiple endocrine neoplasia type 1. This is the combination of parathyroid hyperplasia or adenoma, pancreatic endocrine tumours and pituitary adenoma. The genetic abnormality is in a proto-oncogene on the long arm of chromosome 11 (11q13), and is autosomal dominant with a high degree of penetrance.

Hyperparathyroidism is the presenting feature in 80% of patients with MEN-1. Pancreatic endocrine tumours are present in 70%, of which 60% are gastrinomas and 30% are insulinomas. 30% of patients have a pituitary prolactinoma diagnosed during life, but is found in closer to 50% at post-mortem.

The association of medullary cell carcinoma of the thyroid and pheochromocytoma is the basis of MEN-2, which has two variants. The genetic defect is within a tumour suppressor gene on chromosome 10q11.2. MEN-2A is also known as Sipple's syndrome, and in addition to medullary cell carcinoma and pheochromocytoma there may also be parathyroid hyperplasia and nephrolithiasis. MEN-2B has the characteristic features of mucosal neuromas and a phenotype resembling Marfan's syndrome. A third variant, which is familial medullary cell carcinoma in isolation, is also recognised.

[Q: 2196] OnExamination 2012 -
Endocrinology

A 69-year-old man is admitted with rapidly worsening nausea, vomiting, polyuria, polydipsia and confusion. He has been treated by his GP for chronic back pain which was thought to be related to his work as a builder.

On examination he is drowsy and confused, his BP is 110/70 mmHg and his pulse is 88 and regular.

Investigations show:

Haemoglobin 13.8 g/dl(13.5-17.7)

White cell count $6.2 \times 10^9/L$ (4-11)

Platelets $186 \times 10^9/L$ (150-400)

Sodium 146 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 167 $\mu\text{mol/l}$ (79-118)

Urea 13.2 mmol/l (2.5-6.7)

Glucose 5.4 mmol/l (<7.0)

Calcium 3.6 mmol/l (2.20-2.61)

Which of the following is true with respect to his hypercalcaemia?

- 1- A normal alkaline phosphatase would increase suspicion of underlying bony metastases
- 2- A raised alkaline phosphatase would increase suspicion of underlying myeloma
- 3- Abdominal pain is uncommonly seen
- 4- It is likely to be associated with PR prolongation
- 5- It is likely to be associated with QT shortening

Answer & Comments

Answer: 5- It is likely to be associated with QT shortening

Raised alkaline phosphatase associated with hypercalcaemia is more likely to be due to bony metastases; normal alkaline

phosphatase raises the possibility of underlying myeloma.

At this level of calcium, abdominal pain is commonly seen and there is increased risk of acute pancreatitis.

[Q: 2197] OnExamination 2012 -
Endocrinology

A 54-year-old man presents to the clinic for review. He has impaired glucose tolerance.

His blood pressure is currently managed with lisinopril and indapamide, and his BMI is 29. On examination in the clinic his BP is 145/80 mmHg.

Which of the following is the strongest independent predictor of cardiovascular death in a patient with impaired glucose tolerance?

- 1- Blood pressure
- 2- BMI
- 3- LDL cholesterol
- 4- Smoking history
- 5- Triglycerides

Answer & Comments

Answer: 5- Triglycerides

The answer is option E, triglycerides.

Some of the best data for risk assessment in this population come from the Paris prospective study. In the cohort of 943 men who had a diagnosis of either impaired glucose tolerance or type 2 diabetes, triglycerides were seen as the strongest independent risk factor for cardiovascular death, ahead of other more established risk factors such as smoking, body weight or blood pressure.

[Q: 2198] OnExamination 2012 -
Endocrinology

A 61-year-old man with type 2 diabetes comes to the clinic for review.

He is currently managed with metformin 500 mg and gliclazide 40 mg. He is also treated with ramipril 10 mg, amlodipine 5 mg, bisoprolol 5 mg, atorvastatin 10 mg and aspirin 75 mg.

On examination his BP is 140/80 mm hg, his pulse is 70 and his BMI is 28.

Investigations show:

Haemoglobin 12.4 g/dl(13.5-17.7)

White cells $7.2 \times 10^9/L$ (4-11)

Platelet $229 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.9 mmol/l (3.5-5)

Creatinine 123 micromol/l (79-118)

HDL cholesterol 0.7 mmol/l (0.8-1.8)

LDL cholesterol 2.2 mmol/l (<4.0)

Triglycerides 3.4 mmol/l (0.7-2.1)

HbA1c 7.5% (<5.5)(56 mmol/mol (<36))

Which of the following strategies is likely to be most effective in reducing his overall 10 year cardiovascular risk?

- 1- Further anti-hypertensive medication with a target of 130/70 mmHg
- 2- Further hypoglycaemic medication with a target of 6.5%
- 3- Increasing his statin dosage
- 4- Increasing consumption of omega-3 fatty acids
- 5- Weight loss of 5 kg

Answer & Comments

Answer: 4- Increasing consumption of omega-3 fatty acids

The answer is option D, increasing consumption of omega 3 fatty acids.

Elevated triglycerides are common in patients with type 2 diabetes, even in those who are established on effective statin therapy.

His blood pressure is only just above target, and in the absence of probable renal disease, further lowering of his BP may not substantially increase benefit.

A study (ACCORD) suggests that in those with a previous cardiac history, targeting HbA1c reduction to below 7% may be associated with increased sudden death. However, a recent meta-analysis (Ray KK et al, Lancet,2009), concluded that intensive glucose control in type 2 diabetes has no significant effect on all-cause mortality, and a well-designed retrospective study (Currie CJ et al. Lancet 2010) has shown that a HbA1c of about 7.5% has a favourable effect on survival.

The PROCAM, Paris Prospective Study, Copenhagen Male Study and Helsinki Heart Studies have all indicated that elevated triglyceride levels are associated with increased cardiovascular risk, particularly in the presence of low HDL cholesterol, a situation seen most commonly in patients with type 2 diabetes.

Trials of omega 3 supplementation suggest that it is associated with triglyceride reduction of up to 38%.

[Q: 2199] OnExamination 2012 - Endocrinology

A 54-year-old truck driver with a history of type 2 diabetes comes to the clinic for review.

He is concerned as he is finding his sugars hard to keep under control, with morning self-monitored blood glucose sometimes rising as high as 8 mmol/l or more. Current medication for blood sugar control includes metformin 1 g twice daily and gliclazide 160 mg twice daily.

On examination his BP is 148/81 mmHg, his BMI is 29 kg/m².

Investigations show:

Haemoglobin 13.0 g/dl(13.5-18)

White cell count $5.3 \times 10^9/L$ (4-10)

Platelets $231 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 5.4 mmol/l (3.5-5)

Creatinine 138 µmol/l (60-120)

HbA1c 8.4%(<5.5)

According to the ADA/EASD consensus algorithm, which of the following is the most appropriate management for him?

- 1- Add acarbose
- 2- Add pioglitazone
- 3- Start a basal bolus insulin regime
- 4- Start basal insulin at night
- 5- Start BD mixed insulin

Answer & Comments

Answer: 2- Add pioglitazone

The preferred pathway of the consensus is to follow well validated therapies, progressing from metformin to metformin and sulphonylurea (SU) or insulin, and eventually to insulin.

However, hazardous occupations may allow the addition of therapies from the less well validated group, which includes pioglitazone.

If heavy goods vehicle drivers commence insulin therapy then they must relinquish their licence; this would mean this patient losing his livelihood.

Other professions where insulin-related hypoglycaemia may present a problem include:

Taxi driving

Operating machinery

Working changing shift patterns.

Given the history of problems controlling fasting blood sugar, acarbose may not be particularly useful as it mainly deals with post prandial blood glucose.

[Q: 2200] OnExamination 2012 - Endocrinology

A 38-year-old lady was diagnosed with gestational diabetes at 28 weeks of pregnancy.

She had a BMI of 38 kg/m² and denied any osmotic symptoms. Her fetal ultrasound at 24 weeks gestation reported normal fetal growth.

She has been complying with a healthy diet and her capillary blood glucose monitoring had revealed readings usually between 8 to 12 mmol/L (3.0-6.0). Her recent HbA1c measured 6.8% (3.8-6.4).

What is the next most appropriate management step?

- 1- Gliclazide therapy
- 2- Insulin therapy
- 3- Metformin therapy
- 4- Pioglitazone therapy
- 5- Repeat HbA1c in a fortnight

Answer & Comments

Answer: 3- Metformin therapy

2.5% of pregnancies in England and Wales involve women with diabetes. Approximately 87% of these are due to gestational diabetes, 7.5% type 1 diabetes and 5% type 2 diabetes. There are a number of risks to both mother and fetus, including miscarriage, pre-eclampsia, preterm labour, stillbirth, congenital malformations, macrosomia, birth injury, perinatal mortality and neonatal hypoglycaemia.

Risk factors for gestational diabetes are BMI >30 kg/m², previous macrosomic baby (>4.5kg), previous gestational diabetes, first-degree relative with diabetes, ethnic origin (South Asian, Caribbean, Middle Eastern). Screening with fasting plasma glucose, random blood glucose, glucose challenge tests and urinalysis is recommended for any

women with one of these risk factors. The 2-hour 75g oral glucose tolerance test is used to definitively diagnose gestational diabetes. This is performed at 16-18 weeks in women who have been affected in a previous pregnancy (with home BM monitoring prior to this, and a repeat test at 28 weeks if this is normal) and 24-28 weeks for women with any other risk factor.

If it is safely achievable, women with gestational diabetes should aim to keep fasting blood glucose between 3.5-5.9mmol/litre and one hour postprandial blood glucose below 7.8mmol/litre during pregnancy. It is important to note HbA1c should not be routinely used to monitor glycaemic control in the second and third trimesters.

Most gestational diabetes will respond to changes in diet and exercise. Only 10-20% of women need oral hypoglycaemia agents or insulin therapy. Women should therefore be given dietary advice, and those with a pre-pregnancy BMI of >27 should be advised to restrict calorie intake and exercise for at least 30 minutes daily.

Hypoglycaemic therapy should be considered for women in whom diet and exercise fails to maintain blood glucose targets during a period of 1-2 weeks. If there is any evidence of fetal macrosomia therapy should be initiated immediately. Treatment should be tailored to the individual women, but in general may include oral hypoglycaemics (metformin and glibenclamide) and insulin. There is insufficient evidence regarding long-acting insulin analogues, and isophane insulin therefore remains the first choice for long-acting insulin during pregnancy. Insulin aspart and lispro are safe rapid-acting analogues.

Women with insulin-treated gestational diabetes should be advised of the risk of hypoglycaemia (which they may be unaware of) and provided with a concentrated glucose solution.

During labour and birth, capillary blood glucose should be monitored on an hourly basis in patients with diabetes and maintained between 4 and 7mmol/litre. This may require the use of a sliding scale.

In this patient diet has failed to achieve adequate glycaemic control, and it is therefore reasonable to start metformin. None of the other oral hypoglycaemics listed are indicated in pregnancy. Waiting another two weeks to instigate therapy exposes both mother and foetus to potential harm. Insulin can be used if glycaemic control is not achieved with metformin.

[Q: 2201] OnExamination 2012 - Endocrinology

A 55-year-old man with type 2 diabetes has noticed elevation of his blood glucose levels on a new treatment for his lipids.

He says his diet and exercise levels are unchanged his HbA1c has also deteriorated by about 0.5%.

Which one of the following drugs is the likely cause?

- 1- Cholestyramine
- 2- Ezetimibe
- 3- Fenofibrate
- 4- Nicotinic acid
- 5- Rosuvastatin

Answer & Comments

Answer: 4- Nicotinic acid

The mechanism of the effect of nicotinic acid on glucose is not entirely clear but, in some patients, it may increase blood glucose. For the majority of patients with diabetes it has a minimal effect.

A number of postulated mechanisms have been suggested for this. Since nicotinic acid inhibits triglyceride synthesis, it may be that the increased availability of free fatty acids

stimulates hepatic glucose output by increasing gluconeogenesis or replacing glucose as the primary energy source. Higher levels of fatty acids may also block glucose uptake by skeletal muscle. Direct effects on beta-cell function have also been postulated.

A recent meta-analysis showed an increase in risk of inducing diabetes in patients treated with intensive statin therapy, compared to moderate doses. However, discussion in the literature has suggested there may have been a number of confounding factors leading to increased diabetic risk in these patients. Regardless of this, it did not look at whether statins worsened HbA1c in established diabetics, and therefore you cannot extrapolate its findings to this question.

Cholestyramine interacts with a number of medications (including oral hypoglycaemics), due to impact on drug absorption. However, in clinical practice it doesn't usually worsen diabetic control (and in fact some studies have shown improved glycaemic control).

Fenofibrate and ezetimibe have not been shown to worsen diabetic control.

[Q: 2202] OnExamination 2012 - Endocrinology

Which of the following statements regarding bariatric surgery is correct?

- 1- Associated with a significant post-operative mortality
- 2- Associated with nutritional deficiencies
- 3- Contraindicated in adolescents
- 4- Indicated in patients with a BMI <35 kg/m²
- 5- Has no effect on cardiovascular mortality

Answer & Comments

Answer: 2- Associated with nutritional deficiencies

Bariatric surgery is a major gastrointestinal procedure. Bariatric surgery in adolescents

raises social, psychological and developmental issues, but adolescents are not excluded from surgery, and some hospitals have specialised programmes for younger patients.

Potential candidates for surgery are those with a body mass index (BMI) exceeding 40, or BMI >35 with serious co-morbidities (for example, sleep apnoea, type 2 diabetes). Post-operative mortality ranges from 0.1-2%.

Vomiting is a risk associated with bariatric surgery, as is dumping syndrome and nutritional deficiencies. There is no evidence as yet, that bariatric surgery reduces cardiovascular mortality in patients.

[Q: 2203] OnExamination 2012 - Endocrinology

A 70-year-old man who has had type 2 diabetes for 20 years is referred to the clinic because of poor glycaemic control despite recent dietetic input.

He has a history of two previous myocardial infarctions, and gets exertional angina at 50 yards. He has previously had angioplasty to both his lower limbs and despite this has a claudication distance of 40 yards. He has New York Heart Association failure class II-III.

Additionally he has diabetic maculopathy, and distal sensory neuropathy.

His home blood monitoring readings are 10-15 mmol/l before breakfast.

His current treatment includes; metformin 500 mg tds, glimepiride 4 mg daily, insulin detemir 20 units at night, perindopril 8 mg OD, furosemide 80 mg daily, aspirin 75 mg daily and atorvastatin 20 mg daily.

On examination his BMI is 30, with a BP of 140/70 mmHg.

Investigations show:

HbA1c 9.2% (3.8-6.4)

Fasting glucose 13.4 mmol/l (3.0-6.0)

Creatinine 130 µmol/l (60-110)

Liver function Normal

Which of the following strategies is the most appropriate for his glycaemic control?

- 1- Add pioglitazone 30 mg daily
- 2- Add prandial insulin (for example, NovoRapid) three times daily
- 3- Add premixed insulin (for example, Humalog 25) twice daily and stop Lantus
- 4- Substitute metformin with Avandamet 4/500 mg twice daily
- 5- Up titrate the dose of insulin detemir

Answer & Comments

Answer: 5- Up titrate the dose of insulin detemir

This patient has uncontrolled glycaemia despite the current dose of insulin glargine, oral hypoglycaemic therapy and dietary intervention.

Pioglitazone is already contraindicated because of the history of heart failure.

The current basal insulin regime of the insulin analogue detemir is failing to control his glycaemia, however the current dose is inadequate. Current practice would favour increasing the dose of detemir, aiming for a fasting (pre-breakfast) BM of <7.0.

Only once fasting readings of this level are achieved, (with a sub-optimal HbA1c), would one think of adding a prandial insulin.

The caveat would be nocturnal hypoglycaemia, in which case a change in the insulin regime would be warranted, however this was not mentioned in the vignette.

[Q: 2204] OnExamination 2012 - Endocrinology

A 51-year-old district nurse presented with a history of near fainting episodes, which were promptly relieved by eating chocolates.

At her last hospital admission, her simultaneous blood results were as follows:

Plasma glucose 1.8 mmol/l (3.0-6.0)

Serum insulin 58 pmol/l (<21)

C-peptide Undetectable

What is the most likely diagnosis?

- 1- Alcohol induced hypoglycaemia
- 2- Exogenous insulin administration
- 3- Growth hormone deficiency
- 4- Insulinoma
- 5- Sulfonylurea induced hypoglycaemia

Answer & Comments

Answer: 2- Exogenous insulin administration

The vignette of a middle-aged woman who has spontaneous hypoglycaemia and inappropriately high insulin (should be undetectable in presence of hypoglycaemia) would suggest insulinoma.

Yet, the C peptide is undetectable (indicating she has been administering insulin as the C peptide is released with endogenous insulin), and her occupation suggests drug abuse, in this case insulin.

[Q: 2205] OnExamination 2012 - Endocrinology

A 32-year-old woman presented with a six week history of 7 kg weight loss and heat intolerance.

Investigations revealed:

Free T₄ 45 pmol/L (10-22)

TSH <0.05 mU/L (0.4-5)

Which of the following features would support a diagnosis of Graves' disease?

- 1- Family history of radio-iodine treatment
- 2- Lid lag
- 3- Multinodular goitre
- 4- Pretibial myxoedema

5- Unilateral exophthalmos

Answer & Comments

Answer: 4- Pretibial myxoedema

This is a difficult question.

The specific features that would support a diagnosis of Graves' would include

Exophthalmos

Thyroid bruit and

Pretibial myxoedema.

The latter is pathognomonic as exophthalmos may be a feature (rarely) of hashitoxicosis.

[Q: 2206] OnExamination 2012 - Endocrinology

A 47-year-old schoolteacher presents to her GP with fatigue.

The GP noted her to be hypercalcaemic with an albumin of 39 g/L (37-49), globulin of 28g/L and Ca++ of 2.80 mmol/l (2.2-2.6).

Which of the following statements is true?

- 1- 24 hour urinary calcium assay is of no use at all.
- 2- Modern assays for PTH and PTHrp may cross-react so assays are unreliable.
- 3- Primary hyperparathyroidism will be diagnosed only if the PTH is at least three times the normal range.
- 4- The most likely diagnosis is myeloma.
- 5- The patient could undergo parathyroidectomy if renal stones are found on ultrasound

Answer & Comments

Answer: 5- The patient could undergo parathyroidectomy if renal stones are found on ultrasound

Twenty four hour urinary calcium may be useful if used in comparison to the serum

calcium in order to distinguish familial hypocalciuric hypercalcaemia from primary hyperparathyroidism.

Parathyroid hormone (PTH) may be less than twice the upper limit of normal in primary hyperparathyroidism.

Several indications for surgery exist including:

Calcium more than 1 mg/dl above upper normal limit

Greater than 30% decline in renal function

Renal stones

Age less than 50

Unwillingness of patient to follow advice of medical surveillance.

Myeloma is unlikely given the normal immunoglobulins.

[Q: 2207] OnExamination 2012 - Endocrinology

A 35-year-old woman is noted by her GP to have ++ glycosuria. Her BMI is 35 kg/m² and a fasting plasma glucose is 7.4 mmol/l (3.0-6.0).

Which one of the following measures would be most effective in reducing her insulin resistance?

- 1- Glibenclamide
- 2- Insulin
- 3- Metformin
- 4- Weight loss
- 5- Repaglinide

Answer & Comments

Answer: 4- Weight loss

The most appropriate treatment of this obese female with type 2 diabetes, which would also substantially reduce insulin concentrations, is weight loss.

Glibenclamide may be associated with increased insulin resistance as it stimulates insulin secretion, as does repaglinide.

Metformin would improve insulin sensitivity but would not do it as much as weight loss.

The unfortunate thing is that weight loss is the most difficult strategy for the patient to adhere to.

[Q: 2208] OnExamination 2012 - Endocrinology

A 60-year-old male with diet controlled type 2 diabetes mellitus is commenced on metformin due to deteriorating glycaemic control.

Which of the following is true regarding metformin?

- 1- It does not require any functioning pancreatic islet cells for its action
- 2- It is contraindicated in patients suffering a myocardial infarction (MI)
- 3- It is safe in patients with renal impairment
- 4- It may cause metabolic alkalosis
- 5- It often causes hypoglycaemia

Answer & Comments

Answer: 2- It is contraindicated in patients suffering a myocardial infarction (MI)

Metformin is a biguanide which acts to improve insulin sensitivity through mechanisms that involve hepatic gluconeogenesis and improved muscle glucose utilisation.

Thus, some insulin must be produced for it to have an effect.

It is associated with hypoglycaemia although this side effect is unusual.

It is contraindicated in subjects with renal failure, hepatic failure and heart failure due to the association with lactic acidosis.

The BNF states that there should be a six week "cooling off" period post-MI before the commencement or recommencement of metformin.

[Q: 2209] OnExamination 2012 - Endocrinology

A 16-year-old female presents with hypertension and increasing weight.

Which of the following features would be most suggestive of Cushing's syndrome rather than simple obesity?

- 1- Abdominal striae
- 2- Acanthosis nigricans
- 3- Buffalo hump (interscapular fat pad)
- 4- Moon face
- 5- Proximal myopathy

Answer & Comments

Answer: 5- Proximal myopathy

Proximal myopathy, easy bruising and thin skin are clinical features that are most suggestive of Cushing's syndrome.

Otherwise, abdominal striae, buffalo hump, and acanthosis nigricans are all features of obesity.

Similarly oligomenorrhoea would be a feature of obesity/polycystic ovarian syndrome.

[Q: 2210] OnExamination 2012 - Endocrinology

A 40-year-old female who has been prescribed thyroid replacement therapy has routine thyroid function tests.

On examination she appeared clinically euthyroid with no abnormal findings.

Her thyroid function tests revealed:

TSH 3.2 mU/L (0.4-5.0)

Total T₄ 20 nmol/L (55-144)

Free T₄ 2.6 pmol/L (10-22)

Total T₃ 2.5 nmol/L (0.9-2.8)

Which one of the following statements is correct?

- 1- Her thyroid hormone replacement is adequate
- 2- Investigation of pituitary function is required
- 3- She has a thyroiditis
- 4- She has sick euthyroid syndrome
- 5- She has tertiary hypothyroidism

Answer & Comments

Answer: 1- Her thyroid hormone replacement is adequate

This question is extremely poorly presented as no one, except for the MRCP, measures total thyroid hormone concentrations.

However, this patient has normal TSH, low total T4 with normal total T3 and really low free T4 which would suggest that she is taking T3 as replacement therapy. This may explain why no fT3 figures are provided.

Consequently she is receiving adequate replacement as reflected by the normal thyroid-stimulating hormone (TSH).

She does not have sick euthyroidism as it states in the run in that these measurements were routine. Although TSH is normal and tT4 and fT4 low, secondary/tertiary hypothyroidism would not explain the plum normal total T3 concentration.

She may well have had a thyroiditis such as Hashimoto's to have given her the hypothyroidism originally but she is now on replacement therapy and the former would not explain her thyroid function tests.

[Q: 2211] OnExamination 2012 - Endocrinology

A 50-year-old woman presented with a recently discovered, solitary, thyroid nodule.

Which of the following would suggest a diagnosis of thyroid malignancy?

- 1- Elevated serum thyroglobulin concentration.
- 2- Features of thyrotoxicosis.
- 3- Ipsilateral Horner's syndrome
- 4- Previous I131 therapy.
- 5- Tenderness over the nodule.

Answer & Comments

Answer: 3- Ipsilateral Horner's syndrome

The association of Horner's syndrome and a thyroid nodule would suggest invasion of the sympathetic chain and would suggest that this thyroid nodule is malignant.

Previous I131 is not associated with the development of malignancy.

Thyroglobulin may be elevated in any thyroiditis.

Tenderness over the nodule would suggest a thyroiditis and thyrotoxicosis suggests a functional adenoma making the malignancy extremely unlikely.

[Q: 2212] OnExamination 2012 - Endocrinology

To which of the following drug classes does the oral hypoglycaemic agent, pioglitazone, belong?

- 1- A biguanide
- 2- A peroxisome proliferator activating receptor (PPAR)-alpha agonist
- 3- A peroxisome proliferator activating receptor (PPAR)-gamma agonist
- 4- A sulphonylurea
- 5- An alpha-glucosidase inhibitor

Answer & Comments

Answer: 3- A peroxisome proliferator activating receptor (PPAR)-gamma agonist

Pioglitazone belongs to the PPAR gamma agonist class of blood glucose lowering agents.

Through activation of this receptor they modulate adipocyte function and improve insulin sensitivity.

Blood glucose lowering effect is around 1-1.3% HbA1c, but associated adverse events include fluid retention and decreased bone mineral density.

Pioglitazone is contraindicated in patients with a prior history of heart failure.

[Q: 2213] OnExamination 2012 - Endocrinology

A 48-year-old male is referred with impotence. He has a history of angina, hypertension and type 2 diabetes.

Which one of the following drugs that he takes would present a contraindication to his being able to receive sildenafil?

- 1- Aspirin
- 2- Bendroflumethiazide
- 3- Isosorbide mononitrate
- 4- Lisinopril
- 5- Metformin

Answer & Comments

Answer: 3- Isosorbide mononitrate

Nitrates and sildenafil are contraindicated due to the precipitant drops in blood pressure.

Viagra is also associated with increases in intraocular pressure so should be avoided in

Glaucoma

Hereditary retinal disease

Those with hypotension.

[Q: 2214] OnExamination 2012 - Endocrinology

When considering diabetic retinopathy which of the following statements is most accurate?

- 1- Microaneurysms (MA) represent sacular dilatation of retinal arterioles
- 2- Hard exudates (HE) represent calcium deposits in the retina
- 3- Cotton wool spots (CWS) represent infarcts of the nerve fibre layer of the retina
- 4- Haemorrhages close to the fovea are not potentially sight threatening
- 5- Laser photocoagulation is applied directly to new vessels to destroy them

Answer & Comments

Answer: 3- Cotton wool spots (CWS) represent infarcts of the nerve fibre layer of the retina

- A. MAs are capillary aneurysms.
- B. HEs are collections of exudated lipid and protein.
- C. This is correct, multiple CWS are a pre-proliferative sign.
- D. Haemorrhages (or HEs) close to the fovea represent a risk of macular oedema and are therefore sight threatening.
- E. Laser destroys ischaemic but viable retina to reduce the secretion of angiogenic growth factors and allow new vessel regression. it is not applied directly to new vessels as this would cause bleeding.

[Q: 2215] OnExamination 2012 - Endocrinology

A 45-year-old woman with a longstanding history of lithium use for bipolar disorder presents to the clinic for review.

She has a history of polyuria and polydipsia. On examination her BP is 135/72 mmHg, pulse is 71 and regular.

Investigations show:

Haemoglobin 11.8 g/dl(11.5-16.0)

White cell count $6.9 \times 10^9/L$ (4-11)

Platelets $199 \times 10^9/L$ (150-400)

Sodium 149 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 122 $\mu\text{mol/l}$ (79-118)

Glucose 5.4 mmol/l (<7.0)

Urinary osmolality 280 mOsm/kg(>300) after fluid restriction

Which of the following is the most likely diagnosis?

- 1- Cranial diabetes insipidus
- 2- Diuretic abuse
- 3- Nephrogenic diabetes insipidus
- 4- Psychogenic polydypsia
- 5- SIADH

Answer & Comments

Answer: 3- Nephrogenic diabetes insipidus

Whilst cranial diabetes insipidus (DI) is not impossible, it is less likely than nephrogenic DI in a patient taking chronic lithium therapy.

Diuretic abuse and psychogenic polydypsia are ruled out by the fluid deprivation test.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) results in water retention and hyponatraemia.

[Q: 2216] OnExamination 2012 - Endocrinology

You are reviewing a 23-year-old man who has history of Klinefelter's syndrome.

He is concerned about long term health risks associated with low testosterone levels.

Which of the following are likely consequences of his Klinefelter's?

- 1- Increased bone mineral density

2- Increased libido

3- Increased percentage of free testosterone

4- Low HDL cholesterol

5- Low LDL cholesterol

Answer & Comments

Answer: 4- Low HDL cholesterol

Klinefelter's is associated with a decrease in libido and men with the condition often find it very difficult to form lasting relationships.

Bone mineral density is decreased, and they are at increased risk of osteoporotic fractures.

Low-density lipoprotein (LDL) levels may be normal or increased, and triglyceride levels are often elevated.

Overall testosterone levels are low; Klinefelter's itself does not impact on the fraction which is protein bound however.

[Q: 2217] OnExamination 2012 - Endocrinology

A 19-year-old man from a travelling family comes to the endocrine clinic for review. He has bony aches and pains and feels tired all the time.

On examination his BP is 110/72 mmHg, pulse is 70 and regular. His BMI is 21, and he is only 160 cm in height. According to his mother this is much shorter than his brothers. He has bilateral shortened fifth digits on both hands.

Investigations show:

Haemoglobin 12.9 g/dl(13.5-17.7)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

Calcium 2.00 mmol/l (2.2-2.61)

Phosphate 1.6 mmol/l (0.8-1.5)

Which of the following is the most appropriate treatment?

- 1- Calcitonin
- 2- Calcium and vitamin D
- 3- Cinacalcet
- 4- Magnesium sulphate
- 5- Sevelamer

Answer & Comments

Answer: 2- Calcium and vitamin D

This patient has pseudohypoparathyroidism. This is caused by a maternally inherited G-protein abnormality. There is a characteristic phenotype with short stature, dysmorphic features (including short 4th or 5th metacarpals) and intellectual impairment. In addition there is resistance to a variety of hormones that act via cAMP (including PTH, TSH and gonadotrophins). Spontaneous or paternally inherited mutations cause dysmorphic features alone. Biochemically there is hypocalcaemia with raised PTH concentrations, raised TSH with low T4 and raised gonadotrophins. Hypocalcaemia causes paraesthesia, cramps, tetany, and carpopedal spasm, whereas hypothyroidism causes fatigue. The mainstay of treatment is calcium and vitamin D.

Sevelamer is a phosphate binder, so only really has a role in renal impairment.

Cinacalcet is used in the treatment of tertiary hyperparathyroidism.

Calcitonin is a second or third line therapy used in the treatment of osteoporosis.

There is no evidence that the patient is magnesium deficient, so magnesium sulphate is also an inappropriate answer.

[Q: 2218] OnExamination 2012 - Endocrinology

Bromocriptine is recognised as a dopamine

agonist and is used in the treatment of a range of disorders including prolactin secreting pituitary adenoma and Parkinson's.

Which of the following is associated with bromocriptine therapy?

- 1- Diarrhoea is commonly seen
- 2- Excessive sleepiness is commonly seen
- 3- Nasal congestion is rarely seen
- 4- Pulmonary fibrosis is not a recognised association
- 5- Tinnitus is rarely seen

Answer & Comments

Answer: 5- Tinnitus is rarely seen

Excessive sleepiness is seen only rarely in conjunction with bromocriptine therapy, it is seen more commonly with modern agents such as ropinirole.

With respect to gastrointestinal adverse events, it is constipation that is commonly seen, with diarrhoea only rarely associated with bromocriptine therapy.

Pulmonary fibrosis is rarely associated with bromocriptine therapy, although nasal congestion is actually a common feature of treatment.

[Q: 2219] OnExamination 2012 - Endocrinology

A 19-year-old man comes to the clinic with short stature and bony aches and pains. He attends a day care centre as he was identified as requiring special needs support at a young age.

On examination his BP is 135/72 mmHg, his pulse is 69 and regular. He is short at 160 cm in height and you notice a shortened fifth digit on both hands.

Investigations show:

Haemoglobin 13.0 g/dl(13.5-17.7)

White cell count $6.9 \times 10^9/L$ (4-11)

Platelets $207 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 114 $\mu\text{mol/l}$ (79-118)

Alkaline phosphatase 165 U/l (39-117)

Calcium 2.05 mmol/l (2.20-2.62)

Which of the following hormonal conditions is most likely to be present in addition to his abnormality of calcium metabolism?

- 1- Addison's disease
- 2- Hypergonadism
- 3- Hyperthyroidism
- 4- Hypogonadism
- 5- Hypothyroidism

Answer & Comments

Answer: 5- Hypothyroidism

Hyperthyroidism is incorrect because the G protein receptor mutation associated with pseudohypoparathyroidism is a non-functioning one.

Mutations in the gonadotrophin receptor are less common than those seen causing hypothyroidism; mutations leading to low levels of cortisol are rarer still but are reported in some patients.

[Q: 2220] OnExamination 2012 - Endocrinology

A 30-year-old woman is known to have a pituitary microadenoma for which she takes long term dopamine agonist therapy.

At her last clinic follow up she is well, has no symptoms of milk leakage, and her libido and sex life have returned to normal. She wishes to start a family with her partner.

Which of the following is the correct advice for her?

- 1- She should continue her bromocriptine throughout the pregnancy

- 2- She should not start a family until post surgical removal
- 3- She should stop her bromocriptine once she knows she is pregnant
- 4- She should stop her bromocriptine prior to trying to get pregnant
- 5- She should switch the bromocriptine to cabergoline prior to getting pregnant

Answer & Comments

Answer: 3- She should stop her bromocriptine once she knows she is pregnant

Many women with a microprolactinoma can be maintained on dopamine agonists without the need to progress to surgery which itself carries associated morbidity.

As such there is no need to stop therapy or progress to surgery before trying for a child, indeed stopping therapy will reduce the chance of ovulation.

There is no evidence that bromocriptine is required to be continued throughout the pregnancy.

[Q: 2221] OnExamination 2012 - Endocrinology

A 39-year-old man presents to his GP for review.

He has a history of carpal tunnel syndrome and osteoarthritis of his weight bearing joints, and has recently begun to suffer from symptoms of sleep apnoea.

On examination he has a prominent jaw line and macroglossia. His BP is elevated at 155/95 mmHg. There is peripheral visual field loss.

Investigations show:

Haemoglobin 13.9 g/dl (13.5-17.7)

White cell count $8.2 \times 10^9/L$ (4-11)

Platelets $202 \times 10^9/L$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Fasting glucose 8.8 mmol/l (<7.0)

Which of the following is true?

- 1- Growth hormone antagonists do not improve surgical survival
- 2- Pegvisomant can be used where IGF-1 is not normalised post surgery
- 3- Prolactin is most likely to be normal
- 4- Random growth hormone is always elevated
- 5- Risk of colonic carcinoma is not increased in this patient

Answer & Comments

Answer: 2- Pegvisomant can be used where IGF-1 is not normalised post surgery

Growth hormone antagonists used prior to surgery improve metabolic risk factors for surgery, such as hypertension and hyperglycaemia, as such even use over a few weeks before adenomectomy may impact positively on morbidity / mortality associated with surgery.

Prolactin may be elevated due to mass effect, and risk of colonic carcinoma is elevated in patients with acromegaly.

Growth hormone secretion is pulsatile, as such it may not always be elevated, and therefore IGF-1 is a better screening test for acromegaly.

[Q: 2222] OnExamination 2012 - Endocrinology

A 42-year-old man comes to the clinic with thirst, weight loss and polyuria. He tells you that his mother and aunt both have diabetes.

He himself is overweight with a BMI of 27, but tells you that he is pleased to have lost 7 kg in weight over the past few months, although he does admit to feeling weaker recently.

Investigations show:

Haemoglobin 13.8 g/dl(13.5-18)

White cell count $5.1 \times 10^9/l$ (4-10)

Platelets $199 \times 10^9/l$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 131 µmol/l (60-120)

Fasting glucose 14.1 mmol/l (<7.0)

According to the ADA/EASD consensus algorithm 2006 which of the following is the most appropriate initial therapy for him?

- 1- Acarbose
- 2- Gliclazide
- 3- Metformin and Insulin
- 4- Metformin
- 5- Pioglitazone

Answer & Comments

Answer: 3- Metformin and Insulin

This man has significant hyperglycaemia and symptoms of catabolism, weight loss, thirst, polyuria, etc.

In this case consensus guidelines recommend moving straight to insulin therapy, both for rapid control of glucose levels with symptom resolution, and because type 1 diabetes cannot be excluded in this case.

Depending on circumstances, oral medications can be added later and insulin even withdrawn in some cases.

[Q: 2223] OnExamination 2012 - Endocrinology

A 50-year-old man presented with a milky discharge from his nipples. He had a history of depression and gastro-oesophageal reflux disease and was on a number of medications.

Plasma prolactin 650 mU/L (< 360)

Which of the following is the most likely cause of his symptoms?

- 1- Amitryptiline
- 2- Cimetidine
- 3- Fluoxetine
- 4- Metoclopramide
- 5- Omeprazole

Answer & Comments

Answer: 4- Metoclopramide

This man has galactorrhoea and raised prolactin.

The most likely culprit is metoclopramide through its action on dopamine. It releases prolactin through dopamine antagonism.

[Q: 2224] OnExamination 2012 - Endocrinology

A 51-year-old man with type 2 diabetes was admitted to the coronary care unit with an acute myocardial infarction (MI) and left ventricular failure. He was commenced on intravenous sliding scale insulin at admission.

His other medications comprised gliclazide 80 mg twice daily, aspirin 75 mg OD, ramipril 5 mg daily, isosorbide mononitrate 20 mg BD, furosemide 40 mg OD and simvastatin 40 mg OD. On stopping his sliding scale insulin, his blood glucose meter readings vary between 15 to 20 mmol/l.

He was very obese with a BMI of 38.

Investigations showed:

Serum Sodium 134 mmol/l (137-144)

Serum Potassium 4.7 mmol/l (3.5-4.9)

Serum Urea 8.9 mmol/l (2.5-7.5)

Serum Creatinine 186 µmol/l (60-110)

Haemoglobin HbA1c 9.4 % (3.8-6.4)

What is the next most appropriate measure to optimise his glycaemic control?

- 1- Increase gliclazide dose
- 2- Insulin
- 3- Metformin
- 4- Orlistat
- 5- Pioglitazone

Answer & Comments

Answer: 2- Insulin

This man is obese, has poor glycaemic control and cannot use metformin due to the creatinine above 150, and the recent MI.

Insulin is the most appropriate therapeutic option.

Given the recent MI and use of furosemide, this is enough evidence of cardiac failure to count against use of pioglitazone.

[Q: 2225] OnExamination 2012 - Endocrinology

You are asked to review a 76-year-old man who has been admitted with pneumonia as the nurses notice he is significantly confused.

On examination his BP is 142/72 mmHg, his pulse is 78 and regular. He has signs of right sided pneumonia.

Investigations show:

Haemoglobin 12.9 g/dl (13.5-17.7)

White cell count $12.4 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 127 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Which of the following is likely to be found in this patient?

- 1- Free water excretion is likely to be elevated
- 2- Free water excretion is likely to be normal
- 3- Free water excretion is likely to be reduced
- 4- Sodium excretion is likely to be increased

5- Sodium excretion is likely to be normal

Answer & Comments

Answer: 3- Free water excretion is likely to be reduced

Free water excretion is not elevated or normal in conditions of antidiuretic hormone (ADH) excess, therefore options A and B are incorrect.

There is no effect on sodium excretion in syndrome of inappropriate antidiuretic hormone (SIADH) and therefore options D and E are also incorrect.

However, although 24 hour excretion rates of sodium are generally unchanged, as the urine volume is low with retention of free water, urine concentrations of sodium will appear inappropriately high.

[Q: 2226] OnExamination 2012 - Endocrinology

A 22-year-old woman presented with a five year history of hirsutism, having noticed coarse dark hair under her chin. Being a teacher in a primary school, these symptoms are very distressing for her. She has tried local measures such as shaving and applying depilatory creams but without lasting success.

Her periods are irregular with oligomenorrhoea. She attained menarche at the age of 14 years. She has not yet conceived and has had a coil fitted for contraception. She takes 5 mg diazepam at night.

On examination, she had a BMI of 24. She had coarse, dark hair over her chin, lower back and inner thighs. She does not have galactorrhoea to expression and there were no other clinical features to suggest Cushing's.

Investigations during the follicular phase:

Serum androstenedione 10.1 nmol/l (0.6-8.8)

Serum dehydroepiandrosterone sulphate 11.6 μ mol/l (2-10)

Serum 17-hydroxyprogesterone 18.6 nmol/l (1-10)

Serum oestradiol 380 pmol/l (200-400)

Serum testosterone 2.6 nmol/l (0.5-3)

Plasma luteinising hormone 3.3 U/l (2.5-10)

Plasma follicle-stimulating hormone 3.6 U/l (2.5-10)

What is the next most appropriate investigation?

1- 24 hour urinary free cortisol

2- CT scan of adrenals

3- GnRH test

4- Short Synacthen test with measurement of 17 hydroxy progesterone(17OHP)

5- Ultrasound scan of ovaries

Answer & Comments

Answer: 4- Short Synacthen test with measurement of 17 hydroxy progesterone(17OHP)

In this case the patient has features that would suggest polycystic ovary syndrome (PCOS) yet the 17OHP concentration is elevated and is compatible with non-classical congenital adrenal hyperplasia (CAH) yet just below the threshold of 33 nmol/l confidently to make the diagnosis.

Thus a short Synacthen test would be the most appropriate investigation with measurement of 17OHP.

A rise in 17OHP above 33 nmol/l suggests non-classical CAH.

[Q: 2227] OnExamination 2012 - Endocrinology

A 32-year-old female is being investigated for tinnitus by the ENT department and undergoes an MRI scan.

The scan is normal except for a pituitary tumour of 0.9 cm confined to the pituitary

fossa. Thyroid function tests, prolactin, LH, FSH and estradiol concentrations are all normal.

Which of the following would be the most appropriate management approach for this patient?

- 1- Pituitary biopsy
- 2- Reassure and continued observation
- 3- Stereotactic pituitary irradiation
- 4- Transphenoidal hypophysectomy
- 5- Treat with dopamine agonist therapy

Answer & Comments

Answer: 2- Reassure and continued observation

This patient has a coincidentally noted pituitary tumour, has no endocrine symptoms and appears to have normal endocrine function although we are not provided with information pertaining to cortisol secretory function nor growth hormone.

With this caveat in mind, the most appropriate strategy would be observation and repeat scanning.

[Q: 2228] OnExamination 2012 - Endocrinology

A 52-year-old schoolteacher attends with weight loss and sweats. She is clinically thyrotoxic with a diffuse goitre.

Subsequent investigations show:

Free T₄ 40 pmol/l (9-23)

Free T₃ 9.8 nmol/l (3.5-6)

TSH 6.1 mU/l (0.5-5)

A repeat TFT is similar.

What is the most appropriate investigation for this patient?

- 1- FNA of thyroid gland
- 2- MRI scan pituitary gland

- 3- Radio-isotope uptake scan of thyroid gland
- 4- Repeat TFT checking for antibody interference
- 5- Thyroid auto antibodies

Answer & Comments

Answer: 2- MRI scan pituitary gland

This patient is thyrotoxic; however, as the non-suppressed thyroid-stimulating hormone (TSH) suggests that this is due to excessive TSH production by the pituitary gland, the possibility of a thyrotroph adenoma must be pursued.

In primary hyperthyroidism the TSH should always be suppressed by negative feedback, which is not the case here.

TSH-omas are indeed very rare, but the giveaway would be the normal or elevated TSH with thyrotoxicosis.

[Q: 2229] OnExamination 2012 - Endocrinology

An elderly asthmatic lady on treatment with high dose prednisolone complains of a four week history of right hip pain.

She comments that recently she seems to be developing more facial hair and adds that she has also been diagnosed with high blood pressure and diabetes.

On examination she is noted to be unable to weight bear on the right side.

What is the most likely cause of her hip pain?

- 1- Avascular necrosis of femoral head
- 2- Dislocation of the hip joint
- 3- Fracture neck of femur
- 4- Gout
- 5- Osteoarthritis of the hip joint

Answer & Comments

Answer: 1- Avascular necrosis of femoral head

This question simply tests the knowledge of side effects of corticosteroids (a favourite theme in MRCP 1).

The patient has features of hypercortisolism.

Obviously avascular necrosis of femoral head is the cause of her right hip pain.

[Q: 2230] OnExamination 2012 - Endocrinology

In a study healthy volunteers are given 50 mls of 50% dextrose solution by one of two routes. Route A is intravenous and route B is via a nasogastric tube.

Every 15 minutes the plasma insulin level and glucose are measured and plotted on a graph.

Which of the following statements would best describe the likely results comparing route A to route B in this experiment?

- 1- Insulin and glucose the same in route A and route B
- 2- Insulin higher, glucose higher in route A
- 3- Insulin higher, glucose higher in route B
- 4- Insulin higher, glucose lower in route A
- 5- Insulin higher, glucose lower in route B

Answer & Comments

Answer: 5- Insulin higher, glucose lower in route B

Glucose given via the gut elicits a greater insulin response as compared to the same quantity given intravenously even though the plasma glucose peak is higher when it is given IV. This phenomenon is called the 'incretin effect'.

The incretin effect denominates the phenomenon that oral glucose elicits a higher insulin response than does intravenous glucose.

The two hormones responsible for the incretin effect, glucose-dependent insulinotropic hormone (GIP) and glucagon-like peptide-1

(GLP-1), are secreted after oral glucose loads and augment insulin secretion in response to hyperglycaemia.

Gastric Inhibitory Polypeptide and Glucagon-Like Peptide-1 in the Pathogenesis of Type 2 Diabetes. Diabetes 53:S190-S196, 2004

The investigation of the incretin effect is not usually performed using the same quantity of glucose as in this question. An 'isoglycaemic study' is often used where an infusion of glucose is designed to copy exactly the blood glucose profile generated in an individual or animal by a certain enteral glucose load.

Exenatide (synthetic exendin-4) is a new agent for the treatment of type 2 diabetes. Exendin-4 occurs naturally in the saliva venom of the North American lizard called the Gila Monster. It mimics the action of the gut hormone GLP-1 (Glucagon-like peptide 1).

[Q: 2231] OnExamination 2012 - Endocrinology

A 32-year-old woman with known hypothyroidism is admitted to hospital.

Her blood pressure is 86/53 mmHg and her pulse 100 bpm.

Investigations reveal:

Serum Sodium 126 mmol/L(137-144)

Serum Potassium 5.8 mmol/L(3.5-4.9)

Serum Glucose 3.0 mmol/L(3.0-6.0)

What is the most appropriate investigation?

- 1- Anti-thyroglobulin antibody
- 2- Plasma insulin concentration
- 3- Random serum cortisol concentration
- 4- Short Synacthen test
- 5- Urine and plasma osmolality

Answer & Comments

Answer: 4- Short Synacthen test

This young woman probably has an autoimmune hypothyroidism and now presents with features typical of acute hypoadrenalism.

The biochemistry is also supportive with low sodium, low glucose and elevated potassium.

The diagnosis may be confirmed with inadequate cortisol response in the short Synacthen test.

A random cortisol concentration is not adequate to diagnose hypoadrenalism.

[Q: 2232] OnExamination 2012 - Endocrinology

A 45-year-old woman presents with excessive hair growth on her face, chest and lower abdomen.

Which of the following may be associated with her condition?

- 1- Cyproterone
- 2- Hypoadrenalism
- 3- Minoxidil
- 4- Moxonidine
- 5- Valproate

Answer & Comments

Answer: 3- Minoxidil

Drugs causing hirsutism/hypertrichosis include minoxidil (not moxonidine -a centrally acting anti-hypertensive), phenytoin (not valproate) and cyclosporin.

Polycystic ovaries and congenital adrenal hyperplasia are associated with increased androgens and hirsutism.

Hypoadrenalism may be associated with loss of hair especially pubic hair.

Treatment of hirsutism is with anti-androgens (cyproterone, spironolactone), reduction of free androgens (oestrogen therapy, OCP,

weight loss), and cosmetic treatment for removal of hair.

[Q: 2233] OnExamination 2012 - Endocrinology

A 35-year-old woman presented with a five year history of weight gain associated with a one year history of amenorrhoea.

Over this time she had also noticed hirsutism and had been trying to conceive.

On examination, she had a BMI of 32 kg/m², a pulse was 84 beats per minute, and a blood pressure of 154/100 mmHg. Features suggestive of Cushing's syndrome were also noted.

Which of the following would be the most useful initial investigation?

- 1- 24 hour urinary free cortisol (UFC) concentration
- 2- Combined 9 am ACTH concentration and serum cortisol concentration
- 3- Midnight cortisol concentration
- 4- Serum sodium and potassium concentrations
- 5- The 1 mg overnight dexamethasone suppression test (ODST)

Answer & Comments

Answer: 1- 24 hour urinary free cortisol (UFC) concentration

Of 1 mg ODST or UFC, either test would be appropriate, but UFC is often recommended and has a 95% specificity (85% specificity in the obese) and a 98% sensitivity.

The ODST has a sensitivity and specificity of 98% and 75-80% in obese subjects with a cut-off value of 50 nmol/l.

Therefore, purely for convenience sake, a UFC would probably be the expected response here.

Midnight cortisol is pointless as a screening test expecting the patient to be fast asleep when blood is taken.

Sodium and potassium concentrations offer nothing, nor do ACTH and cortisol.

[Q: 2234] OnExamination 2012 - Endocrinology

Which of the following statements is true of primary hyperparathyroidism (HPT)?

- 1- It is associated with bone resorption by PTH to restore depressed serum calcium levels to normal.
- 2- It is associated with hypocalciuria due to elevated parathyroid hormone (PTH) levels.
- 3- It is usually caused by an adenoma of a single parathyroid gland.
- 4- It progresses to tertiary hyperparathyroidism with time.
- 5- PTH is secreted in a pulsatile manner from the posterior pituitary and acts through PTH receptors on parathyroid cell membranes

Answer & Comments

Answer: 3- It is usually caused by an adenoma of a single parathyroid gland.

Primary hyperparathyroidism has three main causes: adenoma, hyperplasia, and carcinoma. Adenomas clearly are the most prevalent entity representing 80-85% of cases. Hyperplasia is the second most common diagnosis constituting 15% of cases. Carcinoma represents <1% of total cases. All three cause inappropriate PTH release, which leads to hypercalcaemia and (usually) hypercalciuria.

Secondary hyperparathyroidism is described by option A: hypocalcaemia stimulates the parathyroid to produce excess PTH. It may progress to tertiary hyperparathyroidism,

whereby the parathyroid becomes autonomous in producing PTH even without the stimulus of hypocalcaemia, but primary does not.

PTH is produced by the parathyroid gland, not the posterior pituitary.

[Q: 2235] OnExamination 2012 - Endocrinology

An 18-year-old girl receives radioactive iodine (RAI) as treatment of thyrotoxicosis.

Which of the following is the most likely long term complication of this treatment?

- 1- Hypoparathyroidism
- 2- Hypothyroidism
- 3- Increased risk of developing cancer
- 4- Osteoporosis
- 5- Recurrent laryngeal nerve damage

Answer & Comments

Answer: 2- Hypothyroidism

RAI is safe and that is why it is given across all ages as a definitive treatment of thyrotoxicosis.

The most likely side effect of radioactive iodine is hypothyroidism with approximately 80% developing hypothyroidism after therapy.

There is no evidence to suggest that RAI is associated with any cancers.

However, RAI must not be given to pregnant females particularly after the 12th gestational week as it would be taken up by the developing fetal thyroid causing fetal hypothyroidism and is also considered to be teratogenic.

Recurrent laryngeal nerve damage is a potential risk of thyroid surgery, not RAI.

[Q: 2236] OnExamination 2012 -
Endocrinology

Which of the following is correct concerning nitric oxide?

- 1- Acts via cAMP as the second messenger
- 2- Inhibits platelet aggregation
- 3- Is inactivated by superoxide dismutase
- 4- Is manufactured from glycine
- 5- Is synthesised principally by the vascular smooth muscle

Answer & Comments

Answer: 2- Inhibits platelet aggregation

Nitric oxide is a free radical that is produced from L-arginine by nitric oxide synthase in the vascular endothelium.

It is anti-atherogenic, causing vasorelaxation, inhibiting platelet aggregation and foam cell formation.

[Q: 2237] OnExamination 2012 -
Endocrinology

A 62-year-old woman presents to the clinic with incontinence. She tells you that the pattern is always the same; with a warning she needs the toilet coming only a few moments before urine starts to leak, and she cannot get to the bathroom in time.

There is no medical history of note apart from mild hypertension which is managed with amlodipine 5 mg daily.

On examination her BP is 145/85 mmHg, pulse is 80 and regular. Respiratory and abdominal examination is unremarkable.

Investigations show:

Haemoglobin 11.8 g/dl (11.5-16.0)

White cell count $8.1 \times 10^9/L$ (4-11)

Platelets $198 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 122 $\mu\text{mol/l}$ (79-118)

Bladder scan No significant residual after voiding

Which of the following is the most appropriate initial treatment?

- 1- Bladder training
- 2- Doxazosin
- 3- Oxybutynin
- 4- Tamsulosin
- 5- Tolterodine

Answer & Comments

Answer: 1- Bladder training

Doxazosin is an alpha blocker used in the treatment of prostatic hypertrophy and hypertension.

Oxybutynin is first line drug therapy for urge incontinence with tolterodine amongst appropriate second line options.

Tamsulosin is an alpha-1 selective blocker used as an alternative to traditional alpha blockers for prostatic disease.

[Q: 2238] OnExamination 2012 -
Endocrinology

A 62-year-old man presents with rapidly deteriorating health, he has hardly eaten for days and has worsening nausea, vomiting and dehydration. He smokes 20 cigarettes per day and has been deteriorating with weight loss and a cough for some time.

On examination his BP is 110/70 mmHg, pulse is 95 and regular. He looks emaciated.

Investigations show:

Haemoglobin 10.0 g/dl (13.5-17.7)

White cell count $12.3 \times 10^9/L$ (4-11)

Platelets $188 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 187 $\mu\text{mol/l}$ (79-118)

Calcium 3.3 mmol/l (2.2-2.61)

CXR Mass suspicious of a carcinoma

Which of the following is the most likely cause of his hypercalcaemia?

- 1- Bony metastases
- 2- Dehydration
- 3- Excess vitamin D
- 4- Hyperparathyroidism
- 5- PTHrP

Answer & Comments

Answer: 5- PTHrP

Given the presence of a lung mass, it is more likely that the hypercalcaemia is related to PTHrP rather than extensive metastases.

Whilst dehydration will contribute to the degree of hypercalcaemia, it is highly unlikely to be the primary cause here.

Excess vitamin D occurs as a result of sarcoidosis, and with the presence of smoking and a lung mass it is more likely that a carcinoma rather than hyperparathyroidism is the cause.

[Q: 2239] OnExamination 2012 - Endocrinology

A 22-year-old woman comes to see you with her partner. She is keen to start a family but there is a history of nephrogenic diabetes insipidus (DI) affecting her male relatives.

Which of the following is the most likely underlying defect?

- 1- Aquaporin-1 gene mutation
- 2- Aquaporin-2 gene mutation
- 3- Aquaporin-3 gene mutation
- 4- V1 ADH receptor gene mutation
- 5- V2 ADH receptor gene mutation

Answer & Comments

Answer: 5- V2 ADH receptor gene mutation

Autosomal recessive nephrogenic DI is related to mutations in the aquaporin-2 gene, leading to reduced water reabsorption in the distal tubule. Rarer forms of X linked recessive disease have also been described.

On the other hand, the V2 ADH mutation is usually X linked recessive, and is therefore the correct answer here.

Mutations of aquaporin-1, aquaporin-3, and vasopressin-1 receptors are not described in conjunction with nephrogenic DI.

[Q: 2240] OnExamination 2012 - Endocrinology

A 31-year-old man who works as a fitness instructor is referred to the clinic with resistant hypertension.

He is currently taking a combination of amlodipine, ramipril and indapamide. His BP is elevated at 155/95 mmHg. Other physical examination is unremarkable.

Investigations show:

Haemoglobin 12.5 g/dl (13.5-17.7)

White cell count $5.0 \times 10^9/\text{L}$ (4-11)

Platelets $204 \times 10^9/\text{L}$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 3.2 mmol/l (3.5-5)

Creatinine 119 $\mu\text{mol/l}$ (79-118)

Which of the following is the next appropriate investigation?

- 1- Abdominal CT
- 2- Aldosterone / renin ratio
- 3- DMSA
- 4- Renal angiogram
- 5- Urinary electrolytes

Answer & Comments

Answer: 2- Aldosterone / renin ratio

If renovascular disease is suspected, then angiography is a reasonable approach to investigation, but this may follow aldosterone / renin estimation.

CT scanning is appropriate if an adrenal adenoma is suspected.

DMSA has largely fallen out of favour and been replaced by either MRA or traditional angiography.

Urinary electrolytes are of less value as an investigation as they may be confounded by factors such as use of diuretics.

[Q: 2241] OnExamination 2012 - Endocrinology

A 28-year-old woman presents to the clinic because she has had no periods for the past four months, she also suffers from problems with vaginal dryness during intercourse and milk leakage when her boyfriend stimulates her breasts.

On examination her BP is 122/70 mmHg, her pulse is 67, and her BMI is 23. You can express milk on minimal nipple palpation.

You suspect hyperprolactinaemia.

Which of the following prolactin levels fits best with drug related hyperprolactinaemia?

- 1- 800
- 2- 1500
- 3- 3000
- 4- 5000
- 5- 10000

Answer & Comments

Answer: 1- 800

Hyperprolactinaemia is commonly related to medication use.

Levels less than 1000 are most likely to be drug related, the 1500 option is an intermediate level between that seen with drug related hyperprolactinaemia and a microprolactinoma.

The drug class most commonly associated with hyperprolactinaemia are the dopamine antagonists, although a range of others may be implicated, these include :

Antidepressants

Verapamil

Methyldopa

Opiates

Protease inhibitors

Omeprazole

H2 antagonists.

A. 800 is the correct answer because it most closely reflects a prolactin within the range of that usually associated with drug induced hyperprolactinaemia.

B. 1500 is incorrect because it may be due to drug induced hyperprolactinaemia or related to a microadenoma.

C. 3000 is incorrect because it is more consistent with a microprolactinoma.

D. 5000 is incorrect because it is more consistent with either a micro- or macro-prolactinoma.

E. 10000 is incorrect because it is more consistent with a macroprolactinoma.

[Q: 2242] OnExamination 2012 - Endocrinology

A 52-year-old man who works as an HGV driver comes to the clinic for review.

He is currently taking metformin 1 g twice daily. On examination his blood pressure is 142/80 mmHg, and his BMI is 42. His latest pre-clinic HbA1c is 8.8%.

Which of the following according to the ADA/EASD consensus would be the most appropriate therapy for him?

- 1- Albiglutide
- 2- Exenatide
- 3- Liraglutide
- 4- Pramlintide
- 5- Taspoglutide

Answer & Comments

Answer: 2- Exenatide

The consensus recommends the use of proven therapies (sulphonylurea or insulin) as first choice add-in options to metformin.

However in special situations, for example, morbid obesity or risk of hypoglycaemia, exenatide may be considered as an alternative.

Pramlintide is an amylin agonist, the predominant effects of which include

Reduction in glucagon

Inhibition of gastric emptying

Nausea.

The guidelines do not recommend it, and it is only licensed in the United States as an adjunct to insulin therapy.

Albiglutide is a weekly GLP-1 analogue in development. Liraglutide is a daily GLP-1 analogue which shares close homology with human GLP-1.

[Q: 2243] OnExamination 2012 - Endocrinology

A 68-year-old man comes to the clinic for review. His current medication includes metformin 1 g twice daily for his type 2 diabetes.

Most recently he has noticed his morning fasting home monitored blood sugars rising

above 7 mmol/l, and his HbA1c has risen to 8.3% just prior to his clinic visit.

On examination his BMI is 29.

According to the ADA/EASD consensus, which of the following is the most appropriate additional therapy for him?

- 1- Chlorpropamide
- 2- Glibenclamide
- 3- Gliclazide
- 4- Prandial insulin
- 5- Sitagliptin

Answer & Comments

Answer: 3- Gliclazide

The consensus recommends the addition of either insulin or sulphonylurea at step two, as proven blood glucose lowering therapies.

It does not recommend use of older first generation sulphonylureas such as chlorpropamide or glibenclamide, instead recommending use of newer agents such as glipizide, glimepiride or gliclazide.

Sitagliptin is currently not recommended as a step two choice in the consensus.

[Q: 2244] OnExamination 2012 - Endocrinology

A 49-year-old man with newly diagnosed type 2 diabetes comes to the clinic for review.

He is an avid user of the internet and wants to know by what criteria the recommended treatments for his diabetes are decided.

According to the ADA/EASD consensus, which of the following principles is the one upon which therapeutic choices should be based?

- 1- Ability to achieve and maintain glycaemic target
- 2- Lack of weight gain
- 3- Proven avoidance of macrovascular complications

- 4- Proven avoidance of microvascular complications
- 5- Relative safety versus other options

Answer & Comments

Answer: 1- Ability to achieve and maintain glycaemic target

The consensus authors state that ability to achieve and maintain glycaemic control is the most important factor when selecting between diabetes therapies, with

Safety

Tolerability

Side-effects

Ease of use

Expense

being other factors of importance.

[Q: 2245] OnExamination 2012 - Endocrinology

A 59-year-old man is diagnosed with type 2 diabetes after suffering an acute myocardial infarction.

His discharge medication from the cardiac unit includes ramipril 10 mg daily, atorvastatin 10 mg daily, aspirin 75 mg and furosemide 40 mg daily. You are asked to review him for his diabetes care.

On examination his BP is 142/82 mm/Hg, his BMI is 31 kg/m².

Investigations show:

Haemoglobin 13.1 g/dl(13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $199 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 5.4 mmol/l (3.5-5)

Creatinine 152 $\mu\text{mol/l}$ (60-120)

Fasting glucose 9.2 mmol/l (<7.0)

According to the ADA/EASD consensus algorithm, which of the following initial therapies would be most appropriate for him in addition to diet and lifestyle measures?

- 1- Gliclazide
- 2- Metformin
- 3- Pioglitazone
- 4- Exenatide
- 5- Sitagliptin

Answer & Comments

Answer: 1- Gliclazide

In this case, metformin therapy is not recommended, due to the creatinine of 152.

The presence of furosemide, for presumptive treatment of cardiac failure, rules out use of pioglitazone.

Of the choices remaining, the consensus states that in patients who are unable to take metformin, sulphonylurea (SU) or insulin are the other options; so in this case gliclazide monotherapy is the most appropriate option.

[Q: 2246] OnExamination 2012 - Endocrinology

A 29-year-old woman presents to the clinic with diarrhoea which has been progressively worsening over the past six months. Multiple stool samples have proved negative over the past few weeks.

Her GP has been giving her loperamide to no effect. You understand there is a history in the family of hyperparathyroidism, and that her father had a tumour which caused hypoglycaemia. An ultrasound reveals a suspected pancreatic tumour.

Which of the following is a likely feature on biochemistry testing?

- 1- Hyperkalaemia
- 2- Hyponatraemia
- 3- Hypokalaemia

- 4- Increased bicarbonate
5- Increased pH

Answer & Comments

Answer: 3- Hypokalaemia

Decreased pH rather than increased pH occurs because it is small bowel secretions which increase in volume rather than stomach acid.

Hyperkalaemia does not occur, serum bicarbonate is decreased due to bicarbonate loss.

Hypernatraemia would only be seen in a state of severe dehydration.

[Q: 2247] OnExamination 2012 - Endocrinology

A 78-year-old woman with type 2 diabetes and rheumatoid arthritis is brought to the medical admissions unit with confusion. She can give no useful history.

There is a swollen right knee, and a temperature of 38.6°C. A BM reading records 24.8 mmol/l.

Which of the following statements in relation to her condition is correct?

- 1- Insulin inhibits ketogenesis
- 2- Mortality risk is low
- 3- The patient is likely to be hypo-osmolar
- 4- There is osmotic shift to the extravascular space
- 5- Urine dipstick reveals reduced specific gravity

Answer & Comments

Answer: 1- Insulin inhibits ketogenesis

The diagnosis in this patient is hyperglycaemic hyperosmolar non-ketotic coma (HONK or more accurately HHNC). In general there is enough insulin in patients with type 2 diabetes to suppress ketogenesis, but

insufficient to prevent hyperglycaemia and the hepatic resistance to glucagon.

The risk of mortality in HONK is 10-20%, with a strong predilection to thrombotic events. In general, HONK results in osmotic fluid shift to the intravascular space.

Urinalysis reveals increased specific gravity denoting dehydration.

[Q: 2248] OnExamination 2012 - Endocrinology

A 48-year-old lady has obesity with a BMI of 37 kg/m² and her waist measurement is 115 cm (which is very high). She gained most of the weight about 10 years ago and since that time she has tried many different forms of diets and weight-loss clubs. Although she enjoys swimming she is finding it harder to keep up her exercise and walking is restricted to a few hundred metres because of foot pain.

On further questioning, it is evident that her diet is quite reasonable consisting of about 1800 KCal per day. She eats breakfast, bases her meals on starchy foods, eats plenty of fibre and at eats at least five portions of vegetables or fruit per day.

Which of the following management strategies according to NICE guidance on obesity (published December 2006) would be advisable for this lady?

- 1- Diet and physical activity, consider drugs
- 2- Extended period, very low calorie diet
- 3- General advice on healthy weight and lifestyle
- 4- Referral for bariatric surgery
- 5- Referral to specialist obesity service

Answer & Comments

Answer: 1- Diet and physical activity, consider drugs

NICE recommendations are first to classify the level of this lady's obesity. This can easily be

achieved by looking at the tables in the NICE quick-reference guide on obesity.

Classification BMI kg/m²

Healthy weight 18.5-24.9

Overweight 25-29.9

Obesity I 30-34.9

Obesity II 35-39.9

Obesity III 40 or more

Her waist circumference is very high (>88 cm) and, in the absence of co-morbidities, we can see that the initial management should be diet and exercise with consideration of drug treatment which should be discussed.

Extended period (longer than 12 weeks) low-calorie diet and bariatric surgery may be considered but would warrant specialist referral.

[Q: 2249] OnExamination 2012 - Endocrinology

A 19-year-old male presents with concerns regarding his pubertal development.

On examination he is 1.8 m tall, thin and has little pubic and axillary hair. Both testes are approximately 5 ml in volume (NR 15 ml). No other abnormalities are encountered.

Investigations reveal:

LH 3.3 mU/l (3-10)

FSH 5.5 mU/l (3-10)

Testosterone 5.5 nmol/l (9-30)

Which of the following is the most likely diagnosis?

- 1- Anorexia nervosa
- 2- Craniopharyngioma
- 3- Kallmann's syndrome
- 4- Klinefelter's syndrome
- 5- Primary testicular failure

Answer & Comments

Answer: 3- Kallmann's syndrome

This young male has delayed puberty with hypogonadotrophic hypogonadism. The most likely explanation would be Kallmann's syndrome.

Klinefelter's would be associated with elevated luteinising hormone/follicle stimulating hormone (LH/FSH), as would primary testicular failure.

His height of 1.8 m, suggesting that he is tall, would argue against this being anorexia despite his thin appearance. If anorexia had preceded puberty then his stature should also have been affected.

The only other possibility is craniopharyngioma, but this is probably less likely in an otherwise well man, and other possible features should be included to suggest this diagnosis.

You may wish to cry foul at this point, and say that anosmia should be given as a clue to Kallmann's; however, in reality, how often do you ask about sense of smell, let alone test for it

[Q: 2250] OnExamination 2012 - Endocrinology

A 40-year-old man was found to have acromegaly.

What is the most likely cause of death if treatment is unsuccessful?

- 1- Colorectal carcinoma
- 2- Diabetic nephropathy
- 3- Gastric carcinoma
- 4- Left ventricular failure
- 5- Increased intracranial pressure

Answer & Comments

Answer: 4- Left ventricular failure

If treatment of acromegaly is unsuccessful the death rate from cardiovascular, cerebrovascular, respiratory and malignant disease is two to four times that of the general population.

Classically the malignancy associated with acromegaly is tumour of the large intestine.

Mortality is typically due to a cardiovascular cause if the condition is untreated. Thus heart failure is probably a more common cause of death than colonic neoplasia.

[Q: 2251] OnExamination 2012 - Endocrinology

A 58-year-old male is admitted with a blood pressure of 210/120 mmHg and episodic runs of ventricular tachycardia (VT).

Investigations confirm the presence of a right adrenal phaeochromocytoma.

Which one of the following would be the most appropriate initial therapy?

- 1- Amiodarone
- 2- Atenolol
- 3- Lidocaine
- 4- Phenoxybenzamine
- 5- Propafenone

Answer & Comments

Answer: 4- Phenoxybenzamine

This patient has catecholamine-induced severe hypertension and associated paroxysmal ventricular tachycardia.

The patient should initially be alpha-blocked with phenoxybenzamine and then β -blockers introduced.

This should control the runs of VT but for sustained VT lidocaine can be acutely used.

[Q: 2252] OnExamination 2012 - Endocrinology

In the treatment of congenital adrenal hyperplasia (CAH), which of the following statements is correct?

- 1- Efficacy of treatment is best monitored by 17-OH progesterone and androstenedione levels
- 2- Hydrocortisone may be administered once daily
- 3- Hypotension, hyperkalaemia and hyperreninaemia suggest that the dose of mineralocorticoid should be reduced
- 4- Preferred treatment in children is prednisone
- 5- Renin activity levels are of no clinical use in treatment monitoring

Answer & Comments

Answer: 1- Efficacy of treatment is best monitored by 17-OH progesterone and androstenedione levels

In the treatment of CAH the lowest dose of glucocorticoid that suppresses (not totally) adrenal androgens, whilst maintaining normal growth and weight gain, is the optimum dose of glucocorticoid replacement.

Renin activity levels can be used to monitor adequacy of mineralocorticoid and sodium replacement.

Hydrocortisone has a relatively short half life and must therefore be administered twice daily, whilst the preferred mode of glucocorticoid replacement in children is hydrocortisone as it minimises growth suppression.

Over-treatment with mineralocorticoids leads to hypertension, suppressed plasma rennin activity and possibly growth retardation.

[Q: 2253] OnExamination 2012 - Endocrinology

A 60-year-old man who was previously fit and well presented with a six week history of blurring of vision.

His investigation revealed a fasting plasma glucose of 12.9 mmol/L (3.0 - 6.0).

What is the most likely cause of his blurred vision?

- 1- Cataract
- 2- Maculopathy
- 3- Osmotic changes in the lens
- 4- Proliferative diabetic retinopathy
- 5- Retinal vein thrombosis

Answer & Comments

Answer: 3- Osmotic changes in the lens

Without being given too much here, this patient is a newly diagnosed diabetic as we are told he was previously fit and well.

Therefore the most probable explanation for his blurred vision is osmotic change.

[Q: 2254] OnExamination 2012 - Endocrinology

A 16-year-old male presents with polyuria and polydipsia.

Which of the following may confirm the diagnosis of diabetes mellitus?

- 1- A fasting plasma glucose of 7.5 mmol/L
- 2- A finding of 3+ ketonuria
- 3- An HbA1c of 6.0%
- 4- A plasma glucose of 10.2 mmol/l two hours after 75 grams of oral glucose.
- 5- A random plasma glucose of more than 7.5 mmol/L

Answer & Comments

Answer: 1- A fasting plasma glucose of 7.5 mmol/L

The diagnosis is usually relatively easy to confirm in a symptomatic subject.

A random glucose of more than 11.1 mmol/L or a fasting glucose of more than 7.0 mmol/L would be regarded as confirmatory.

There is usually glycosuria in addition to ketonuria.

Isolated ketonuria suggests fasting.

A raised glycosolated haemoglobin (HbA1c) above 6.5% is now considered diagnostic.

A glucose tolerance test is rarely needed.

[Q: 2255] OnExamination 2012 - Endocrinology

Which of the following suggests a poorer prognosis for thyroid cancer?

- 1- Age less than 30.
- 2- Cold nodule on thyroid uptake scan
- 3- High TSH concentration
- 4- Male sex.
- 5- Papillary thyroid cancer with cervical node involvement.

Answer & Comments

Answer: 4- Male sex.

Factors that suggest a poor prognosis in thyroid cancer include

Increasing age

Male sex

Poorly differentiated histological features and

Distant spread.

[Q: 2256] OnExamination 2012 - Endocrinology

A 60-year-old woman presents with vague aches and pains and has a family history of osteoporosis. She is 10 years post-menopausal but has not taken any female HRT.

Dual energy x ray absorptiometry (DEXA) is requested.

Which of the following values of bone mineral density measured by DEXA would signify osteopenia at a measured site?

- 1- A T score of -2.6
- 2- A T score of -1.8
- 3- A Z score of -2.0
- 4- A z score of -1.5
- 5- A T score of -0.9

Answer & Comments

Answer: 2- A T score of -1.8

Osteopenia is defined as a T score of between -1 and -2.5 standard deviations below the bone mineral density of a young female.

Osteoporosis is defined as <-2.5 SD.

These measurements are important as they signify a greatly increased risk of fracture.

Z scores refer to the bone mineral density compared with that of a 'normal' age matched subject.

[Q: 2257] OnExamination 2012 - Endocrinology

A 49-year-old man is referred to the clinic with possible Cushing's syndrome.

He is grossly obese having gained 8 kg during the past six months. He has hypertension on four agents and impaired glucose tolerance.

On examination his BP is 155/85 mmHg, pulse is 75 and regular and his BMI is 35.

Assuming he has Cushing's, which of the following features would you most expect on routine biochemistry?

- 1- Decreased bicarbonate
- 2- Decreased sodium
- 3- Increased bicarbonate
- 4- Increased potassium
- 5- Increased sodium

Answer & Comments

Answer: 3- Increased bicarbonate

Whilst salt and water retention occurs in conjunction with Cushing's syndrome, this does not usually lead to hyponatraemia.

Alkalosis rather than acidosis occurs.

Hypokalaemia rather than hyperkalaemia is seen in some patients.

[Q: 2258] OnExamination 2012 - Endocrinology

A chromophobe adenoma of the pituitary would be expected in which of the following?

- 1- Acromegaly
- 2- Cushing's disease
- 3- Non-functioning pituitary tumour
- 4- Prolactinoma
- 5- TSH secreting tumour

Answer & Comments

Answer: 3- Non-functioning pituitary tumour

A chromophobe adenoma refers to no uptake of dye within the tumourous specimen.

This occurs in the non-secretory/non-functioning pituitary tumours.

[Q: 2259] OnExamination 2012 - Endocrinology

A 55-year-old woman with a history of type 2 diabetes managed with BD mixed insulin comes to the clinic for review.

Her BP is within target at 130/70 mmHg, she has recently lost 4 kg and her BMI is now 28. Her most recent HbA1c is measured at 7.3%. The only abnormality of note on blood testing is triglycerides which are elevated at 2.5 mmol/l.

Which of the following correctly represents the relative increase in cardiovascular risk associated with the elevated triglycerides in this patient?

- 1- 10%
- 2- 30%
- 3- 70%
- 4- 90%
- 5- 120%

Answer & Comments

Answer: 2- 30%

The answer is option B, 30%.

Cardiovascular risk calculators apply a risk multiplier of 1.3 for triglycerides above 1.7 mmol/l.

Hypertriglyceridaemia, usually accompanied by low HDL, is the commonest lipid abnormality seen in patients with type 2 diabetes. This is associated with central adiposity and increased insulin resistance.

Whilst statins are effective in reducing LDL cholesterol in patients with type 2 diabetes, further measures are usually required in controlling hypertriglyceridaemia.

[Q: 2260] OnExamination 2012 - Endocrinology

A 49-year-old man with type 2 diabetes is managed with metformin 1 g twice daily and

has recently been started on exenatide because he is morbidly obese and still failing to achieve adequate blood glucose control.

On examination his BMI is 41.

Investigations show:

Haemoglobin 13.4 g/dl(13.5-18)

White cell count $5.2 \times 10^9/L$ (4-10)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (60-120)

HbA1c 7.2%(<5.5)

He asks about home blood glucose monitoring.

Which of the following is most consistent with the recommendations in the consensus?

- 1- He should monitor morning fasting and post-prandial glucoses three times per week
- 2- He should monitor morning fasting and pre-prandial glucoses three times per week
- 3- He should monitor fasting glucoses every day
- 4- He should monitor fasting glucoses three times per week
- 5- He should not need to self monitor his glucoses

Answer & Comments

Answer: 5- He should not need to self monitor his glucoses

Generally, if patients are not using insulin, sulphonylureas or glinides (repaglinide or netaglinide), then the consensus does not recommend self-monitoring of blood glucose levels.

With respect to insulin titration however, self-monitored blood glucose results play a crucial part in appropriate dose adjustment.

The consensus recommends a target of between 3.9 and 7.2 mmol/l for fasting and pre-prandial glucose levels.

If fasting levels are in range yet the HbA1c is elevated, post-prandial monitoring is recommended, aiming for glucose levels of less than 10 mmol/l.

[Q: 2261] OnExamination 2012 - Endocrinology

A 52-year-old male with a history of dyslipidaemia and hypertension attends the surgery for a 75g oral glucose tolerance test (OGTT) as part of his cardiovascular risk assessment and screening for type 2 diabetes.

He is overweight with a BMI of 29 kg/m², his blood pressure is 135/85 mmHg on a combination of amlodipine and perindopril.

His venous plasma OGTT result is as follows.

0 minutes 6.3 mmol/L (3.0-6.0)

120 minutes 10.4 mmol/L (3.0-6.0)

Which of the following is the correct interpretation of these results?

- 1- Impaired fasting glucose (IFG)
- 2- Impaired fasting glucose and impaired glucose tolerance
- 3- Impaired glucose tolerance (IGT)
- 4- Normal glucose tolerance.
- 5- Type 2 diabetes

Answer & Comments

Answer: 2- Impaired fasting glucose and impaired glucose tolerance

The World Health Organization (WHO) recommend the use of the OGTT for the diagnosis of type 2 diabetes as it incorporates the fasting and two hour post glucose load which can identify different sub groups of diabetic patients and different categories of individuals at risk of type 2 diabetes.

The diagnostic criteria are:

Venous plasma glucose Fasting (mmol/l) 2 hour post glucose (mmol/l)

Diabetic > 7.0 > 11.1

IGT < 7.0 7.8-11.0

IFG 6.1-6.9 < 7.8

In the absence of marked hyperglycaemia and symptoms such as weight loss, polyuria or polydipsia these results should be confirmed by a repeat test on another day.

Reference:

<http://www.gpnotebook.co.uk/simplepage.cfm?ID=-1603600309&linkID=67387&cook=yes>

[Q: 2262] OnExamination 2012 - Endocrinology

A 53-year-old female presents with a four month history of weight gain, episodic sweats and shakiness which occur during episodes of fasting and are relieved by eating chocolate bars.

She informs you that she has a friend who is a nurse and has provided her with a glucose meter. During one of these episodes the glucose concentration was recorded at 2.8 mmol/l (3.0-6.0).

On examination she has a body mass index of 30.2 kg/m², a pulse of 82 bpm and a blood pressure of 144/86 mmHg. No other abnormalities are noted.

Which of the following is the most appropriate next investigation for this woman?

- 1- 72 hour fast
- 2- Fasting insulin and C peptide measurement
- 3- MRI pancreas
- 4- Oral glucose tolerance test
- 5- Sulphonylurea measurement

Answer & Comments

Answer: 1- 72 hour fast

This woman has features of spontaneous hypoglycaemia which is relieved by eating and precipitated by fasting and exercise.

The most relevant investigation to prove or disprove this would be a 72 hour fast which has a virtual 99% sensitivity. If proven then further investigation for an insulinoma or factitious hypoglycaemia is warranted.

[Q: 2263] OnExamination 2012 - Endocrinology

A 38-year-old man presented with intermittent severe headaches. He was prescribed spironolactone 50 mg and bendroflumethiazide 2.5 mg daily for hypertension.

On examination his pulse was 112 beats per minute, with regular rhythm, and blood pressure was 190/110 mmHg.

Investigations revealed:

Serum Sodium 132 mmol/L (137-144)

Serum Potassium 3.4 mmol/L (3.5-4.9)

Serum Urea 7.0 mmol/L (2.5-7.5)

Which one of the following is the most useful investigation in establishing the diagnosis?

- 1- A 24 hour urinary 5-hydroxyindoleacetic acid concentration
- 2- A 24 hour urinary catecholamine concentration
- 3- A 24 hour urinary free cortisol concentration
- 4- A radionuclide Hippuran renogram
- 5- The serum aldosterone: rennin ratio

Answer & Comments

Answer: 2- A 24 hour urinary catecholamine concentration

This question seems nebulous at first but on further investigation it is extremely complex.

The answer is unlikely to be carcinoid given the lack of symptoms of carcinoid syndrome. The flushing attacks of the carcinoid syndrome are accompanied by hypotension. Renal anatomy and function are studied with sequential images using radionuclides that are indexes of tubular function (¹³¹I Hippuran). The clinical history here is not suggestive of renal artery stenosis.

Given the patient's young age, and markedly raised BP on treatment we should consider an endocrine cause.

The electrolyte disturbance is mild and is of dubious relevance in this question.

Diuretic use may be causing the hyponatraemia and hypokalaemia, indeed the commonest cause of hypokalaemia in hypertension is diuretic therapy. However, spironolactone use could, theoretically, mask a more significant hypokalaemia.

There is no clinical history to suggest Cushing's and primary aldosteronism is not associated with a tachycardia. An aldosterone:rennin ratio would not be appropriate at this stage given that the patient is receiving spironolactone.

The history of episodic headaches is central to this question, together with the tachycardia. These paroxysmal headaches suggest the diagnosis of pheochromocytoma; often the symptoms are vague and rarely is the classical presentation encountered.

Patients with pheochromocytoma may develop a severe vascular headache (Bridgwater and Starling, 1982).

Thomas et al. (1966) reviewed the histories of 100 patients with proven pheochromocytoma seen at the Mayo Clinic and found that episodic headache was present in 80%. It was usually of rapid onset, bilateral, severe, throbbing, and associated with nausea in about half of the cases.

[Q: 2264] OnExamination 2012 -
Endocrinology

A 70-year-old male with a five year history of type 2 diabetes mellitus (T2DM) presents for annual review with a blood pressure of 188/88 mmHg.

Clinical examination was normal. An ECG reveals evidence of left ventricular hypertrophy (LVH). Urinary protein creatinine ratio (PCR) is positive.

Which one of the following drugs is the most appropriate treatment for this patient's hypertension?

- 1- Amlodipine
- 2- Atenolol
- 3- Bendroflumethiazide
- 4- Doxazosin
- 5- Ramipril

Answer & Comments

Answer: 5- Ramipril

Regarding the British Hypertensive Society guidelines and NICE guidelines on the treatment of blood pressure in T2DM, this elderly male with diabetes has isolated systolic hypertension associated with LVH (LVH being defined as a complication of hypertension) and proteinuria.

Evidence would support the use of an angiotensin converting enzyme inhibitor (ACEi) as first line treatment for patients with diabetes, in the absence of other compelling diagnoses.

Reference:

Hypertension: management of hypertension in adults in primary care NICE

[Q: 2265] OnExamination 2012 -
Endocrinology

A 17- year-old female presents with tingling and muscle cramps. There is no other past

medical history of note.

Investigations reveal:

Creatinine 68 $\mu\text{mol/L}$ (60-110)

Calcium 1.76 mmol/L (2.2-2.6)

Phosphate 1.4 mmol/L (0.8-1.4)

Albumin 38 g/L (37-49)

Which one of the following investigations is most likely to confirm the diagnosis?

- 1- Alkaline phosphatase concentration
- 2- Computerised tomography (CT) brain scanning
- 3- Parathyroid (PTH) concentration
- 4- Urine calcium concentration
- 5- Vitamin D concentration

Answer & Comments

Answer: 3- Parathyroid (PTH) concentration

This patient has low calcium which is due to hypoparathyroidism.

As PTH promotes the loss of phosphate in the urine, hypoparathyroidism is associated with a high or high-normal serum phosphate concentration.

Vitamin D deficiency is also a possibility although deficiency would have to be longstanding to cause this degree of hypocalcaemia.

Urine calcium concentrations are useful in familial hypercalciuric hypocalcaemia (as opposed to the more common familial hypocalciuric hypercalcaemia).

Hypoparathyroidism is less common than hyperparathyroidism and is associated with other autoimmune conditions such as Addison's disease, thyroid disease and type 1 diabetes mellitus. There are also a number of rarer associations such as DiGeorge syndrome.

Treatment is with alfacalcidol and monitoring is required to maintain the calcium concentration in the reference range.

[Q: 2266] OnExamination 2012 - Endocrinology

A 36-year-old male with insulin-dependent diabetes mellitus (IDDM) of three years duration presented with decreased libido and erectile dysfunction since diagnosis. No abnormalities were noted on genital examination.

Investigations revealed:

plasma testosterone 6.0 nmol/L (9 - 35)

plasma follicle stimulating hormone 1.0 u/L (1-8)

Which of the following investigations is the most appropriate next step?

- 1- Autonomic function testing
- 2- Doppler studies of penile artery
- 3- Nerve conduction studies
- 4- Serum ferritin
- 5- Serum prolactin

Answer & Comments

Answer: 4- Serum ferritin

This IDDM patient appears to have hypogonadotrophic hypogonadism (HH) as reflected by low testosterone and low follicle-stimulating hormone (FSH).

The combination is compatible with a diagnosis of haemochromatosis and measuring ferritin would be a reasonable investigation.

Haemochromatosis typically causes hypogonadotrophic hypogonadism as a consequence of the ferritin deposition within the pituitary rather than primary testicular dysfunction.

Autonomic nerve dysfunction is one of the commoner causes of impotence in a person with diabetes but in this case is not the cause of his HH.

For similar reasons, both nerve conduction studies and Doppler studies are irrelevant.

Prolactin would be a sensible measurement but probably if you were looking to confirm a diagnosis that incorporates the diabetes as well, ferritin would be the investigation of choice.

[Q: 2267] OnExamination 2012 - Endocrinology

Which of the following is a feature of Cushing's syndrome?

- 1- Calcium pyrophosphate arthropathy
- 2- Fibrous dysplasia
- 3- Osteoarthritis
- 4- Osteomalacia
- 5- Vertebral collapse

Answer & Comments

Answer: 5- Vertebral collapse

Vertebral collapse may be due to osteoporosis.

Osteoarthritis and gout would be unusual with elevated corticosteroid concentrations.

Osteomalacia is not a feature.

[Q: 2268] OnExamination 2012 - Endocrinology

A 62-year-old man with a history of type 2 diabetes mellitus takes 24 units BD of mixed insulin. His HbA1c is elevated at 8.3% yet he is having problems with hypoglycaemic episodes either late in the afternoon or during the early hours of the morning. A recent creatinine is 130 µmol/l.

On examination is BP is 148/82 mmHg, pulse is 70 and regular, respiratory and abdominal examination is unremarkable.

Which of the following is the most appropriate next step?

- 1- Advise him to eat a snack before going to bed
- 2- Decrease his BD mixtard dose by 20%
- 3- Increase his BD mixtard dose by 20%
- 4- Split his mixtard into three doses
- 5- Transition him to a basal bolus regime

Answer & Comments

Answer: 5- Transition him to a basal bolus regime

Whilst eating a snack going to bed will help avoid hypoglycaemia, it will also lead to weight gain which he should avoid.

Decreasing his mixtard dose will cause a rise in HbA1c, increasing it will worsen his hypoglycaemic episodes. Given that insulins with a better bolus profile are available, it is not appropriate to split his mixtard into three doses.

[Q: 2269] OnExamination 2012 - Endocrinology

Which of the following antibodies are typically found in auto-immune adrenalitis (Addison's disease)?

- 1- Anti-21 hydroxylase antibody
- 2- Anti-nuclear antibody
- 3- Anti-peroxidase antibody
- 4- Anti-rho antibody
- 5- Anti-tryptophan hydroxylase antibody

Answer & Comments

Answer: 1- Anti-21 hydroxylase antibody

21 Hydroxylase is the enzyme involved in the cholesterol steroid pathway and has been

found to be present in approximately 80% of cases.

[Q: 2270] OnExamination 2012 - Endocrinology

A 17-year-old woman comes to the endocrine clinic for review.

She has primary amenorrhoea. Other history of note includes having no sense of smell.

On examination her BP is 110/70 mmHg, her pulse is 65 and regular. She is 170 cm in height. There is an absence of secondary sexual hair and breast development.

Investigations show:

Haemoglobin 12.8 g/dl(11.5-16.0)

White cell count $5.9 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 143 mmol/l (135-146)

Potassium 3.7 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Androgen insensitivity syndrome
- 2- Autoimmune ovarian failure
- 3- Kallman syndrome
- 4- Noonan's syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 3- Kallman syndrome

Androgen insensitivity syndrome (AIS) presentation is similar, but you would expect the sense of smell to be preserved. Often phenotypic females with AIS also have cryptorchidism where the testes present as bilateral direct inguinal hernias in infancy.

Autoimmune ovarian failure would present as secondary amenorrhoea, and development of

secondary sexual characteristics would be preserved.

Turner's is associated with short stature, webbing of the neck, hypertension and a number of other abnormalities.

Noonan's is phenotypically similar to Turner's in females, but also occurs in males.

[Q: 2271] OnExamination 2012 - Endocrinology

You are taking part in the clinical trials of a new treatment for symptomatic hypoglycaemia which is thought to have a glucagon-like action.

Which of the following features would be consistent with a glucagon-like effect?

- 1- Inhibition of catecholamine secretion
- 2- Stimulation of gastric emptying
- 3- Stimulation of glycogenesis
- 4- Stimulation of glycolysis
- 5- Stimulation of lipolysis

Answer & Comments

Answer: 5- Stimulation of lipolysis

Glucagon leads to stimulation rather than inhibition of catecholamine secretion. It delays gastric emptying and reduces pancreatic exocrine secretions.

With respect to glucose handling, glucagon stimulates glycogenolysis, at the same time inhibiting glycolysis and activating gluconeogenesis.

[Q: 2272] OnExamination 2012 - Endocrinology

A 22-year-old student nurse is admitted after a third episode of collapse whilst on attachment in the Emergency department of the hospital.

She has no past medical history of note and her only medication is the progesterone only pill. On further questioning she says she feels light-headed and hungry to the pit of her stomach before these collapses occur and tells you that none of these attacks have occurred outside the hospital.

On examination her BP is 110/70 mmHg, pulse is 78 and general physical examination is entirely normal.

Investigations show:

Haemoglobin 13.2 g/dl(11.5-16.0)

White cell count $4.4 \times 10^9/L$ (4-11)

Platelets $172 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 micromol/l (79-118)

Glucose (in recovery period) 8.2 mmol/l (>3.0)

Which of the following is the most appropriate next step?

- 1- Admit for a 72 hour fast
- 2- Arrange an exercise provocation test
- 3- Arrange an ultrasound abdomen
- 4- Give her glucagon to carry around in case an attack occurs
- 5- Glucose, insulin and C peptide assay at the time of an attack

Answer & Comments

Answer: 5- Glucose, insulin and C peptide assay at the time of an attack

Given all of this woman's attacks occur within the hospital, and the fact that she potentially has access to insulin, it raises the possibility of exogenous administration of insulin by the patient herself. As such the best way to differentiate between insulinoma and exogenous insulin administration is glucose, insulin and C peptide, as with self administration of insulin, C peptide is low, but in contrast with insulinoma it would be

elevated. The idea of a urine assay for sulphonylureas should also be gently introduced to her.

It is not appropriate to give her glucagon to carry around until the cause of her hypoglycaemia is properly established.

If an insulinoma is suspected, then exercise provocation is usually avoided because of the risk of serious hypoglycaemia, the majority of patients being diagnosed after a 72 hour fast.

An ultrasound of the abdomen would only be considered if an insulinoma was suspected.

[Q: 2273] OnExamination 2012 - Endocrinology

A 52-year-old South Asian woman comes to the clinic complaining of lower back, hip and thigh pain, accompanied by general fatigue and lethargy.

She has a history of hypertension for which she takes ramipril 10 mg daily, but nothing else of note. On further questioning you find out that she spends most of the day inside. On examination her BP is 142/84 mmHg, there is mild proximal muscle weakness, but no other significant findings.

Investigations show:

Haemoglobin 12.8 g/dl(11.5-16.5)

White cells $5.2 \times 10^9/L$ (4-11)

Platelet $188 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.9 mmol/l (3.5-5)

Creatinine 133 $\mu\text{mol/l}$ (79-118)

Calcium 2.05 mmol/l (2.20-2.60)

HbA1c 7.3% (<5.5) (56 mmol/mol)

TSH 4.8 mU/l (0.5-5.0)

Which of the following is the most likely diagnosis?

1- Fibromyalgia

2- Hypothyroidism

3- Osteomalacia

4- Osteoporosis

5- Myositis

Answer & Comments

Answer: 3- Osteomalacia

Osteomalacia is related to low levels of vitamin D and occurs more commonly in patients of South Asian origin, particularly those who have a cultural tendency to spend more time inside.

Symptoms include bony pain, particularly around the hips and lower back, and proximal myopathy.

The low calcium seen on routine blood testing fits with this diagnosis, phosphate is likely to be low, with raised alkaline phosphatase.

Management in this case involves vitamin D supplementation, dietary review to encourage adequate dairy intake, and encouragement to spend more time in the sun.

A. Fibromyalgia is incorrect because the low calcium points us towards an alternative diagnosis, and her pain is confined to a limited region.

B. Hypothyroidism is incorrect because the thyroid-stimulating hormone (TSH) is at the upper end of the normal range.

C. Osteomalacia is correct given this woman's ethnic origin, her symptoms and her low calcium level.

D. Osteoporosis is incorrect because we are not given evidence of fracture, bone mineral density, and the low calcium and proximal myopathy are more in keeping with osteomalacia.

E. Myositis is incorrect because there is no evidence of generalised myopathy, and if this were the diagnosis we might expect a creatine kinase (CK) level in the investigations provided.

[Q: 2274] OnExamination 2012 -
Endocrinology

A 38-year-old patient comes to the clinic with hypertension he is finding difficult to control.

Despite taking ramipril 10 mg, atenolol 50 mg and amlodipine 10 mg, his BP is 155/97 mmHg. He has no other significant past medical history. His BMI is 22 and general examination is unremarkable.

Investigations show

Haemoglobin 13.5 g/dl(13.5-17.7)

White cells $7.9 \times 10^9/L$ (4-11)

Platelets $231 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.1 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

Spot aldosterone:renin ratio 830

Which of the following is the most appropriate next step to optimise his management?

- 1- Add doxazosin
- 2- Add indapamide
- 3- Add moxonidine
- 4- Echocardiogram
- 5- MRI abdomen

Answer & Comments

Answer: 5- MRI abdomen

The spot aldosterone:renin ratio greater than 800 raises the strong possibility that this man is suffering from hyporeninaemic hyperaldosteronism. Quite marked hypokalaemia, even in the presence of ACE inhibition, is a further pointer to the diagnosis.

MRI abdomen is the investigation that is likely to confirm the possibility of an adrenal adenoma.

Whilst addition of further anti-hypertensives may drive his blood pressure closer to goal

they are unlikely to be effective and surgery is the most appropriate intervention.

B-blockers, however, can significantly raise the aldosterone:renin ratio, increasing the risk of false positives.

[Q: 2275] OnExamination 2012 -
Endocrinology

A 73-year-old woman presented with thirst and polyuria of six months duration.

She had suffered several episodes of lower back pain. She was on no medication.

On examination she looked well, had a dorsal kyphosis and a blood pressure of 170/95 mmHg.

Investigations revealed:

Erythrocyte sedimentation rate 15 mm/1st hour (0-30)

Serum Urea 11.9 mmol/L (2.5-7.5)

Serum Creatinine 175 $\mu\text{mol/L}$ (60-110)

Serum Albumin 40 g/L (37-49)

Serum total Calcium 2.98 mmol/L (2.2-2.6)

What is the most likely cause of this lady's hypercalcaemia?

- 1- Metastatic breast cancer
- 2- Myeloma
- 3- Osteoporosis
- 4- Primary hyperparathyroidism
- 5- Sarcoidosis

Answer & Comments

Answer: 4- Primary hyperparathyroidism

The prevalence of hyperparathyroidism is said to be four per 1000 in women over 60, and is two to three times more common in women than men.

The lower back pain may be loin pain due to renal colic caused by renal calculi or due to osteoporosis. The renal impairment may be

associated with renal calculi, perhaps due to calculi-induced hydronephrosis in extreme cases. Renal impairment in hyperparathyroidism is not uncommon. Chronic hypercalcaemia can compromise the renal concentrating ability leading to polydipsia and polyuria.

The kyphosis may be due to osteoporosis which is commonly seen in conjunction with hyperparathyroidism. Classically, hypertension has been associated with hyperparathyroidism.

Associated with myeloma one would expect a drop in albumin concentration together with a markedly elevated erythrocyte sedimentation rate (ESR).

[Q: 2276] OnExamination 2012 - Endocrinology

A 34-year-old man presents with a six month history of tiredness, weight gain and cold intolerance.

On examination he appeared hypothyroid and had a firm goitre.

Investigations reveal:

Free T₄ 6 pmol/l (10-22)

TSH 55 mU/l (0.4-5.0)

What is the most likely diagnosis in this patient?

- 1- De Quervain's thyroiditis
- 2- Hashimoto's thyroiditis
- 3- Iodine deficiency
- 4- Pendred's syndrome
- 5- Primary atrophic hypothyroidism

Answer & Comments

Answer: 2- Hashimoto's thyroiditis

Irrespective of gender, the most likely diagnosis in this hypothyroid man is Hashimoto's disease.

Iodine deficiency is extremely unlikely in the United Kingdom.

Elevated De Quervain's thyroiditis would be associated with acute presentation with a painful goitre, raised temperature and weight loss. Thyroid function tests may be transiently abnormal, often high, but hypothyroidism may ensue.

Pendred's syndrome is hypothyroidism due to dysmorphogenesis, goitre and sensorineural deafness.

Atrophic hypothyroidism would not be associated with goitre.

[Q: 2277] OnExamination 2012 - Endocrinology

A previously well 60-year-old lady is admitted with an acute anterior myocardial infarction. A random blood glucose concentration was found to be 12.1 mmol/L (<6.7).

What is the optimal management of her blood sugar?

- 1- Commence gliclazide
- 2- Commence intravenous insulin plus dextrose
- 3- Commence metformin
- 4- Commence subcutaneous insulin
- 5- No therapy other than continued dietary control

Answer & Comments

Answer: 2- Commence intravenous insulin plus dextrose

The DIGAMI study has demonstrated that there is a survival advantage in initially treating such patients with elevated glucose concentrations with sliding scale insulin for 24 hours post-infarct and then switching to three months subcutaneous insulin. (Almbrand B, Johannesson M, Sjostrand B, Malmberg K, Ryden L. Cost Effectiveness of Intense Insulin

Treatment after Acute Myocardial Infarction in Patients with Diabetes Mellitus. Results from the DIGAMI study Eur Heart J 2000; 21: 733-39).

However, DIGAMI 2 contested these results suggesting no survival benefits between insulin or oral hypoglycaemic agents (OHAs).

However, in the acute setting insulin sliding scale needs to be used.

[Q: 2278] OnExamination 2012 - Endocrinology

A 50-year-old man with a history of diabetes mellitus and hypertension attends an ophthalmic clinic for regular assessment.

On fundoscopy he is diagnosed to have preproliferative diabetic retinopathy.

Which of the following is characteristic of preproliferative diabetic retinopathy?

- 1- Hard exudates
- 2- Macular oedema
- 3- Microaneurysms
- 4- New vessels at the disc
- 5- Venous beading

Answer & Comments

Answer: 5- Venous beading

Microaneurysms and hard exudates are features of background diabetic retinopathy.

Macular oedema is associated with microaneurysms and hard exudates and is due to fluid leakage but is not necessarily a feature pre-proliferative or proliferative retinopathy although it may still require laser photocoagulation.

Venous beading, loops and soft exudates (cotton wool spots) are characteristic of the ischaemia associated with preproliferative diabetic retinopathy.

New vessels suggest proliferative retinopathy.

[Q: 2279] OnExamination 2012 - Endocrinology

A 20-year-old woman comes to the endocrine clinic with excessive hairiness and acne.

She tells you that she has a period only every few months and when she has one it tends to be very heavy.

On examination she has obvious facial acne. Her BP is 142/78 mmHg, pulse is 72 and regular and her BMI is 30. There is facial hair and hair around her upper chest and breasts.

Investigations show:

Haemoglobin 11.9 g/dl(11.5-16.0)

White cell count $6.0 \times 10^9/l$ (4-11)

Platelets $202 \times 10^9/l$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Total testosterone normal

Free androgen index elevated

LH / FSH ratio 2.2

Which of the following is the most likely diagnosis?

- 1- Cushing's syndrome
- 2- Germ cell tumour
- 3- Polycystic ovarian syndrome
- 4- Testicular feminisation
- 5- Turner's syndrome

Answer & Comments

Answer: 3- Polycystic ovarian syndrome

Cushing's is incorrect as more features including marked obesity, hypertension, and impaired glucose tolerance would be expected.

A germ cell tumour would be expected to result in higher androgen levels.

Testicular feminisation results in an absence of secondary sexual hair.

Turner's syndrome results in primary amenorrhoea.

[Q: 2280] OnExamination 2012 - Endocrinology

A 36-year-old man attends clinic with his wife after failing to conceive after 10 years of marriage.

Examination reveals that he is tall, thin and has bilateral gynaecomastia. Investigations show high levels of urinary gonadotrophins.

What is the most likely diagnosis?

- 1- Andropause
- 2- Gaucher's disease
- 3- Klinefelter's syndrome
- 4- Marfan syndrome
- 5- Noonan's syndrome

Answer & Comments

Answer: 3- Klinefelter's syndrome

Gaucher's and Marfan syndrome do not present with infertility.

Noonan's is associated with short stature.

Klinefelter's is a sex chromosome disorder affecting 1:400 - 1:600 male births typically with 47 XXY, XXXYY or XXYY.

Andropause is the term for the gradual decrease in serum testosterone concentration with age, but does not occur, usually, until after the age of 50.

[Q: 2281] OnExamination 2012 - Endocrinology

A 21-year-old woman who is known to suffer from an eating disorder presents to the clinic with increased lethargy, muscle weakness and fasciculations. She tells you that she has even less appetite than usual.

On examination her BP is 105/72 mmHg, pulse is 68 and regular. Her BMI is 16.5.

Investigations show:

Haemoglobin 11.2 g/dl (11.5-16.0)

White cell count $6.1 \times 10^9/L$ (4-11)

Platelets $178 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 81 micromol/l (79-118)

Calcium 2.18 mmol/l (2.2-2.61)

Which of the following is the most likely diagnosis?

- 1- Hypocortisolaemia
- 2- Hypoglycaemia
- 3- Hypomagnesaemia
- 4- Hypophosphataemia
- 5- Hypothyroidism

Answer & Comments

Answer: 3- Hypomagnesaemia

Low magnesium (below 0.7 mmol/l) can be seen in protein malnutrition states which include anorexia and eating disorders.

Symptoms include

Lethargy

Fatigue

Muscle weakness including fasciculations

Changes in personality and

Lack of appetite.

Most patients respond to oral magnesium supplementation.

Given her relatively normal electrolyte status, low cortisol is very unlikely.

We also have no evidence of weight gain, hair loss, skin or menstrual cycle changes to support hypothyroidism.

Hypophosphataemia may occur in this population but is usually related to re-feeding syndrome.

Given glucose production by the liver, hypoglycaemia is extremely rare, even in severe eating disorders.

[Q: 2282] OnExamination 2012 - Endocrinology

A 25-year-old man presents to the endocrine clinic for review after investigations for a raised prolactin. He originally presented to his GP with tiredness.

On examination his BP is 110/70 mmHg, pulse is 70 and regular. There are no abnormal findings at all on general examination.

Investigations show:

Haemoglobin 13.8 g/dl (13.5-17.7)

White cell count $6.0 \times 10^9/L$ (4-11)

Platelets $178 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

TSH 1.5 IU/l (0.5-4.5)

Prolactin 820 mU/l (<400)

MRI pituitary normal

Which of the following correctly reflects what will most likely happen to his prolactin over the next six months?

- 1- It will fall by 50%
- 2- It will fall by 75%
- 3- It will increase by 50%
- 4- It will increase by 75%
- 5- It will stay the same

Answer & Comments

Answer: 5- It will stay the same

A reduction in prolactin levels occurs in around 1/3rd of people presenting with idiopathic hyperprolactinaemia.

A further increase in prolactin is seen in the remainder of those who present initially, but not over the six month time period.

[Q: 2283] OnExamination 2012 - Endocrinology

A 45-year-old man presents with a change in his facial appearance over the past few years, soft tissue swelling, and difficult to manage hypertension.

His GP is concerned that he may have acromegaly and tests an IGF-1 which is elevated, a pituitary MRI confirms an adenoma.

Which of the following describes the most likely defect within somatotrophs resulting in increased growth hormone release?

- 1- Elevation in ATP
- 2- Elevation in cyclic AMP
- 3- Elevation in GTP
- 4- Mutation in the beta sub-unit of the GTP binding protein
- 5- Mutation in the gamma sub-unit of the GTP binding protein

Answer & Comments

Answer: 2- Elevation in cyclic AMP

A significant percentage of growth hormone secreting tumours are thought to have a mutation in the alpha sub-unit of the stimulatory guanosine triphosphate (GTP) binding protein.

This leads to persistent elevation of cyclic adenosine monophosphate (AMP) and hence production of excess growth hormone.

[Q: 2284] OnExamination 2012 - Endocrinology

A 37-year-old woman is trying for a child with her new partner.

She is very concerned as she has had no menstrual periods for the past seven months, but serial pregnancy tests have proved negative.

If she has entered the menopause then which of the following blood tests would fit most with this picture?

- 1- Elevated FSH
- 2- Elevated oestradiol
- 3- Low LH
- 4- Low LHRH
- 5- Low testosterone

Answer & Comments

Answer: 1- Elevated FSH

Testosterone levels vary in women and are increased in women who are overweight because of peripheral conversion to androgens in fat, and in patients with polycystic ovarian syndrome.

Low luteinising hormone (LH) is not consistent with the menopause, nor is low luteinising hormone-releasing hormone (LHRH), as sex hormone releasing hormones would be elevated in an attempt to drive LH and follicle-stimulating hormone (FSH) release.

Elevated oestradiol is not associated with ovarian failure.

[Q: 2285] OnExamination 2012 - Endocrinology

A 28-year-old woman presents to the clinic complaining of increasingly heavy periods, where she bleeds for more days each month. These have changed over the course of the past few months. She does not take regular

contraception and does not have a regular partner.

On examination her BP is 145/80 mmHg, her pulse is 70 and regular, and her BMI is 26.

Investigations show:

Haemoglobin 10.2 g/dl (11.5-16.0)

White cell count $6.0 \times 10^9/L$ (4-11)

Platelets $198 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 108 $\mu\text{mol/l}$ (79-118)

Glucose 5.4 mmol/l (<7.0)

Which of the following hormonal changes is most likely to be found in this patient?

- 1- Decreased TSH
- 2- Hyperinsulinaemia
- 3- Increased testosterone
- 4- Low normal prolactin
- 5- Markedly elevated prolactin

Answer & Comments

Answer: 4- Low normal prolactin

Markedly elevated prolactin is associated with amenorrhoea, as is decreased thyroid-stimulating hormone (TSH), associated with hyperthyroidism and decreased heaviness of menses.

Increased testosterone and hyperinsulinaemia may be associated with polycystic ovarian syndrome, resulting in decreasing frequency of periods which are heavier in nature.

[Q: 2286] OnExamination 2012 - Endocrinology

A 54-year-old man comes to the clinic for review of type 2 diabetes. He is noted to have a BMI of 33 and a particularly elevated waist/hip ratio. You suspect that he has elevated central adiposity.

Which of the following markers fits best with increased central adiposity?

- 1- Low alanine aminotransferase
- 2- Low plasma urate
- 3- Raised HDL cholesterol
- 4- Raised LDL cholesterol
- 5- Raised triglycerides

Answer & Comments

Answer: 5- Raised triglycerides

The answer is option E, raised triglycerides.

Raised triglycerides are indicative of disordered free fatty acid handling, a sign of inability of fat cells to store lipid; this is associated with peripheral insulin resistance and abnormal glucose levels.

Disordered free fatty acid handling is associated with increased central fat, increased cardiovascular risk, and hepatic steatosis. Weight loss is an important treatment option in this case.

In such cases you should consider looking for other features of the metabolic syndrome.

[Q: 2287] OnExamination 2012 - Endocrinology

A 62-year-old man comes to the surgery for review.

He has a history of peripheral vascular disease, characterised by intermittent claudication, particularly when he walks up a slight incline. He has a history of smoking 20 cigarettes per day.

Medication includes amlodipine 10 mg, valsartan 40 mg and atorvastatin 10 mg.

On examination his BP is 135/72 mmHg, his pulse is 82. His BMI is 32. There are trophic changes on examination of both legs consistent with chronic peripheral vascular disease.

Investigations show:

Haemoglobin 12.3 g/dl (13.5-17.7)

White cells $6.2 \times 10^9/L$ (4-11)

Platelet $234 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 118 micromol/l (79-118)

HDL cholesterol 0.8 mmol/l (0.8-1.8)

LDL cholesterol 2.0 mmol/l (<4.0)

Triglycerides 2.8 mmol/l (0.7-2.1)

Glucose 6.2 mmol/l (<7.0)

Which of the following is the most appropriate way to impact on his cardiovascular risk?

- 1- Add in a fibrate or omega 3 fatty acids
- 2- Further reduce his blood pressure
- 3- Increase his dose of atorvastatin
- 4- Start metformin
- 5- Start pioglitazone

Answer & Comments

Answer: 1- Add in a fibrate or omega 3 fatty acids

The answer is option A, add in a fibrate or omega 3 fatty acids.

This patient's blood pressure is relatively close to target, and increasing his blood pressure medication is unlikely to impact much further on his overall cardiovascular risk profile.

Statins also result in only a modest reduction in triglycerides versus their impact on LDL cholesterol.

Other options (metformin or pioglitazone) centre on the fact that he has impaired fasting glucose, but in reality neither agent is licensed for the treatment of pre-diabetes.

As such the most appropriate option is to consider medication such as a fibrate or omega 3 fatty acids, target at triglyceride

reduction. Triglycerides above 1.7 are thought to be associated with around a 30% relative increase in cardiovascular disease events.

[Q: 2288] OnExamination 2012 - Endocrinology

A 42-year-old woman comes to the clinic complaining of weight loss of 3 kg over the course of the past six weeks, heat intolerance and palpitations. She is referred by her GP with abnormal thyroid blood tests; apparently her mother also suffered from an overactive thyroid gland.

On examination she has a BMI of 19 kg/m², her BP is 142/72 mmHg and her pulse is 95. She has a fine tremor. Her thyroid is diffusely enlarged.

Investigations show

Haemoglobin 13.0 g/dl(11.5-16.5)

White cell count 8.2 x 10⁹/L (4-11)

Platelets 170 x 10⁹/L (150-400)

Serum Sodium 141 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Creatinine 110 µmol/l (79-118)

TSH <0.05 mU/l (0.5-5.0)

Anti-thyroid antibody Positive

Which of the following findings on examination or investigation would you also expect?

- 1- Decreased sex hormone-binding globulin (SHBG) levels
- 2- Decreased uptake on thyroid scan, with one 'hot' area
- 3- Globally decreased uptake on thyroid scan
- 4- Orange peel skin on both shins
- 5- Periods of bradycardia on 24 hour tape recording

Answer & Comments

Answer: 4- Orange peel skin on both shins

Graves' thyrotoxicosis is associated with pre-tibial myxoedema, commonly described as orange peel skin present on both shins. It is usually associated with

Tachycardia

Increased levels of SHBG

Globally increased uptake on thyroid scan.

Decreased uptake on the scan and one hot area would be a feature of a thyroxine producing thyroid adenoma.

Currently this patient has no features consistent with Graves' ophthalmopathy, but these may become apparent later in the time course of the disease.

[Q: 2289] OnExamination 2012 - Endocrinology

A 58-year-old woman with a history of Hashimoto's disease and hypothyroidism presents to the emergency department some 24 hours after taking 80 x 100 microgram tablets of thyroxine because she intended to kill herself.

On examination her BP is 135/84 mmHg, and she has a resting tachycardia of 122.

Investigations show

Haemoglobin 13.4 g/dl(11.5-16.5)

White cell count 5.2 x 10⁹/L (4-11)

Platelets 191 x 10⁹/L (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 105 µmol/l (79-118)

ECG Confirms tachycardia, but no ischaemic changes seen

Which of the following is the most appropriate way to manage her overdose?

- 1- Activated charcoal
- 2- Carbimazole
- 3- Diazepam

4- Propranolol

5- Propylthiouracil

Answer & CommentsAnswer: 4- Propranolol

Overdoses of thyroxine are relatively rare, and a number of strategies have been described in their management.

In reality, patients may be partially protected from thyroid hormone excess by production of reverse T3. As such, the vast majority can be managed with regular propranolol to alleviate symptoms of tachycardia and anxiety.

In severe cases, plasmapheresis to remove protein bound thyroxine, and cholestyramine to reduce enterohepatic circulation of thyroxine have been advocated.

[Q: 2290] OnExamination 2012 - Endocrinology

A 38-year-old woman is about to be discharged after a thyroidectomy when she reports to the FY2 that she has a hoarse voice. You fear a recurrent laryngeal nerve injury.

Which of the following structures is most closely related to the recurrent laryngeal nerve?

- 1- Brachiocephalic vein
- 2- Carotid artery
- 3- Inferior thyroid artery
- 4- Jugular vein
- 5- Superior thyroid artery

Answer & CommentsAnswer: 3- Inferior thyroid artery

The superior thyroid artery runs closest to the superior laryngeal nerve.

The carotid artery, jugular vein and brachiocephalic vein do not have a close relationship to the recurrent laryngeal nerve.

[Q: 2291] OnExamination 2012 - Endocrinology

You review a 54-year-old man with respect to his diabetes control. He has had type 2 diabetes for some five years and currently takes metformin 1 g twice daily.

There is a history of hypertension for which he takes ramipril and amlodipine, and he has microalbuminuria.

On examination his BMI is 27 (lost 4 kg over the past six months but not by trying), and his BP is 143/78 mmHg.

Investigations show:

Haemoglobin 12.9 g/dl(13.5-18)

White cell count $5.3 \times 10^9/L$ (4-10)

Platelets $202 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 124 $\mu\text{mol/l}$ (60-120)

HbA1c 9.1%(<5.5)

Total cholesterol 5.4 mmol/l (<4.5)

HDL cholesterol 0.7 mmol/l (>1.0)

According to the ADA/EASD consensus algorithm, which of the following would be the most appropriate addition to his glucose lowering therapy?

- 1- Start bedtime intermediate acting insulin
- 2- Start BD mixed insulin
- 3- Start glimepiride
- 4- Start pioglitazone
- 5- Start prandial insulin

Answer & CommentsAnswer: 1- Start bedtime intermediate acting insulin

This man's HbA1c is high at 9.1%, he has a low high density lipoprotein (HDL) cholesterol, is losing weight, and has a history of microalbuminuria.

The two established therapy options at this stage, as stated in the consensus, are either to add a sulfonylurea (SU) or insulin. Given his need for greatly improved metabolic control, insulin is the better option here.

The guidelines recommend starting with either morning or evening long-acting insulin, or with bedtime intermediate acting insulin.

[Q: 2292] OnExamination 2012 - Endocrinology

A 63-year-old patient with bipolar disorder and type 2 diabetes trips over a step and sustains an injury to her left hand. She is unable to dorsiflex her left hand, and an orthopaedic registrar diagnosis a ruptured extensor tendon.

She is receiving treatment for an infected diabetic foot ulcer.

Which of the following therapies may be implicated in this injury?

- 1- Aripiprazole
- 2- Exenatide
- 3- Fusidic acid
- 4- Levofloxacin
- 5- Naproxen

Answer & Comments

Answer: 4- Levofloxacin

The quinolones have recently been associated with tendon rupture. Rupture has been reported in the Achilles, shoulder and hand.

This may occur due to disruption of the extracellular matrix and depletion of collagen which is observed in animal models.

Aripiprazole is a second generation antipsychotic, and exenatide is a glucagon like-peptide 1 analogue used in the management of type 2 diabetes. Neither of these products has been associated with tendon rupture.

[Q: 2293] OnExamination 2012 - Endocrinology

A 60-year-old male with a 8 year history of type 2 diabetes is being treated with metformin 1g twice daily and gliclazide 160 mg twice daily. He is obese, has gained weight over the last year and his HbA1c has deteriorated from 59 to 64mmol/mol (20?42). He is being considered for treatment with either insulin or pioglitazone. The patient wants to know the side effects of pioglitazone.

Which of the following is regarded as a typical side effect of pioglitazone therapy?

For further information click on:

Pioglitazone [requires login]

- 1- Acanthosis nigricans
- 2- Fluid retention
- 3- Lactic acidosis
- 4- Myositis
- 5- Photosensitivity rash

Answer & Comments

Answer: 2- Fluid retention

Pioglitazone may cause fluid retention in up to 10% of patients. This effect may be exacerbated by concomitant use with other drugs that cause fluid retention (e.g. NSAIDs, calcium antagonists). Pioglitazone is contra-indicated in patients with cardiac failure. Weight gain with pioglitazone is caused by a combination of fat accumulation and fluid retention. Lactic acidosis is a recognised side-effect of metformin. Some sulphonylureas may cause a photosensitivity rash. Statins and fibrates are associated with myositis.

[Q: 2294] OnExamination 2012 - Endocrinology

A 52-year-old male with a five year history of type 2 diabetes is diagnosed with ischaemic heart disease and has recently commenced

simvastatin 40 mg daily, as his cholesterol was 6.2 mmol/l.

He re-attends complaining of various muscle aches and pains and you find that his liver function tests are markedly deranged, including elevated alkaline phosphatase. You stop the simvastatin and his symptoms subside but his cholesterol remains elevated at 6.3 mmol/l.

Which of the following is the most appropriate strategy to treat his hypercholesterolaemia?

- 1- Bezafibrate
- 2- Ezetimibe
- 3- No treatment required
- 4- Rosuvastatin 40 mg daily
- 5- Simvastatin 20 mg daily

Answer & Comments

Answer: 2- Ezetimibe

This patient has ischaemic heart disease and type 2 diabetes mellitus and so should be receiving a statin as his cholesterol is also elevated.

He has been intolerant of simvastatin with myalgia and raised liver function tests. The options are to consider an alternative statin or to choose a different lipid-lowering agent.

In young patients with risk factors no other lipid lowering therapy can compare with the evidence base for survival benefit from statins. Consideration should be given to using an alternative statin if possible.

Myalgia is a side effect of all statins but the incidence is probably less with rosuvastatin and pravastatin. Starting at a low dose and gradually titrating up can also minimise the risk of side effects: for example, start at 5 mg of rosuvastatin.

If starting another statin, cautious monitoring of LFTs should be performed. If there is a history of statin-related hepatitis or

rhabdomyolysis, statins should generally be avoided in the future if possible.

Consequently ezetimibe would be the most appropriate agent that would be expected to reduce cholesterol concentrations by 25%. It acts to prevent the absorption of cholesterol and is absorbed very little itself so consequently has few side effects.

Fibrates are particularly useful for hypertriglyceridaemia, but can also cause myalgia, particularly if used in combination with a statin.

Reference:

Armitage J. *The safety of statins in clinical practice. Lancet 2007; 370: 1781-90.*

Eckel RH. *Approach to the patient who is intolerant of statin therapy. J Clin Endocrinol Metab 95: 2015-2022, 2010*

[Q: 2295] OnExamination 2012 - Endocrinology

A 16-year-old female with Addison's disease is intolerant of her hydrocortisone treatment which she takes at a dose of 20 mg in the morning and 10 mg in the evening.

Which of the following doses of prednisolone would provide an equivalent daily dose to her hydrocortisone?

- 1- 5 mg
- 2- 7.5 mg
- 3- 10 mg
- 4- 12.5 mg
- 5- 15 mg

Answer & Comments

Answer: 2- 7.5 mg

The equivalent ratio of prednisolone to hydrocortisone is approximately 1:4.

For dexamethasone to hydrocortisone the ratio is roughly 1:24.

Glucocorticoid strengths

[Q: 2296] OnExamination 2012 - Endocrinology

A 40-year-old female with no prior history of thyroid disease presents with a five day history of an acutely painful, left-sided goitre. Clinically she appeared euthyroid, and was afebrile.

Investigations revealed the following:

Haemoglobin 13.0 g/dL (11.5-16.5)

White cell count $7.0 \times 10^9/L$ (4-11 $\times 10^9$)

Platelet count 200×10^9 (150-400 $\times 10^9$)

What is the most likely diagnosis?

- 1- De Quervain's thyroiditis
- 2- Haemorrhage into a cyst
- 3- Hashimoto's thyroiditis
- 4- Staphylococcal abscess
- 5- Thyroid carcinoma

Answer & Comments

Answer: 2- Haemorrhage into a cyst

The left side of this patient's goitre becomes acutely swollen with no other signs and FBC is normal which suggests acute haemorrhage into a cyst.

Thyroid cancer is usually painless.

De Quervain's thyroiditis is a diffusely tender goitre typically with systemic features such as weight loss, pyrexia and a raised erythrocyte sedimentation rate (ESR).

[Q: 2297] OnExamination 2012 - Endocrinology

Which of the following concerning diabetic retinopathy is correct?

- 1- Improved glycaemic control is more effective than hypertensive control in reducing progression of disease.
- 2- Is unusual in patients with type 2 diabetes

- 3- Normal visual acuity is seen in proliferative retinopathy.
- 4- Progression may be reduced with statin therapy
- 5- Soft exudates are a feature of background retinopathy.

Answer & Comments

Answer: 3- Normal visual acuity is seen in proliferative retinopathy.

Diabetic retinopathy occurs in both type 1 and 2 DM and may be a presenting feature in type 2 as the condition may have existed for many years prior to diagnosis.

Progression may be slowed with improved glycaemic and hypertensive control but the latter has been shown to be more effective at reducing progression (UKPDS).

There are no data at present to suggest that statin therapy reduces disease progression.

Soft exudates are a feature of pre-proliferative Rn and despite quite marked new vessel disease the visual acuity may be normal.

[Q: 2298] OnExamination 2012 - Endocrinology

A 30-year-old lady with longstanding type 1 diabetes presents with a three month history of pain and stiffness of the right shoulder.

Passive and active movements of the shoulder are equally restricted.

What is the most likely diagnosis?

- 1- Adhesive capsulitis
- 2- Calcific tendinitis
- 3- Osteoarthritis
- 4- Pyrophosphate arthropathy (pseudogout)
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 1- Adhesive capsulitis

Adhesive capsulitis (frozen shoulder) is strongly associated with diabetes with as many as 40% of patients developing this problem at some stage.

The restricted active and passive movements confirm that this patient's problems are either capsular or articular in origin rather than periarticular tendon problems where active movements are generally more restricted than passive movements.

The shoulder joint is rarely affected by primary osteoarthritis.

[Q: 2299] OnExamination 2012 - Endocrinology

A 35-year-old female is found to have a solitary mass on the chest x ray.

Biopsy confirms this to be a carcinoid tumour of the lung.

Which of the following are likely to be associated with this lesion?

- 1- Carcinoid syndrome
- 2- Cushing's syndrome
- 3- Hyponatraemia
- 4- Pellagra
- 5- Pulmonary hypertension

Answer & Comments

Answer: 2- Cushing's syndrome

Carcinoid tumours of the foregut (such as lung), unlike tumours of the midgut, are not associated with carcinoid syndrome, but may secrete corticotropin-releasing hormone/adrenocorticotrophic hormone (CRF/ACTH) resulting in ectopic Cushing's syndrome.

Other associated conditions where foregut carcinoid tumours are found in the pancreas

are associated with Zollinger-Ellison syndrome and VIPoma.

A bronchial carcinoid tumour has rarely been reported in association with acromegaly (ectopic growth hormone-releasing hormone [GHRH]).

They may also be found in association with multiple endocrine neoplasia (MEN) type 1 where pancreatic neuroendocrine tumours predominate.

[Q: 2300] OnExamination 2012 - Endocrinology

Which of the following doses of prednisolone is equivalent in its glucocorticoid potency to 20mg of hydrocortisone?

- 1- 2 mg
- 2- 5 mg
- 3- 10 mg
- 4- 15 mg
- 5- 20 mg

Answer & Comments

Answer: 2- 5 mg

It is important to know the relative potencies of the glucocorticoids.

Dexamethasone for instance is roughly 30 times more potent than hydrocortisone.

[Q: 2301] OnExamination 2012 - Endocrinology

A 20-year-old male is referred with hypogonadotrophic hypogonadism. He also gives a history of an inability to smell.

Which of the following tests would assist in the diagnosis of his condition?

- 1- Enzyme linked immunosorbent assay (ELISA)
- 2- Fluorescent in situ hybridisation (FISH)
- 3- Northern blot

4- Southern blot

5- Western blot

Answer & Comments

Answer: 2- Fluorescent in situ hybridisation (FISH)

Kallman's syndrome may arise due to abnormalities of the KAL-1 or KAL-2 gene (encoding anosmin-1 and FGF-1).

Whilst the majority of cases are sporadic, perhaps up to 50% of cases are due to genetic inheritance.

Kallman's presents with hypothalamic gonadotrophin releasing hormone deficiency and deficient olfactory sense - hyposmia or anosmia.

FISH, using a specific chromosomal probe, is currently the best means of a genetic diagnosis of this condition.

[Q: 2302] OnExamination 2012 - Endocrinology

Oral therapy with which of the following may cause galactorrhoea?

- 1- Bromocriptine
- 2- Cabergoline
- 3- Cimetidine
- 4- Domperidone
- 5- Spironolactone

Answer & Comments

Answer: 4- Domperidone

Domperidone is a dopamine antagonist producing large rises in prolactin concentrations.

Spironolactone has no effect on prolactin and cimetidine produces hyperprolactinaemia only when given intravenously.

Both bromocriptine and cabergoline are dopamine agonists and reduce prolactin.

[Q: 2303] OnExamination 2012 - Endocrinology

A 48-year-old man returns from his job running a bar in Tenerife for a holiday to the United Kingdom.

He has been suffering increased bony aches and pains, particularly in his knees over the past few weeks and admits to problems in his relationship over the past year or two due to failure to 'perform in bed'.

On examination he looks tanned, his BP is 152/90 mmHg, pulse is 75 and regular and he has a BMI of 29. There are signs of chronic liver disease.

Investigations show:

Haemoglobin 16.7 g/dl(13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $298 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 90 U/l (5-40)

Fasting glucose 8.4 mmol/l (<7.0)

Ferritin 640 mcg/l (20-60)

Which of the following is the most likely unifying diagnosis?

- 1- Alcoholic liver disease
- 2- Haemochromatosis
- 3- Non-alcoholic steatohepatitis (NASH)
- 4- Type 2 diabetes
- 5- Wilson's disease

Answer & Comments

Answer: 2- Haemochromatosis

Alcoholic liver disease may result in many of the features seen, including elevation in

ferritin, but the constellation of features is more consistent with haemochromatosis.

NASH may also produce an elevation in ferritin and features of cirrhosis, but would be unlikely to produce pigmentation.

Wilson's presents at an earlier age and isolated type 2 diabetes would not ordinarily be expected to be associated with features of chronic liver disease.

[Q: 2304] OnExamination 2012 - Endocrinology

A 35-year-old man presents to the dermatology clinic with a strange rash which affects the dorsum of his hands and feet and the extensor surface of his arms. He has no past medical history of note.

On examination his BP is 122/72 mmHg, pulse is 70 and regular. He has a number of lesions, formed by rings of papules, about 1-5 cm in diameter. The centres of these lesions look depressed, with slightly increased pigmentation, but the overlying skin is normal.

Investigations show:

Haemoglobin 13.3 g/dl(13.5-17.7)

White cell count $5.6 \times 10^9/L$ (4-11)

Platelets $199 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 92 $\mu\text{mol/l}$ (79-118)

ESR 12 mm/hr(<10)

Which of the following is the most likely diagnosis?

- 1- Erythema multiforme
- 2- Erythema nodosum
- 3- Granuloma annulare
- 4- Lichen planus
- 5- Psoriasis

Answer & Comments

Answer: 3- Granuloma annulare

The clinical scenario described is not typical of any of the other options given:

Erythema multiforme is described usually as multiple target lesions

Erythema nodosum as raised red papules on the shins

Lichen planus often associated with changes within the buccal mucosa, and

Psoriasis associated with scaling lesions.

[Q: 2305] OnExamination 2012 - Endocrinology

A 39-year-old woman presents with pain and tenderness over the anterior neck, agitation and palpitations. She has also had flu-like symptoms and generalised aches and pains over the past few weeks.

On examination her BP is 135/72 mmHg, her pulse is 90 and regular. She has a fine tremor and is tender over her thyroid.

Investigations show:

Haemoglobin 11.9 g/dl(11.5-16.0)

White cell count $9.8 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 117 $\mu\text{mol/l}$ (79-118)

TSH <0.05 IU/l (0.5-4.5)

Thyroid radio-isotope scanuptake decreased

What is the most likely diagnosis?

- 1- Graves' disease
- 2- Struma ovarii
- 3- Sub-acute thyroiditis
- 4- Thyrotoxicosis factitia
- 5- Toxic multinodular goitre

Answer & Comments

Answer: 3- Sub-acute thyroiditis

Graves' disease and toxic multinodular goitre are associated with increased radio-isotope uptake, diffuse in the case of Graves' and within the multiple nodules in the case of toxic goitre.

Thyrotoxicosis factitia and struma ovarii are associated with reduced radio-isotope uptake, but those diagnoses do not fit with the clinical picture seen here.

[Q: 2306] OnExamination 2012 - Endocrinology

A 48-year-old man with a history of obesity and alcoholism comes to the endocrine clinic for assessment.

He has difficulties with hypertension for which he currently takes three agents, and diabetes which is currently managed with metformin monotherapy. On examination his BP is 160/94 mmHg. His pulse is 75 and regular.

Investigations show:

Haemoglobin 13.5 g/dl (13.5-17.7)

White cell count $8.2 \times 10^9/L$ (4-11)

Platelets $184 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 132 micromol/l (79-118)

Cortisol post low dose dexamethasone 30 nmol/l

Which of the following is the most likely diagnosis?

- 1- Conn's syndrome
- 2- Cortisol producing adrenal adenoma
- 3- Ectopic ACTH production
- 4- Pituitary adenoma
- 5- Pseudo Cushing's

Answer & Comments

Answer: 5- Pseudo Cushing's

The lower limit of detectability for cortisol is 28 nmol/l. As such a result of 30 after low dose dexamethasone suppression test is consistent with a euadrenal state.

Before the development of more effective assays, the upper limit of normal was said to be 140 nmol/l, although around 10% of patients with Cushing's have cortisol below 140.

This patient does not fit the Conn's phenotype, and the potassium of 4.8 is also high for a patient with aldosterone excess.

Given the cortisol is only just above the lower limit of detectability, all of the options for Cushing's are incorrect.

[Q: 2307] OnExamination 2012 - Endocrinology

A 16-year-old girl presents to the clinic with her mother. They are concerned as she has not yet started her periods. You take an extended history and examine her.

Which of the following would suggest delayed puberty?

- 1- Absent mood swings
- 2- Absent pubic hair by age 13
- 3- Breast development only occurring at the age of 13
- 4- Failure to begin periods by age 16
- 5- Shorter than expected height compared to her parents

Answer & Comments

Answer: 4- Failure to begin periods by age 16

Recognised signs of delayed puberty in girls include:

Absence of breast development by age 14 years

Pubic hair absent by age 14

More than five years between the start and completion of breast growth

Menarche has not occurred by age 16.

Recognised signs of delayed puberty in boys include:

No testicular enlargement by age 14 years

Pubic hair absent by age 15

More than five years between the start and completion of growth of the genitalia.

[Q: 2308] OnExamination 2012 - Endocrinology

A 33-year-old woman is currently treated with carbimazole and thyroxine in a block replace regimen for Graves' disease, and she is thinking about a decision with respect to radioiodine therapy.

Her thyroid function has been stable over the past few months and her most recent TSH is measured at 2.5 mU/l. She is concerned however that her eyes are more itchy and swollen and that she needs treatment from the ophthalmologist.

Which of the following would prompt urgent referral with respect to her thyroid eye disease?

- 1- Change in the intensity or quality of colour vision
- 2- Increased itchiness of both eyes
- 3- Intermittent diplopia
- 4- Increased light sensitivity
- 5- Orbital ache

Answer & Comments

Answer: 1- Change in the intensity or quality of colour vision

Thyroid eye disease occurs in between 25 and 50% of patients with Graves' disease.

Impaired perception of colour implies acute progressive neuropathy and as such is a consideration for urgent ophthalmological referral.

Other indications for urgent referral include

Sudden deterioration in visual acuity

Globe subluxation

Swelling of the optic disc

Corneal opacity and

An inability for the eyelids to sufficiently cover the cornea.

High dose corticosteroids are the mainstay of initial therapy for thyroid eye disease.

The role of radiotherapy remains controversial, with surgical decompression preferred by many ophthalmologists.

A. Is the correct answer, as it is an indication of acute progressive neuropathy.

B. Is incorrect because increased itchiness is a common feature of thyroid eye disease, a failure to respond to topical steroids may prompt referral.

C. Intermittent diplopia is incorrect because it is only progressive or worsening diplopia that should prompt referral.

D. Increased light sensitivity is incorrect because progressively worsening light sensitivity over one to two months prompts referral.

E. Orbital ache is incorrect because this is a common feature of thyroid eye disease, particularly in the mornings.

[Q: 2309] OnExamination 2012 - Endocrinology

A 29-year-old woman is admitted for investigation of recurrent collapses.

She says that she feels butterflies in her stomach and very faint prior to when she

collapses. On some occasions these events have been aborted by eating food. She also says that she has put on 6 kg in weight over the past few months.

On examination her BMI is 29 kg/m². Her BP is 125/75 mmHg, her pulse is 75. Physical examination is unremarkable.

Investigations show

Haemoglobin 12.4 g/dl(11.5-16.5)

White cell count 6.2 x 10⁹/L (4-11)

Platelets 280 x 10⁹/L (150-400)

Serum Sodium 143 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Fasting glucose 4.5 mmol/l (4.5-5.6)

Which of the following is the next most appropriate investigation?

- 1- 72 hour supervised fast
- 2- CT abdomen
- 3- Pancreatic USS
- 4- Proinsulin measurement
- 5- Urine sulphonylurea assay

Answer & Comments

Answer: 1- 72 hour supervised fast

This patient's history is suggestive of recurrent hypoglycaemia, but bloods taken in between attacks are entirely normal. Among the causes of recurrent hypoglycaemic episodes in seemingly healthy patients, discriminating between sulphonylurea-induced hypoglycaemia and insulinoma is extremely important due to the different management strategies. Inappropriately high serum levels of insulin and C-peptide during episodes are characteristic features of both conditions. In contrast, hypoglycaemia caused by exogenous insulin is associated with low serum C-peptide. The history of weight gain which this patient reports is supportive of increased appetite in response to hyperinsulinaemia. In

the exam you would expect the question to include a family or personal history of diabetes mellitus, or for the patient to have an occupation which allows them access to hypoglycaemics, to lead you to a diagnosis of inappropriate use of sulphonylureas.

The diagnosis of insulinoma can be difficult, as tumours can be small and may only secrete insulin episodically.

In this case the optimal investigation would be a prolonged fast, up to 72 hours, followed if necessary, by a period of supervised exercise. In the vast majority of cases this is enough to precipitate release of insulin from an insulinoma. During any period of hypoglycaemia, you should measure insulin, glucose, sulphonylureas, C-peptide, proinsulin and beta-hydroxybutyrate.

Determination of sulphonylureas in serum or urine is possible with liquid chromatography, and should be sent at the time of an episode to exclude this diagnosis. A negative sample at a time of normoglycaemia does not assist with the diagnosis, and therefore is not indicated as a first line investigation in this case where insulinoma should be suspected. Some laboratories will decline to process a sample if it was taken during a period of normoglycaemia. It should however be done if the patient suffers an episode of hypoglycaemia whilst in hospital.

No imaging technique has been shown to be sufficiently sensitive to localise insulinomas, and therefore is not the investigation of choice here.

Proinsulin is the precursor of insulin and C-peptide. Only 1-3% is secreted intact, but it has a longer half-life than insulin and can bind to the insulin receptor. Levels are elevated in insulinomas, which is most marked in the fasting state.

As an aside, in children and younger adults, the differential diagnosis of hypoglycaemia is

broader and includes a number of inherited metabolic defects.

[Q: 2310] OnExamination 2012 - Endocrinology

A 17-year-old boy has learning difficulties and is seen in the genetics clinic as his maternal uncles also had learning difficulties. Examination reveals that the patient has large ears and large testes.

What is the most likely genetic diagnosis?

- 1- 47 XYY
- 2- Acromegaly
- 3- Fragile X syndrome
- 4- Klinefelter's syndrome
- 5- Mosaic Down's syndrome

Answer & Comments

Answer: 3- Fragile X syndrome

In addition to moderate to severe mental retardation, other characteristics of individuals with fragile X syndrome may include:

- Large ears
- Macro-orchidism
- Prognathism
- Speech delays
- Prominent forehead
- Double-jointedness
- Autistic symptoms
- Occasional self-mutilation.

The face is typically long and narrow, with a high arched palate and large ears. Otitis media, strabismus, and dental problems may be present.

Other common characteristics include:

Hyperextensible joints

Hypotonia

Heart problems including mitral valve prolapse.

In males, abnormally large testes are a distinctive feature.

In young children:

Delayed motor development

Hyperactivity

Behavioural problems

Toe walking

Occasional seizures

can occur.

[Q: 2311] OnExamination 2012 - Endocrinology

A 25-year-old woman is admitted on the medical intake.

She is 10 weeks post partum and has been generally unwell for two weeks with malaise sweats and anxiety.

On examination she is haemodynamically stable, and clinically euthyroid.

TFTs show the following:

Free T₄ 33 pmol/L(9-23)

Free T₃ 8 nmol/L(3.5-6)

TSH <0.02 mU/L(0.5-5)

What is the appropriate management?

- 1- Carbimazole 40 mg/day
- 2- Lugol's iodine
- 3- Propranolol 20 mg tds
- 4- Propylthiouracil 50 mg/tds
- 5- Radioactive iodine therapy

Answer & Comments

Answer: 3- Propranolol 20 mg tds

The diagnosis here is likely to be post partum thyroiditis which tends to occur within the three months of delivery followed by a hypothyroid phase at three to six months, followed by spontaneous recovery in one third of cases. In the remaining two-thirds, a single-phase pattern or the reverse occurs.

Management is centred on symptomatic treatment using β -blockers for relief of tremor or anxiety, and observation for the development of persistent hypo- or hyperthyroidism.

Graves' disease is a less likely diagnosis based on the proximity to delivery and the absence of any other signs to suggest Graves' ophthalmopathy, goitre and bruit.

Hashitoxicosis is a possibility but is less likely than Graves'.

[Q: 2312] OnExamination 2012 - Endocrinology

A 26-year-old male body builder is referred to the clinic by his GP. He and his wife have been trying to conceive for three years. The GP found him to be azoospermic.

An MRI of the pituitary demonstrates no abnormality.

The results of his initial investigations are shown below:

TSH 3.7 pmol/l (0.5-5.0)

T₄ 11.1 pmol/l (12.5-25.0)

IGF- 116.1 nmol/l (9-36)

LH <1.0 IU/l (3.6-17.1)

FSH <1.0 IU/l (2.25-20)

Testosterone 16.0 nmol/l (9-34.7)

What is the likely diagnosis?

- 1- Anabolic steroid use
- 2- Androgen insensitivity syndrome
- 3- Kallman's syndrome
- 4- Non-functioning pituitary adenoma

5- Testicular teratoma

Answer & Comments

Answer: 1- Anabolic steroid use

The most likely diagnosis is steroid-induced hypogonadism. Body builders may be involved in the illicit use of anabolic and androgenic steroids. These results are consistent with ongoing use of androgens. The hypogonadism if persistent may be treated with human chorionic gonadotropin.

In the event of a non-functioning pituitary tumour the testosterone would be low together with the luteinising hormone (LH) and follicle-stimulating hormone (FSH) and an MRI of the pituitary would not miss this diagnosis. The growth hormone axis would also be likely to be suppressed, and a low IGF-1 would result.

In the event of androgen insensitivity the patient may appear phenotypically female.

One would expect a low testosterone in isolated gonadotrophin deficiency.

Kallman's syndrome results in hypogonadotrophic hypogonadism.

A teratoma is unlikely to cause hypogonadotrophic hypogonadism.

[Q: 2313] OnExamination 2012 - Endocrinology

Which of the following statements regarding individuals with porphobilinogen (PBG) deaminase deficiency is correct?

- 1- Excrete faecal PBG between acute attacks
- 2- Experience significant photosensitivity
- 3- Have a greater than 75% chance of remaining asymptomatic throughout their lives
- 4- Have markedly increased faecal protoporphyrin excretion during attacks

5- When manifesting clinical disease generally present within the first decade of life

Answer & Comments

Answer: 3- Have a greater than 75% chance of remaining asymptomatic throughout their lives

Porphobilinogen (PBG) deaminase deficiency is the basis of acute intermittent porphyria (AIP).

Photosensitivity is unusual in AIP and patients excrete urinary PBG between and during acute attacks.

Faecal porphyrin excretion is usually normal or slightly increased.

Clinical disease is manifested more frequently in females, and only rarely presents before puberty: 90% of affected individuals remain asymptomatic throughout their lives.

[Q: 2314] OnExamination 2012 - Endocrinology

A 45-year-old obese male with a two year history of type 2 diabetes has recently commenced metformin at a dose of 500 mg twice daily.

However, he re-attends clinic and reports numerous gastrointestinal side effects including bloating and flatulence. He is keen to stop metformin and commence an alternative agent.

Which of the following drugs is the most appropriate choice?

- 1- Acarbose
- 2- Exenatide
- 3- Insulin
- 4- Pioglitazone
- 5- Repaglinide

Answer & Comments

Answer: 4- Pioglitazone

Treatment options for type 2 diabetes are complex.

Metformin is indicated in patients who are overweight or obese, whose blood glucose is inadequately controlled with lifestyle interventions. It can also be first-line in patients who are not overweight. If blood glucose control remains inadequate another oral hypoglycaemia should be added, usually an sulphonylurea. Gradual increases in the dose of metformin reduces the risk of side effects, and modified release preparations reduce the risk further. The dose should be reviewed if the creatinine excess 130mmol/L or the eGFR is below 45, and stopped with a creatinine over 150mmol/L or eGFR below 30.

Sulphonylureas can be used as first-line if the patient is not overweight, metformin is contraindicated or not tolerated, or a rapid response to therapy is required. Patients should be warned of the risk of hypoglycaemia.

Thiazolidinediones are used in patients who have inadequate glycaemic control with a combination of metformin and sulphonylurea, in whom there are concerns regarding insulin therapy (e.g. where there is likely to be significant insulin resistance). They can be associated with significant oedema and weight gain, and should not be used in those with heart failure or those at high risk of fracture. This class of drugs interacts with PPAR γ receptors and can significantly reduce insulin resistance. They can be used in combination with sulphonylureas for patients who are intolerant of metformin.

Acarbose is only indicated in those patients unable to use other oral glucose-lowering medications.

Exenatide can be used just prior to insulin in patients with a BMI of over 35.

Repaglinide is an insulin secretagogue, which can be used if other classes of treatment fail.

Insulin is typically only started in patients who have failed an adequate trial of oral glucose-lowering treatments.

[Q: 2315] OnExamination 2012 - Endocrinology

A 26-year-old man presented with polydipsia and polyuria for the last two years.

Investigations reveal:

Serum Urea 8.4 mmol/L (2.5-7.5)

Serum Creatinine 108 mol/L (60-110)

Serum corrected Calcium 2.82 mmol/L (2.2-2.6)

Serum phosphate 0.73 mmol/L (0.8-1.4)

Plasma parathyroid hormone 6.8 pmol/L (0.9-5.4)

Which of the following is directly responsible for his increased intestinal calcium reabsorption?

- 1- 1,25 Dihydroxy vitamin D
- 2- 25 Hydroxy vitamin D
- 3- Calcitonin
- 4- Hypophosphataemia
- 5- Parathyroid hormone

Answer & Comments

Answer: 1- 1,25 Dihydroxy vitamin D

This patient has hypercalcaemia due to hyperparathyroidism.

However, the intestinal absorption of calcium is facilitated by 1,25 dihydroxy-vitamin D, which stimulates the microvillous membrane of the enterocyte to synthesise the calcium-binding carrier protein necessary for active calcium ion absorption .

[Q: 2316] OnExamination 2012 - Endocrinology

A 26-year-old man presented with polydipsia and polyuria for the last two years.

Investigations showed:

Serum Urea 8.4 mmol/L(2.5-7.5)

Serum Creatinine 108 µmol/L(60-110)

Serum corrected Calcium 2.82 mmol/L(2.2-2.6)

Serum phosphate 0.73 mmol/L(0.8-1.4)

Plasma parathyroid hormone 6.8 pmol/L(0.9-5.4)

Which of the following mechanisms is responsible for the hypophosphataemia observed?

- 1- Increased deposition of calcium phosphate crystals in soft tissues
- 2- Increased gastrointestinal secretion of phosphates
- 3- Increased renal tubular secretion of phosphates
- 4- Reduced gastrointestinal absorption of phosphates
- 5- Reduced renal tubular reabsorption of phosphates

Answer & Comments

Answer: 5- Reduced renal tubular reabsorption of phosphates

This patient has mild hypercalcaemia, elevated PTH and low phosphate indicating primary hyperparathyroidism.

The hypophosphataemia is due to the reduced renal reabsorption of phosphate.

[Q: 2317] OnExamination 2012 - Endocrinology

Which of the following is a metabolic effect of exenatide?

- 1- Accelerates gastric emptying

- 2- Improves insulin sensitivity
- 3- Inhibits insulin release
- 4- Promotes gluconeogenesis by the liver
- 5- Suppresses appetite

Answer & Comments

Answer: 5- Suppresses appetite

Exenatide mimics the effect of the gut hormone GLP-1 (glucagon-like peptide 1) and has favourable effects on the metabolism of individuals with diabetes mellitus.

Exenatide suppresses appetite, inhibits glucose production in the liver, slows gastric emptying and stimulates insulin release. It does not increase insulin sensitivity which is achieved by drugs such as metformin and the glitazones.

In summary exenatide has the following metabolic effects

Stimulates insulin release

Inhibits glucose production by the liver

Slows gastric emptying

Suppresses appetite.

[Q: 2318] OnExamination 2012 - Endocrinology

A 65-year-old male undergoes a CT headscan after falling from a ladder and knocking himself out.

The CT report reveals that he has a 1.3 cm macroadenoma which does not encroach upon the optic chiasm. On recovery he is perfectly well and examination is entirely normal, including full visual fields to confrontation.

Investigations reveal normal thyroid function, testosterone concentration and short Synacthen test results. His prolactin concentration is 550 mU/L (50-450).

What is the most appropriate treatment for this patient?

- 1- Advise trans-sphenoidal hypophysectomy
- 2- Arrange pituitary radiotherapy
- 3- Arrange serial imaging
- 4- No further investigation/treatment required
- 5- Treat with cabergoline

Answer & Comments

Answer: 3- Arrange serial imaging

This man has a co-incidentally detected pituitary macroadenoma.

The small elevation in prolactin probably reflects stalk compression and does not indicate that this is a prolactinoma. In macroprolactinomas, the prolactin concentration is greater than 2000 mU/L.

In this man's case, with no visual field defects and the tumour being distant from the chiasm, the most appropriate treatment would be observation with serial scanning to assess for any change in size that would then merit surgical intervention.

However, this man who is eupituitary may never encounter any growth in this co-incidentally detected non-functional pituitary tumour.

[Q: 2319] OnExamination 2012 - Endocrinology

A 17-year-old female attends clinic complaining of hirsutism and oligomenorrhoea.

Which of the following would be most suggestive of a diagnosis of polycystic ovarian syndrome (PCOs)?

- 1- Increased androstenedione concentration
- 2- Increased FSH concentration
- 3- Increased insulin concentration

- 4- Increased prolactin concentration
- 5- Increased sex hormone binding globulin (SHBG) concentration

Answer & Comments

Answer: 1- Increased androstenedione concentration

PCOs is associated with a raised luteinising hormone:follicle-stimulating hormone (LH:FSH) ratio, with insulin resistance and hyperandrogenism as evidenced by raised androstenedione and slightly raised testosterone.

Elevated prolactin concentrations although a feature of PCOs are not specific of the diagnosis and may suggest microprolactinoma.

Although insulin resistance is a feature of PCOs, a raised insulin concentration is rather irrelevant and no one would measure this in clinical practice. It is often elevated in association with testosterone secreting tumours.

[Q: 2320] OnExamination 2012 - Endocrinology

A 17-year-old girl complains of feeling tired and lethargic for the last six months. She also has generalised abdominal discomfort and constipation. She denies depression but her performance at school has deteriorated this year.

Examination shows a pale and thin young woman. Her blood pressure is 110/60 mmHg.

Hb 13.4 g/l (11.5-16.5)

WBC $4.8 \times 10^9/L$ (4-11)

Platelet $290 \times 10^9/L$ (150-400)

ESR 37mm/hr(0-20)

Na 131mM(135-144)

K 2.7mM(3.4-4.5)

Urea 3.0mM(3-7)

Creat 90mM(50 - 100)

Bicarbonate 35mM(20-28)

Alkaline phosphatase 90iu/l (50-110)

Bilirubin 12(0-17)

AST 30 iu/l (5-40)

Albumin 36g/l (33-44)

CXR normal

Which of the following is the most likely underlying diagnosis?

- 1- Addison's disease
- 2- Anorexia nervosa
- 3- Conn's syndrome
- 4- Cushing's syndrome
- 5- Pheochromocytoma

Answer & Comments

Answer: 2- Anorexia nervosa

This patient has anorexia nervosa with self-induced vomiting, which would explain the low Na, K and alkalosis.

Addison's disease causes hyponatraemia and hyperkalaemic acidosis, whilst Cushing's disease causes hypokalaemic alkalosis. The clinical presentation does not fit with the latter.

Conn's syndrome (adrenal adenoma) is associated with hypertension and hypokalaemia.

[Q: 2321] OnExamination 2012 - Endocrinology

In the treatment of osteoporosis, which of the following best describes the drug raloxifene?

- 1- A bisphosphonate
- 2- A calcium receptor modulator
- 3- A PTH receptor agonist
- 4- A selective oestrogen receptor modulator
- 5- An oestrogen

Answer & Comments

Answer: 4- A selective oestrogen receptor modulator

Raloxifene is the first of the so-called selective oestrogen receptor modulators.

There are fundamentally two types of oestrogen receptor, alpha and beta, distributed at locations such as breast, uterus, bone and in the vasculature.

Raloxifene acts as an oestrogen agonist at some sites, for example, bone to increase mineralisation, but acts as an antagonist at other sites, for example, uterus/breast (preventing endometrial/breast hyperplasia).

[Q: 2322] OnExamination 2012 - Endocrinology

A 48-year-old man presented to his general practitioner with a two year history of generalised headaches.

He had also noticed a recent increase in his shoe size. He denied any visual symptoms. He has no significant past medical history of note and is not on any regular medications.

On examination, he had coarse facial features with prognathism. His visual fields were full to confrontation.

Investigations showed:

Insulin-like growth factor - 143 nmol/L(5.6-23.3)

Plasma prolactin 868 mU/L(<360)

MRI scan suggests a pituitary adenoma measuring 8 mm without any extrasellar extension.

What is the most appropriate treatment for this man?

- 1- Bromocriptine
- 2- Cabergoline
- 3- Octreotide
- 4- Pegvisomant

5- Pituitary surgery

Answer & Comments

Answer: 5- Pituitary surgery

Surgery is the most appropriate primary management for acromegaly as demonstrated clinically and supported by the biochemistry in this case.

[Q: 2323] OnExamination 2012 - Endocrinology

A 75-year-old man is admitted with a blood sugar of 40 mmol/l and lobar pneumonia and dies despite treatment.

Post-mortem examination reports the presence of amyloid polypeptide on pancreatic histology.

Which of the following would be suggested by this?

- 1- That he has chronic pancreatitis as a cause of diabetes
- 2- That he has diabetes secondary to amyloidosis
- 3- That he has type 1 diabetes
- 4- That he has type 2 diabetes
- 5- This can be a non-specific finding

Answer & Comments

Answer: 4- That he has type 2 diabetes

The presence of amyloid polypeptide on pancreatic histology is highly suggestive of type 2 diabetes.

Although the primary defect in type 2 diabetes is insulin resistance, loss of insulin secretory function over time does occur in patients with type 2 diabetes and reduction in beta cell mass due to amyloid deposition may partly account for this.

[Q: 2324] OnExamination 2012 -

Endocrinology

You are asked to review a 72-year-old man with chronic lung disease on the respiratory ward. He was admitted a few days earlier with left lower lobe pneumonia but remains confused.

On examination his temperature is 37.2°C, BP is 148/72 mmHg, and pulse is 80 and regular. He does not look fluid overloaded and has some residual signs at his left base.

Investigations show:

Haemoglobin 13.1 g/dl (13.5-17.7)

White cell count $12.3 \times 10^9/L$ (4-11)

Platelets $208 \times 10^9/L$ (150-400)

Sodium 122 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (79-118)

The nurses have tried fluid restricting him but his sodium remains stubbornly low.

Which of the following is the management of choice?

- 1- Further fluid restriction
- 2- Intranasal vasopressin
- 3- IV 1.8% sodium chloride
- 4- Oral demeclocycline
- 5- Oral furosemide

Answer & Comments

Answer: 4- Oral demeclocycline

Given that fluid restriction has failed already and the patient is still confused, further fluid restriction seems inappropriate.

Vasopressin is a treatment for diabetes insipidus, and 1.8% saline can be used in an emergency situation as a treatment for syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Lithium induces nephrogenic DI but is not an appropriate therapy for SIADH.

[Q: 2325] OnExamination 2012 - Endocrinology

A 25-year-old woman comes to the GP surgery a few weeks after the birth of her first child. Unfortunately she suffered a postpartum haemorrhage and required a three unit blood transfusion.

Over the past few weeks she has been feeling increasingly tired but puts this down to post pregnancy blues. She tells you that she seems to be losing her hair.

On examination her BP is 100/60 mmHg, pulse is 62 and regular.

Investigations show:

Haemoglobin 10.5 g/dl (11.5-16.0)

White cell count $7.3 \times 10^9/L$ (4-11)

Platelets $207 \times 10^9/L$ (150-400)

Sodium 130 mmol/l (135-146)

Potassium 5.1 mmol/l (3.5-5)

Creatinine 122 $\mu\text{mol/l}$ (79-118)

TSH 0.3 IU/l (0.5-4.5)

Which of the following is the most likely diagnosis?

- 1- Addison's disease
- 2- Graves' disease
- 3- Hashimoto's thyroiditis
- 4- Post-partum thyroiditis
- 5- Sheehan's syndrome

Answer & Comments

Answer: 5- Sheehan's syndrome

We are given the low thyroid-stimulating hormone (TSH) as well as electrolyte disturbance, showing that this is panhypopituitarism leading to adrenal insufficiency, rather than Addison's.

Graves' is associated with thyrotoxicosis, and we have no evidence of that here apart from the low TSH, which is in fact consistent with

pituitary failure rather than elevated thyroxine leading to negative feedback on TSH production.

Hashimoto's and postpartum thyroiditis would not be associated with the electrolyte disturbance seen here.

[Q: 2326] OnExamination 2012 - Endocrinology

A 49-year-old man is referred to the endocrinology clinic for review because he has noticed changes in his facial appearance. He also suffers from hypertension and has problems with excessive sweating.

On examination his BP is 156/95 mmHg. You notice that he has prognathism and acne.

Which of the following initial screening tests is most reasonable for acromegaly?

- 1- Growth hormone
- 2- IGF-1
- 3- Insulin suppression test
- 4- MRI pituitary
- 5- Visual field testing

Answer & Comments

Answer: 2- IGF-1

Growth hormone is incorrect because release of growth hormone is pulsatile, as such according to the time of day when it is measured the chances of a false negative result may be increased.

Glucose tolerance test rather than insulin tolerance testing is used for diagnosis of acromegaly, with failure to suppress growth hormone levels indicating a positive result.

MRI pituitary and visual field testing are clearly not initial tests, but part of pre-operative work up.

[Q: 2327] OnExamination 2012 - Endocrinology

You are asked to see a 62-year-old woman on the surgical ward a few hours after she has undergone a thyroidectomy. The nurses are concerned because she tells them she feels unwell.

Which of the following symptoms would be most consistent with hypocalcaemia as a result of inadvertent parathyroidectomy?

- 1- Hyperventilation
- 2- Nausea
- 3- Paraesthesia
- 4- Polyuria
- 5- Thirst

Answer & Comments

Answer: 3- Paraesthesia

Symptoms of hypocalcaemia include

Paraesthesia (usually fingers, toes and around mouth)

Tetany

Carpopedal spasm (wrist flexion and fingers drawn together)

Muscle cramps.

With worsening hypocalcaemia,

Long QT

Bronchospasm

Laryngospasm and

Seizures

are all possible.

Nausea, polyuria and thirst are all possible symptoms associated with hypercalcaemia.

Whilst hyperventilation may result in a reduction in ionised calcium, and hence paraesthesia, it is not per se a cause of low calcium levels.

[Q: 2328] OnExamination 2012 -
Endocrinology

A 64-year-old man comes to the clinic for review of his type 2 diabetes. He is currently managed with metformin 1 g BD and sitagliptin 100 mg.

On examination his blood pressure is 156/90 mmHg, his pulse is 80 and his BMI is 30. Of note on routine investigations is a raised triglyceride level of 3.1 mmol/l (0.7-2.1).

Which of the following is associated with elevated triglycerides?

- 1- Decreased hepatic fat
- 2- Increased insulin resistance
- 3- Increased subcutaneous fat
- 4- Reduced cardiovascular risk
- 5- Reduced insulin requirements

Answer & Comments

Answer: 2- Increased insulin resistance

The answer is option B, increased insulin resistance.

Elevated triglycerides are associated with disordered energy handling by adipocytes. This is not only manifest by raised lipid levels, but also by an inability of cells to take up glucose properly, leading to increased insulin resistance. This leads to increased insulin requirements.

This increased insulin resistance is associated with a constellation of other cardiovascular risk factors including hypertension, hypercoagulability, and low HDL cholesterol.

Hepatic fat content is a determinant of postprandial triglyceride levels in type 2 diabetes, and increased hepatic fat is associated with elevated triglyceride levels.

A statement by the American Heart Association in 2011 showed that subcutaneous fat may serve as a protective factor with regard to the metabolic

consequences of obesity, and a relative paucity (ie, lipodystrophy) is associated with hypertriglyceridemia.

[Q: 2329] OnExamination 2012 -
Endocrinology

A 62-year-old man comes to the clinic for review of his diabetes.

Current medication includes metformin 1 g BD and 40 units BD mixed insulin. Other medication includes candesartan 16 mg and amlodipine 10 mg.

On examination his BP is 155/84 mmHg, his pulse is 70 and regular. His BMI is 31.

Investigations show:

Haemoglobin 12.0 g/dl(13.5-17.7)

White cells $7.8 \times 10^9/L$ (4-11)

Platelet $192 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 5.1 mmol/l (3.5-5)

Creatinine 127 micromol/l (79-118)

Alanine aminotransferase 110 U/l (5-40)

Alkaline phosphatase 94 U/l (39-117)

HDL cholesterol 0.7 mmol/l (0.8-1.8)

LDL cholesterol 2.4 mmol/l (<4.0)

Triglycerides 3.2 mmol/l (0.7-2.1)

Which of the following conditions is associated with this clinical picture?

- 1- Acute pancreatitis
- 2- Autoimmune hepatitis
- 3- Chronic pancreatitis
- 4- Non-alcoholic steatohepatitis (NASH)
- 5- Unpredictable hypoglycaemia

Answer & Comments

Answer: 4- Non-alcoholic steatohepatitis (NASH)

NASH - hypertriglyceridaemia and raised transaminases are suggestive of increased hepatic fat. Over time it is thought that around 10% of patients who have non-alcoholic steatosis progress to chronic inflammation and NASH.

A proportion of these may go on to develop cirrhosis and end stage liver disease, and a smaller proportion of these go on to get hepatocellular carcinoma.

Key to the management of NASH is weight loss, which is associated with a reduction in lipid overflow.

NB - candesartan can also cause elevated liver enzymes.

[Q: 2330] OnExamination 2012 - Endocrinology

A 51-year-old woman presents to the clinic complaining of thirst and lethargy. She has noticed her symptoms increasing over the past few months and is worried that she may be suffering from diabetes mellitus.

On examination her BP is 122/72 mmHg, her pulse is 72 and regular, her BMI is 21. General physical examination is unremarkable.

Investigations show

Haemoglobin 12.5 g/dl(11.5-16.5)

White cells $8.8 \times 10^9/L$ (4-11)

Platelets $193 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Calcium 2.81 mmol/l (2.20-2.67)

Phosphate 0.7 mmol/l (0.8-1.5)

Glucose 5.1 mmol/l (<7.0)

Which of the following is the most likely diagnosis?

- 1- Familial hypercalcaemic hypocalciuria
- 2- Hypercalcaemia of malignancy

3- Primary hyperparathyroidism

4- Secondary hyperparathyroidism

5- Tertiary hyperparathyroidism

Answer & Comments

Answer: 3- Primary hyperparathyroidism

The most likely diagnosis is primary hyperparathyroidism.

She has only mildly elevated serum calcium, and given that her phosphate is low and there is no evidence of renal impairment, primary hyperparathyroidism is the most likely diagnosis.

Familial hypercalcaemic hypocalciuria may present with a similar blood picture, but is very rare. Parathyroid hormone (PTH) is likely to be normal or elevated.

Management of the condition depends on

The degree of calcium elevation

Symptoms

Bone mineral density.

[Q: 2331] OnExamination 2012 - Endocrinology

A 45-year-old woman comes to the clinic complaining of tiredness and requests a general check up.

She has found it difficult to maintain a stable weight over the past couple of years, and has only achieved this by quite severe dieting. On examination her BP is 145/72 mmHg, her pulse is 62, and her BMI is 27 kg/m².

Investigations show

Haemoglobin 13.1 g/dl(11.5-16.5)

White cell count $7.8 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

TSH 11.1 mU/l (0.5-5.0)

Free thyroxine 10.2 pmol/l (10-25)

LDL cholesterol 4.3 mmol/l (<4.0)

Triglycerides 3.1 mmol/l (0.5-1.7)

Which of the following is the most appropriate treatment?

- 1- Atorvastatin 10 mg
- 2- No therapy
- 3- Simvastatin 10 mg
- 4- Thyroxine 50 mcg
- 5- Thyroxine 100 mcg

Answer & Comments

Answer: 4- Thyroxine 50 mcg

This patient has subclinical hypothyroidism, and given that her TSH is more than 10, she has a risk of progression to clinical hypothyroidism of up to 20% per year. Her lipid abnormalities are also significant, and driven by the lack of T4; as such, low dose thyroxine is a better treatment than starting statin therapy.

Where the TSH is outside the normal range but less than 10, the risk of progression to clinical hypothyroidism is lower, and the lipid abnormalities are less marked.

[Q: 2332] OnExamination 2012 - Endocrinology

A 16-year-old female weighing 80 kg presents with a six month history of excessive weight gain and weakness.

On examination she had central obesity with abdominal striae, a blood pressure of 178/96 mmHg and proximal muscle weakness.

Urinalysis showed glucose ++.

What is the most appropriate initial investigation for this patient?

- 1- 1 mg overnight dexamethasone suppression test
- 2- 9 am plasma cortisol concentration
- 3- 24 hour urinary free cortisol concentration
- 4- ACTH concentration
- 5- A short Synacthen test

Answer & Comments

Answer: 3- 24 hour urinary free cortisol concentration

This patient is likely to have Cushing's syndrome.

It is a difficult choice between an overnight dexamethasone suppression test and the urine free cortisol estimation but on balance, the simplest test would be urine free cortisol assessment.

In the dexamethasone suppression test 25-30 micrograms/kg is used (maximum 2 mg), so the amount suggested in this question is too small.

9 am cortisol and adrenocorticotrophic hormone (ACTH) concentrations will not confirm the diagnosis.

A short Synacthen test is used to confirm hypoadrenalism.

[Q: 2333] OnExamination 2012 - Endocrinology

A 53-year-old female with surgically treated acromegaly is receiving treatment with octreotide therapy due to persistently elevated growth hormone concentrations following surgery.

What is the mechanism of action of octreotide?

- 1- Inhibition growth hormone receptor
- 2- Inhibition of dopamine D2 receptor
- 3- Inhibition of GHRH receptor
- 4- Inhibition of IGF-1 receptor

5- Stimulation of the somatostatin receptor

Answer & Comments

Answer: 5- Stimulation of the somatostatin receptor

Octreotide is a somatostatin analogue and directly inhibits growth hormone secretion through interaction with somatostatin receptors.

It is also used in the treatment of neuroendocrine tumours such as carcinoid tumours again through interaction with somatostatin receptors.

[Q: 2334] OnExamination 2012 - Endocrinology

A 72-year-old woman with a history of type 2 diabetes for the past eight years is currently managed with oral metformin and gliclazide. She had an inferior myocardial infarction some four years earlier.

On examination her BP is 142/83 mmHg, pulse is 67 and regular. Her chest is clear and there is no ankle swelling.

Which of the following findings on laboratory investigation or clinical examination would be most associated with increased cardiovascular risk?

- 1- HbA1c 7.4% (<5.5)
- 2- HDL cholesterol 2.3 mmol/l (1.0-2.3)
- 3- LDL cholesterol 2.4 mmol/l (<4.0)
- 4- Triglyceride 2.8 mmol/l (0.5-1.7)
- 5- Urate 0.4 mmol/l (0.18-0.42)

Answer & Comments

Answer: 4- Triglyceride 2.8 mmol/l (0.5-1.7)

The answer is triglyceride 2.8 mmol/l.

High triglycerides and low high-density lipoprotein (HDL) cholesterol are the commonest lipid abnormality seen in type 2

diabetes, and both are associated with increased cardiovascular risk.

In total, triglycerides above 1.7 are thought to be associated with a 30% increase in relative cardiovascular risk.

An HbA1c of 7.4% would not be considered to be a very excessive cardiovascular risk indicator in a 72-year-old patient with type 2 diabetes.

The ACCORD study suggested that targeting lower HbA1c in patients with long established diabetes may be associated with increased mortality, although this effect has not been seen in other studies.

Low-density lipoprotein (LDL) cholesterol of 2.4 is only just above target.

[Q: 2335] OnExamination 2012 - Endocrinology

A 17-year-old female with type 1 diabetes, who is known to be poorly compliant with treatment, is admitted with diabetic ketoacidosis.

The respiratory rate is 41 per minute and the blood pressure 85/66 mmHg. She is confused and lethargic. An arterial blood gas shows the pH to be 7.01, and the potassium is 4.9 mmol/l.

Which condition carries the highest risk of mortality to this patient?

- 1- Cerebral oedema
- 2- Cerebrovascular accident
- 3- Myocardial infarction
- 4- Seizure
- 5- Ventricular tachycardia

Answer & Comments

Answer: 1- Cerebral oedema

The risk of mortality in some reported series of diabetic ketoacidosis (DKA) is 5%.

The incidence of cerebral oedema in paediatric patients treated for DKA is approximately 1%. The risk of cerebral oedema is highest in paediatric and adolescent patients, and is rarer in adults.

The rate of fluid, sodium and insulin replacement seems not to be related to the development of cerebral oedema, and often its development may be idiosyncratic. Thus the warning signs of cerebral oedema - headache, lethargy, confusion, reduced conscious level, incontinence, papillary changes - must be considered in this patient group.

Ventricular tachycardia is a theoretical risk in the presence of hypokalaemia, which is not present at this stage.

Seizures may occur as a consequence of the underlying cerebral oedema.

[Q: 2336] OnExamination 2012 - Endocrinology

A 26-year-old woman was being treated in the outpatient clinic for autoimmune hypothyroidism.

She was taking 150 µg of thyroxine and 200 mg of amiodarone.

Investigations reveal:

Plasma prolactin 654 mU/L(<360)

Plasma Free T₄ 24 pmol/L(10-22)

Plasma Free T₃ 5.2 pmol/L(5-10)

Plasma thyroid-stimulating hormone 68 mU/L (0.4-5)

What is the most likely explanation for her high TSH levels?

- 1- Amiodarone effect
- 2- Hyperprolactinaemia
- 3- Poor compliance with medications
- 4- Thyroid hormone resistance
- 5- TSH producing pituitary adenoma

Answer & Comments

Answer: 3- Poor compliance with medications

This young woman has a slightly elevated thyroxine (T₄) and an elevated thyroid-stimulating hormone (TSH).

The most probable explanation is poor compliance. This also explains the slightly high prolactin concentration too; a consequence of reduced dopaminergic tone on the lactotrophs.

The typical scenario is that the patients take their medication in the days before the clinic.

The most likely explanation is that thyroid hormone isn't being absorbed or even taken, (the compliance argument). Given that amiodarone has no effect on thyroid hormone absorption, it can't be the answer here.

[Q: 2337] OnExamination 2012 - Endocrinology

A 16-year-old girl is diagnosed with Turner's syndrome.

Which of the following autoimmune conditions is most commonly associated with Turner's?

- 1- Addison's disease
- 2- Autoimmune hepatitis
- 3- Hashimoto's thyroiditis
- 4- Sjogren's syndrome
- 5- Vitamin B₁₂ deficiency

Answer & Comments

Answer: 3- Hashimoto's thyroiditis

Hypothyroidism is quite common occurring in up to 24% of patients with Turner's syndrome.

It is typically autoimmune in origin - Hashimoto's thyroiditis - though the exact explanation for its high prevalence is not known.

[Q: 2338] OnExamination 2012 -
Endocrinology

A 48-year-old female with a three year history of type 2 diabetes presents at annual review. Despite optimisation of her oral hypoglycaemic therapy she has gained approximately 5 kg in weight over the last year and her HbA1c has deteriorated.

She is also treated with ramipril, bendroflumethiazide, and amlodipine, but her blood pressure remains difficult to control with a recording of 172/102 mmHg.

On examination, she has developed abdominal striae, thin skin is noticeable with bruising and she also has a proximal weakness. A diagnosis of Cushing's syndrome is suspected.

What is the most appropriate investigation for this patient?

- 1- 9 am ACTH concentration
- 2- 9 am cortisol concentration
- 3- 24 hour urine free cortisol concentration
- 4- Adrenal CT
- 5- Chest x ray

Answer & Comments

Answer: 3- 24 hour urine free cortisol concentration

Appropriate screening tests for Cushing's syndrome include a 1 mg overnight dexamethasone suppression test (1 mg dexamethasone given at 11 pm and the cortisol measured at 9 am the following morning).

A cortisol concentration less than 50 nmol/l after this test would be regarded as normal.

Another equally good and easy to perform test is a 24 hour urine collection measuring free cortisol in the urine. An elevated cortisol (usually above 250 nmol/day) suggests Cushing's syndrome.

Random cortisol or 9 am cortisol provides no diagnostic information whatsoever.

Chest x ray and adrenal CT are useful in investigating the possible cause of Cushing's syndrome.

[Q: 2339] OnExamination 2012 -
Endocrinology

In the treatment of congenital adrenal hyperplasia (CAH) which of the following statements is correct?

- 1- Efficacy of treatment is best monitored by 17-OH progesterone and androstenedione levels
- 2- Hydrocortisone may be administered once daily
- 3- Hypotension, hyperkalaemia and hyperreninaemia suggest that the dose of mineralocorticoid should be reduced
- 4- Preferred treatment in children is prednisone
- 5- Renin activity levels are of no clinical use in treatment monitoring

Answer & Comments

Answer: 1- Efficacy of treatment is best monitored by 17-OH progesterone and androstenedione levels

The treatment of CAH is the lowest dose of glucocorticoid that suppresses (not totally) adrenal androgens, whilst maintaining normal growth and weight gain. Renin activity levels can be used to monitor adequacy of mineralocorticoid and sodium replacement.

Hydrocortisone has a relatively short half life and must therefore be administered twice daily whilst the preferred mode of glucocorticoid replacement in children is hydrocortisone as it minimises growth suppression.

Over-treatment with mineralocorticoids leads to hypertension, suppressed plasma rennin activity and possibly growth retardation.

[Q: 2340] OnExamination 2012 - Endocrinology

A 55-year-old female complaining of vague tiredness is found to have a serum corrected calcium concentration of 2.9 mmol/l.

Examination was unremarkable.

Which of the following results confirms the suspected diagnosis of primary hyperparathyroidism?

- 1- High normal 1,25-dihydroxyvitamin D concentration
- 2- High normal 24 hour urinary calcium concentration
- 3- High normal plasma parathyroid hormone (PTH) concentration
- 4- Low normal plasma phosphate concentration
- 5- Low normal serum 25-hydroxyvitamin D concentration

Answer & Comments

Answer: 3- High normal plasma parathyroid hormone (PTH) concentration

A high or even normal PTH concentration in the presence of hypercalcaemia would support the diagnosis of hyperparathyroidism.

A high urinary calcium concentration may be expected as would a low plasma phosphate but neither confirm the diagnosis.

Elevated 1,25 vitamin D suggests a diagnosis of hypervitaminosis D.

[Q: 2341] OnExamination 2012 - Endocrinology

Which of the following compounds has a vasodilating effect?

- 1- Antidiuretic hormone (ADH)

2- Calcitonin gene related peptide

3- Endothelin

4- Renin

5- Somatostatin

Answer & Comments

Answer: 2- Calcitonin gene related peptide

ADH acts on the vasopressor receptors to cause vasoconstriction.

Endothelin is also a vasoconstrictor as is renin.

Somatostatin is also recognised to produce vasoconstriction of the splanchnic system.

[Q: 2342] OnExamination 2012 - Endocrinology

A 41-year-old woman presented asking for treatment to prevent osteoporosis. She was one year post-menopausal, is aware of flushes at night and has a family history of osteoporosis.

Which one of the following therapies would be most appropriate?

- 1- Calcium and vitamin D supplements
- 2- Continuous oestrogen
- 3- Cyclical etidronate and calcium
- 4- Cyclical oestrogen and progestogen
- 5- Vitamin D supplements

Answer & Comments

Answer: 4- Cyclical oestrogen and progestogen

This patient with a family history of osteoporosis is one year post-menopausal and has symptoms.

Calcium and vitamin D supplements with a good diet would be unnecessary and are unproven in this age group.

There is no suggestion that she has had a hysterectomy and so an unopposed oestrogen would be contra-indicated.

Etidronate is licensed for the prevention of further osteoporotic fractures, prophylaxis against corticosteroid induced osteoporosis and use when hormone replacement therapy (HRT) is contra-indicated.

In this patient's case, and in the absence of any specific contra-indications - thromboembolic disease, breast cancer - combined HRT would be the treatment of choice despite the recent literature indicating increased risk of vascular disease. One would use HRT in the symptomatic (menopausal symptoms) but not in the asymptomatic where possibly bisphosphonates would be preferred.

[Q: 2343] OnExamination 2012 - Endocrinology

A 33-year-old female presents with tiredness and lethargy.

Five years previously she had undergone a frontal surgery for a craniopharyngioma following presentation with amenorrhoea and headache. Post-operatively she developed seizures and was treated with sodium valproate.

She was demonstrated to be hypopituitary and receives hydrocortisone, thyroxine, oestrogen replacement therapy and desmopressin.

Which of the following investigations would you select to confirm a growth hormone deficiency (GHD)?

- 1- Clonidine test
- 2- GHRH/arginine test
- 3- IGF-1 concentration
- 4- Insulin tolerance test
- 5- L-dopa test

Answer & Comments

Answer: 2- GHRH/arginine test

This patient is more than likely to be GH deficient which would explain the lethargy but this requires confirmation before initiating treatment.

Although an insulin tolerance test is the gold standard for the diagnosis of GHD, it is contraindicated due to the epilepsy.

Therefore GHRH/arginine is regarded as a suitable alternative.

[Q: 2344] OnExamination 2012 - Endocrinology

A 72-year-old male presents with a two month history of weight loss and weakness.

Examination reveals a BMI of 24.5 kg/m² and a blood pressure of 146/90 mmHg.

Examination of the lower limbs reveals a bilateral weakness of knee extension. He is unable to rise from the squatting position. There is absence of the knee reflex but the ankle reflexes are preserved and both plantars are flexor. There are no abnormalities on sensory examination.

Which of the following tests may be diagnostic?

- 1- Oral glucose tolerance test
- 2- Thyroid function test
- 3- Urine free cortisol concentration
- 4- Vitamin B₁₂ concentration
- 5- Vitamin D concentration

Answer & Comments

Answer: 1- Oral glucose tolerance test

This patient presents with weight loss, and reduced quadriceps strength, bilaterally with absent knee reflexes. This is a typical presentation of diabetic amyotrophy.

Osteomalacia, hyperthyroidism and Cushing's would be unlikely as the proximal myopathy involves quadriceps and hamstrings and knee reflexes would be preserved.

Subacute combined degeneration of the cord does not present with such features.

[Q: 2345] OnExamination 2012 - Endocrinology

During routine investigation of a healthy couple for primary subfertility semen analysis reveals azoospermia.

On examination of the male there are no abnormalities on general examination and testicular examination shows a normal testicular volume.

Investigations reveal:

LH 5.1 IU/L(2-10)

FSH 4.3 IU/L(2-10)

Testosterone 15.3 nmol/L(9-30)

Which of the following is the most likely cause of his azoospermia?

- 1- Androgen insensitivity
- 2- Genital tract obstruction
- 3- Idiopathic testicular failure
- 4- Kallman's syndrome
- 5- Sperm autoimmunity

Answer & Comments

Answer: 2- Genital tract obstruction

Azoospermia can occur because of reproductive tract obstruction or inadequate production of spermatozoa. It is diagnosed after centrifuged samples of complete semen specimens are analysed microscopically. History, physical examination and hormone analysis are needed to determine the cause. In less than 10% of cases a testicular biopsy is required to diagnose the cause of azoospermia.

Obstructive azoospermia may be congenital (absence of the vas deferens, idiopathic epididymal obstruction) or acquired (from infection, vasectomy, trauma). Couples in whom the man has congenital reproductive tract obstruction should have cystic fibrosis gene mutation analysis for both partners, as there is a high risk of the male being a CF carrier. Acquired obstruction of the genital tract can be treated using microsurgical reconstruction. Alternatively, sperm can be retrieved from the testes and subsequently used for assisted reproduction.

The cause of non-obstructive azoospermia needs to be identified prior to any treatment.

Androgen insensitivity syndrome results from the inability of cells to respond to androgens. In males, this can prevent masculinisation of the genitalia and development of secondary sexual characteristics. You would therefore expect some phenotypic abnormalities, as well as elevated LH levels.

LH is raised in cases of idiopathic testicular failure.

Kallman's syndrome is hypothalamic gonadotrophin releasing hormone (GnRH) deficiency associated with hyposmia or anosmia. Serum LH and FSH are low.

Antisperm antibodies can cause 'immune infertility'. Sperm are usually present in semen but are unable to penetrate the cervical mucus to gain access to the ovum.

[Q: 2346] OnExamination 2012 - Endocrinology

A 17-year-old male with type 1 diabetes presents for annual review.

He takes three times daily short acting insulin with evening dose long acting insulin. His glycaemic control is good as reflected by an HbA1c of 6.5% (3.8-6.4).

He seeks advice regarding his ability to pursue a future career.

Which one of the following occupations would he be able to pursue?

- 1- A chef in the army catering corps
- 2- A police officer
- 3- A steward on board a cruise liner
- 4- An airline steward
- 5- An oil rig engineer

Answer & Comments

Answer: 4- An airline steward

Careers opportunities are affected by insulin use in diabetes mellitus and it is important to know these restrictions in order that you can provide appropriate advice to your patient.

Any employment in the armed forces, fire service or police force is not permissible unless already a member of the armed forces.

Offshore work also is not an option.

[Q: 2347] OnExamination 2012 - Endocrinology

A 69-year-old woman with a long history of rheumatoid arthritis comes to the clinic for review.

She has been feeling particularly tired over the past few months and has suffered three bouts of pneumonia in the past year. Her rheumatoid is particularly active, and she has significant ongoing pain affecting her toes, fingers, wrists and elbows.

Current medication includes methotrexate with folic acid cover.

On examination her BP is 142/81 mmHg, pulse is 72 and regular and she is afebrile. There is evidence of active synovitis affecting a number of joints. You can also palpate her spleen on examination of the abdomen.

Investigations show:

Haemoglobin 10.1 g/dl (13.5-17.7)

White cell count $4.1 \times 10^9/L$ (4-11)

Neutrophils $0.5 \times 10^9/L$ (2-7.5)

Platelets $152 \times 10^9/L$ (150-400)

ESR 65 mm/hr (<10)

Sodium 139 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 123 micromol/l (79-118)

Which of the following is the most likely diagnosis?

- 1- Felty's syndrome
- 2- Methotrexate toxicity
- 3- Myelodysplasia
- 4- Myelofibrosis
- 5- Non-Hodgkin's lymphoma

Answer & Comments

Answer: 1- Felty's syndrome

This patient has Felty's syndrome as characterised by very active rheumatoid disease on the background of splenomegaly and elevated erythrocyte sedimentation rate (ESR) and neutropenia.

Felty's syndrome is a complication of rheumatoid arthritis (RA), defined as the triad of RA, neutropenia and splenomegaly. It is rare, and is most commonly seen in those with severe disease of more than 10 years duration. The cause is unknown, but it is linked with the HLA-DR4 genotype. 95% of patients are positive for rheumatoid factor.

Felty's can be asymptomatic, or can present with recurrent infections. The neutropenia is often severe (<0.2), which can lead to serious (and sometimes fatal) infections. Extra-articular features of RA are often present. Hepatomegaly and lymphadenopathy may be present. The diagnosis is clinical. Rarely, splenic rupture, hyperviscosity and leukaemia can complicate the condition.

Treatment is with immunomodulators, usually methotrexate. Alternative options are

hydroxychloroquine, ciclosporin, leflunomide and cyclophosphamide. Rituximab has been trialled with some success, but entercept has been linked with a reduction in neutrophil count. Splenectomy is generally reserved for those not responding to medical treatment. Patients should be immunised against influenza and pneumococcus if the neutropenia persists for more than a couple of weeks.

Methotrexate toxicity is the major differential, but the splenomegaly and evidence of active inflammation makes Felty's the more likely diagnosis.

Whilst haematological malignancies are also possible differentials, they would not be top of the list ahead of Felty's. However, a bone marrow biopsy could be indicated if symptoms and signs fail to improve with intensification of immunomodulator therapy.

[Q: 2348] OnExamination 2012 - Endocrinology

A 62-year-old man with a long history of type 2 diabetes presents with a swollen left ankle and forefoot. He says that it has been like that for a little while, and he does not notice much pain in the joint apart from an occasional ache.

He has significant neuropathy with numbness to pain and fine touch to his mid shins.

On examination his BP is 152/82 mmHg, his pulse is 82 and regular. His left ankle and forefoot are slightly warm to the touch, erythematous and swollen with obvious bony deformity.

Investigations show:

Haemoglobin 10.4 g/dl(13.5-17.7)

White cell count $9.1 \times 10^9/L$ (4-11)

Platelets $158 \times 10^9/L$ (150-400)

ESR 15 mm/hr(<10)

Sodium 138 mmol/l (135-146)

Potassium 3.7 mmol/l (3.5-5)

Creatinine 140 micromol/l (79-118)

HbA1c 8.4%(<5.5)

Which of the following interventions is most likely to impact on the condition of his left ankle?

- 1- Aircast boot immobilisation
- 2- Alendronate
- 3- Improved blood pressure control
- 4- Improved glucose control
- 5- IV antibiotic therapy

Answer & Comments

Answer: 1- Aircast boot immobilisation

This patient is most likely to be suffering from a Charcot's ankle. As such the most effective treatment is a period of immobilisation in a specially made cast.

The normal ESR and white cell count are against an alternative inflammatory or infective diagnosis.

Whilst there is some evidence that bisphosphonates improve the prognosis of the condition, they are likely to be ineffective in the absence of immobilisation.

It is clear that improved blood pressure control and diabetes control will impact on progression of microvascular disease, but they will not impact on the gross Charcot's deformity that this patient already has.

Given infection is highly unlikely, IV antibiotics will not have any impact in this case.

[Q: 2349] OnExamination 2012 - Endocrinology

A 62-year-old woman comes to the renal clinic reporting increased tiredness. Her creatinine has been stable at around 240 $\mu\text{mol/l}$ for the past few years and she takes multiple agents to control her blood pressure.

On examination her BP is 135/72 mmHg, her pulse is 69 and regular, and her BMI is 26. General physical examination is unremarkable.

Investigations show:

Haemoglobin 11.0 g/dl(11.5-16.0)

White cell count $9.3 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 5.2 mmol/l (3.5-5)

Creatinine 242 $\mu\text{mol/l}$ (79-118)

Prolactin 700mU/l (<400)

Which of the following is the most likely diagnosis?

- 1- Amlodipine associated hyperprolactinaemia
- 2- Macroprolactinoma
- 3- Microprolactinoma
- 4- Ramipril associated hyperprolactinaemia
- 5- Renal failure associated hyperprolactinaemia

Answer & Comments

Answer: 5- Renal failure associated hyperprolactinaemia

Amlodipine and ramipril are not thought to be associated with a significant elevation in prolactin levels.

Macroprolactinoma would be associated with levels of prolactin of 3,000-6,000 or higher.

Microprolactinoma is associated with levels of prolactin of 1,000-3,000mU/l.

[Q: 2350] OnExamination 2012 - Endocrinology

You are considering prescribing intranasal calcitonin for the treatment of osteoporosis in a 70-year-old woman who has failed to tolerate weekly and then monthly

bisphosphonate therapy. She does not want to inject a PTH analogue or denosumab.

Which of the following correctly describes one of the actions of calcitonin?

- 1- Increased bone turnover
- 2- Increased osteoblast activity
- 3- Increased osteoclast activity
- 4- Increased urinary hydroxyproline excretion
- 5- Increased urinary sodium excretion

Answer & Comments

Answer: 5- Increased urinary sodium excretion

Calcitonin is associated with a marked decrease in bone turnover, and consequently a decrease in urinary hydroxyproline excretion.

Rather than increasing osteoblast activity, its primary mode of action is to decrease osteoclast activity.

It leads to a reduction in tubular reabsorption of sodium, and hence increased sodium excretion.

[Q: 2351] OnExamination 2012 - Endocrinology

A 42-year-old woman presents with lethargy and bony aches and pains. She is a frequent shift worker and works up to three nights per week.

There is no significant past medical history. On examination her BP is 122/71 mmHg, pulse is 70 and regular. She looks pale but examination is otherwise normal.

Investigations show:

Haemoglobin 11.5 g/dl(11.5-16.0)

White cell count $4.9 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 90 micromol/l (79-118)

Calcium 2.14 mmol/l (2.2-2.61)

Alkaline phosphatase 145 U/l (39-117)

Which of the following is the most appropriate treatment?

- 1- Calcium and vitamin D supplementation
- 2- Cinacalcet
- 3- Low phosphate diet
- 4- Recombinant PTH
- 5- Shift pattern change

Answer & Comments

Answer: 1- Calcium and vitamin D supplementation

It is likely that this patient has osteomalacia, characterised by bony aches and pains, a low calcium and a mildly elevated bony alkaline phosphatase.

It is unlikely she will be able to change her shift pattern to increase sun exposure, making calcium and vitamin D supplementation the treatment of choice.

Cinacalcet is a treatment for tertiary hyperparathyroidism, and low phosphate diet may have a role in the management of renal impairment.

Recombinant parathyroid hormone (PTH) is a treatment for severe osteoporosis if bisphosphonates are unsuitable or not tolerated.

[Q: 2352] OnExamination 2012 - Endocrinology

A 52-year-old taxi driver with type 2 diabetes comes for review.

He is currently managed with metformin 1 g twice daily but finds it very difficult to comply with diet and lifestyle recommendations because of the nature of his work.

There is a past history of myocardial infarction for which he takes ramipril 10 mg, atorvastatin 10 mg, aspirin 75 mg and furosemide 40 mg daily.

On examination he has a BMI of 31.

Investigations show:

Haemoglobin 12.5 g/dl(13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $205 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 130 mol/l (60-120)

HbA1c 8.4%(<5.5)

According to ADA/EASD consensus, which of the following therapies would be most appropriate to gain additional glycaemic control?

- 1- Exenatide
- 2- Gliclazide
- 3- Insulin
- 4- Pioglitazone
- 5- Vildagliptin

Answer & Comments

Answer: 2- Gliclazide

Gliptins are not recommended in the current consensus.

This is because of:

Limited long term evidence with respect to glycaemic control

Modest short term effects

Potential for effects on the immune system.

Pioglitazone carries a contraindication with respect to heart failure and is therefore not an option.

Exenatide is not endorsed in the guidelines yet as an established therapy.

This leaves insulin and gliclazide as the options; insulin would put his taxi driving licence at risk, so gliclazide is the best possible choice.

Whilst it may be associated with increased risk of hypoglycaemia it is at least one of the shorter acting sulphonylureas (SUs) available.

[Q: 2353] OnExamination 2012 - Endocrinology

A 53-year-old male presents with a three month history of polyuria with polydipsia.

Which of the following measurements would confirm a diagnosis of diabetes mellitus?

- 1- A fasting plasma glucose of 6.5 mmol/L
- 2- A fasting plasma glucose of 7.5 mmol/l
- 3- A plasma glucose of 10 mmol/l at the end of an oral glucose tolerance test
- 4- A random glucose of 10.5 mmol/l
- 5- A urine dipstick analysis showing +++ glucose

Answer & Comments

Answer: 2- A fasting plasma glucose of 7.5 mmol/l

Diabetes mellitus is diagnosed on the basis of symptoms plus a random glucose above 11.1 mmol/l or fasting plasma glucose above 7 mmol/l or the two hour oral glucose tolerance test.

Impaired glucose tolerance would be indicated by a post OGTT plasma glucose between 7.7 and 11.1 or a fasting plasma glucose between 6.1 and 7.

[Q: 2354] OnExamination 2012 - Endocrinology

A 40-year-old man was referred to the endocrine clinic for his resistant hypertension.

He was taking the following medications: atenolol 50 mg once daily, ramipril 10 mg

once daily, doxazosin 4 mg daily, amlodipine 10 mg daily and bendroflumethiazide 2.5 mg daily.

On examination his pulse was 64 beats per minute, his blood pressure was 162/96 mmHg, heart sounds were normal and there were no cushingoid features.

Investigations showed:

Serum urea 4.4 mmol/L(2.5-7.5)

Serum creatinine 88 µmol/L(60-110)

Serum potassium 3.6 mmol/L(3.5-4.9)

Which is the most important medication to be discontinued before testing his aldosterone/plasma renin activity ratio?

- 1- Amlodipine
- 2- Atenolol
- 3- Doxazosin
- 4- Hydralazine
- 5- Verapamil

Answer & Comments

Answer: 2- Atenolol

Screening for hyperaldosteronism should be considered for hypertensive patients with hypokalaemia (not due to treatment), those with marked diuretic-induced hypokalaemia (<3.0) and those with refractory hypertension (failure to respond to three or more agents).

Primary hyperaldosteronism was previously believed to account for less than 1% of hypertension, but recent studies have shown a much higher prevalence (up to 12%) and have demonstrated that most patients are normokalaemic. Primary hyperaldosteronism may therefore be the most common potentially curable cause of hypertension, and as such should always be considered.

The renin/aldosterone ratio, together with cortisol, can be used to diagnose primary hyperaldosteronism when you would expect

the aldosterone to be high, renin low and normal cortisol.

Patients ingesting large amounts of sodium, those with renal impairment, or those taking β -blockers can have false-positive results. Salt-restriction, ACE inhibitors and angiotensin-receptor blockers, spironolactone and other diuretics can lead to false-negative results. α -blockers (for example, doxazosin) and calcium channel blockers (for example, amlodipine) are the hypertensives of choice in patients undergoing renin/aldosterone ratio measurements.

The effect of drugs on renin and angiotensin is seen below:

Drug Renin Aldosterone Effect

Non-dihydropyridine CCB Minimal Minimal No effect

Dihydropyridine CCB Minimal Decreased/minimal No effect

α -blockers Nil Nil No effect

Hydralazine Minimal Minimal No effect

ACE inhibitors & ARBs Increased Decreased False negative

Diuretics Increased markedly Increased False negative

Minoxidil Increased Minimal False negative

B-blockers Decreased Minimal False positive

Methyldopa Decreased Minimal False positive

Aldosterone levels can fall with severe illness, so testing should be done following recovery.

[Q: 2355] OnExamination 2012 - Endocrinology

A 60-year-old lady with dyslipidaemia, hypertension and angina has recently been diagnosed with impaired glucose tolerance (IGT).

Clinically she is obese with a BMI of 32 kg/m², her blood pressure is 140/80 mmHg. She is aware that having impaired glucose tolerance is a risk factor for type 2 diabetes and would like to discuss strategies to attenuate this risk.

Which of the following has been shown best to reduce the incidence of type 2 diabetes in individuals with IGT?

- 1- Acarbose 100 mg tds
- 2- Gliclazide
- 3- Intensive lifestyle change
- 4- Metformin 850 mg bd
- 5- Pioglitazone 15 mg daily

Answer & Comments

Answer: 3- Intensive lifestyle change

Both the diabetes prevention programme (DPP) and Finnish diabetes prevention study showed a 58% reduction in incidence of type 2 diabetes after intervention which involved intensive dietary change, increased physical activity and weight loss.

This compares with a 31% reduction in incidence when metformin was used.

Acarbose has also been shown to reduce the incidence of diabetes in combination with lifestyle change when compared with placebo.

The ACT now study has suggested that pioglitazone reduces progression from prediabetes to Type 2 diabetes, although it is not licensed for this purpose.

It was not licensed in the United Kingdom for diabetes prevention.

[Q: 2356] OnExamination 2012 - Endocrinology

A 45-year-old male presents with sweats and change in appearance.

A diagnosis of acromegaly is confirmed with failure to suppress GH concentrations on an

oral glucose tolerance test. MRI reveals a 0.5 cm microadenoma of the pituitary.

Which of the following is the most appropriate therapeutic option for this patient?

- 1- Depot somatostatin analogue
- 2- Dopamine agonist therapy
- 3- Pituitary surgery
- 4- Short acting somatostatin analogue
- 5- Stereotactic pituitary irradiation

Answer & Comments

Answer: 3- Pituitary surgery

Surgery is the most appropriate primary therapy for acromegaly with a cure rate of above 80% expected for a tumours of this size.

Although somatostatin analogues are very effective at suppressing growth hormone (GH) concentrations to what would be regarded as a 'cure' range (GH less than 5 μ u/l on day profile) their expense limits use on the longer term basis.

However in patients unsuitable for surgery or in those not cured following surgery SMS would be employed.

[Q: 2357] OnExamination 2012 - Endocrinology

Which of the following is regarded as a physiological effect of thyroid hormones?

- 1- Decrease gluconeogenesis
- 2- Enhance insulin sensitivity
- 3- Reduce myocardial oxygen demand
- 4- Reduce nerve conduction
- 5- Reduce oxidation of fatty acids in tissues

Answer & Comments

Answer: 2- Enhance insulin sensitivity

Thyroid hormones enhance

Insulin-dependent entry of glucose into cells

Myocardial oxygen consumption

Nerve conduction

Gluconeogenesis and

Oxidation of fatty acids.

[Q: 2358] OnExamination 2012 - Endocrinology

A 45-year-old female attends clinic complaining of tiredness. She is hypothyroid and takes thyroxine 150 micrograms daily.

Which of the following is the most useful test for assessing the appropriateness of thyroid hormone replacement in primary hypothyroidism?

- 1- Free T3 and T4 concentrations
- 2- Skin biopsy
- 3- Thyroid binding globulin
- 4- Total T3 and T4
- 5- TSH

Answer & Comments

Answer: 5- TSH

Thyroid-stimulating hormone (TSH) has been recognised as an exquisitely sensitive indicator of thyroid status.

A normal TSH result suggests adequate thyroid hormone replacement and euthyroidism.

Similarly elevated TSH with normal thyroid hormone concentrations would suggest poor compliance and suppressed TSH with normal high thyroxine (T4) suggests over-replacement.

[Q: 2359] OnExamination 2012 -
Endocrinology

A 26-year-old man with a three year history of type 1 diabetes presents with fever, vomiting and is dehydrated.

Investigations revealed:

Sodium 148 mmol/L (137-144)

Potassium 3.3 mmol/L (3.5-4.9)

Urea 24 mmol/L (2.5-7.5)

Glucose 33 mmol/L (3.0-6.0)

Blood pH 7.18 (7.36-7.44)

What would be the typical total body water deficit associated with his diabetic ketoacidosis (DKA)?

- 1- 1 litre
- 2- 3 litres
- 3- 6 litres
- 4- 8 litres
- 5- 10 litres

Answer & Comments

Answer: 3- 6 litres

The typical fluid deficit associated with DKA is approximately 6 litres.

The initial half of this amount is derived from intracellular fluid and precedes signs of dehydration, while the other half is from extracellular fluid and is responsible for clinical signs of dehydration.

Appropriate fluid replacement requires 1 litre of normal saline over the first 1/2 hour, then 1 litre over the next hour, then 1 litre over the next two hours followed by 1 litre every 4 hours depending on the degree of dehydration.

[Q: 2360] OnExamination 2012 -
Endocrinology

A 57-year-old male with diabetes requests

sildenafil for erectile dysfunction.

Which of the following are contraindicated with sildenafil?

- 1- Carbamazepine
- 2- Carvedilol
- 3- Indomethacin
- 4- Nicorandil
- 5- Valsartan

Answer & Comments

Answer: 4- Nicorandil

Sildenafil is contraindicated if the patient is taking nitrates, or nitrate derivatives (nicorandil).

We are informed on the prescribing information that if the patient takes nitrates then they should be stopped for the period during which sildenafil is used.

[Q: 2361] OnExamination 2012 -
Endocrinology

A 37-year-old female with type 2 diabetes and obesity requests help with regard to weight loss. She has tried to lose weight with dietary manoeuvres but has succeeded in losing only 3 kg over the last year. She is currently receiving no treatment.

On examination her BMI is 33.5 kg/m² and her blood pressure is 142/84 mmHg. Her most recent HbA1c is 6.9% (3.8-6.4).

She asks whether there are any pharmacological therapies that may be appropriate for assisting with weight reduction.

Which of the following agents is appropriate for assisting with weight loss in this patient?

- 1- Dexfenfluramine
- 2- Insulin detemir
- 3- Metformin
- 4- Orlistat

5- Phentermine

Answer & Comments

Answer: 4- Orlistat

This patient has demonstrated a 3 kg weight loss over the past year but, like many, has become rather stuck.

The NICE criteria for orlistat previously stated it should be used in patients who have demonstrated dietary compliance with at least a 2.5 kg weight reduction prior to initiating orlistat. This is not now a requirement. Continued weight reduction is required if the patient is to remain on the drug (5% body weight at 12 weeks).

Orlistat functions through inhibiting the absorption of dietary fat from the gastrointestinal tract. Consequently, its side effects include flatulence and diarrhoea.

Dexfenfluramine is associated with systemic hypertension and strokes and is now withdrawn as an anti-obesity agent, as is phentermine (valvular fibrosis) in the successful but dangerous combination Phen-Fen.

Metformin is not an agent that would create weight loss, but merely improves insulin sensitivity and maintains weight (or gain weight as in sulphonylurea therapy). Similarly this patient's HbA1c is well controlled on diet alone.

Insulin detemir has been associated with less weight-gain or even slight weight-loss compared with other insulins. However, her HbA1c is at target (less than 7%) and therefore she does not require additional anti-glycaemic therapy at this time.

[Q: 2362] OnExamination 2012 - Endocrinology

A 55-year-old female presents with episodic sweats and tremors which are relieved by

glucose. She has gained approximately 6 kg in weight of late and drinks approximately 10 units of alcohol weekly.

Her investigations show normal full blood count, normal urea and electrolytes and a fasting plasma glucose concentration of 4 mmol/l (3.0-6.0).

What is the most appropriate investigation for this patient?

- 1- 72 hour fast
- 2- CT scan of pancreas
- 3- EEG
- 4- Insulin and C peptide concentration
- 5- Oral glucose tolerance test

Answer & Comments

Answer: 1- 72 hour fast

This patient describes symptoms suggestive of hypoglycaemia which are relieved by carbohydrate. The likely cause is an insulinoma which is producing the weight gain.

The standard method for achieving a diagnosis is during a 72 hour fast by demonstration of inappropriately high insulin and C peptide during spontaneous hypoglycaemia.

Measurement of C peptide is useful for excluding factitious hypoglycaemia from self injection of insulin. Insulin preparations contain no C peptide.

[Q: 2363] OnExamination 2012 - Endocrinology

A 32-year-old woman presents with a one year history of secondary amenorrhoea.

She had been prescribed temazepam and dihydrocodeine.

On examination she had galactorrhoea. Her serum prolactin was noted to be 6000 mU/l (<450 mU/l).

What is the most likely diagnosis?

- 1- Drug-induced hyperprolactinaemia
- 2- Hypothyroidism
- 3- Pituitary dependent Cushing's disease
- 4- Pituitary microadenoma
- 5- Stress

Answer & Comments

Answer: 4- Pituitary microadenoma

The patient has amenorrhoea, galactorrhoea and a grossly elevated prolactin concentration of 6000. The diagnosis is likely to be a prolactinoma, most likely due to a pituitary microadenoma (microprolactinoma).

The prescribed drugs would not cause hyperprolactinaemia.

Drugs that are responsible include:

Dopamine antagonists

Antipsychotics (haloperidol, sulpiride)

Metoclopramide

Domperidone

Selective serotonin reuptake inhibitors (SSRIs) to a lesser extent.

There is nothing in this patient's history to suggest either hypothyroidism or Cushing's.

Hypothyroidism may cause hyperprolactinaemia but is usually mild.

Stress would not produce such a picture.

[Q: 2364] OnExamination 2012 - Endocrinology

A diagnosis of diabetes mellitus is being considered in 32-year-old woman who is 16 weeks pregnant. Her body mass index (BMI) was 22 kg/m² (18 - 25).

A 75g oral glucose tolerance test (OGTT) revealed:

TimePlasma glucose concentration

0 hr 6.0 mmol/l (3.0-6.0)

2hr 12.5 mmol/l (<11.1)

Which of the following is the most appropriate step in the management of this patient?

- 1- Glipizide therapy
- 2- Insulin therapy
- 3- Low calorie diet and exercise
- 4- Metformin therapy
- 5- Repeat her oral glucose tolerance test in four weeks

Answer & Comments

Answer: 3- Low calorie diet and exercise

2.5% of pregnancies in England and Wales involve women with diabetes. Approximately 87% of these are due to gestational diabetes, 7.5% type 1 diabetes and 5% type 2 diabetes. There are a number of risks to both mother and fetus, including miscarriage, pre-eclampsia, preterm labour, stillbirth, congenital malformations, macrosomia, birth injury, perinatal mortality and neonatal hypoglycaemia.

Risk factors for gestational diabetes are BMI >30 kg/m², previous macrosomic baby (>4.5kg), previous gestational diabetes, first-degree relative with diabetes, ethnic origin (South Asian, Caribbean, Middle Eastern). Screening with fasting plasma glucose, random blood glucose, glucose challenge tests and urinalysis is recommended for any women with one of these risk factors. The 2-hour 75g oral glucose tolerance test is used to definitively diagnose gestational diabetes. This is performed at 16-18 weeks in women who have been affected in a previous pregnancy (with home BM monitoring prior to this, and a repeat test at 28 weeks if this is normal) and 24-28 weeks for women with any other risk factor.

If it is safely achievable, women with gestational diabetes should aim to keep

fasting blood glucose between 3.5-5.9mmol/litre and one hour postprandial blood glucose below 7.8mmol/litre during pregnancy. It is important to note HbA1c should not be routinely used to monitor glycaemic control in the second and third trimesters.

Most gestational diabetes will respond to changes in diet and exercise. Only 10-20% of women need oral hypoglycaemia agents or insulin therapy. Women should therefore be given dietary advice, and those with a pre-pregnancy BMI of >27 should be advised to restrict calorie intake and exercise for at least 30 minutes daily.

Hypoglycaemic therapy should be considered for women in whom diet and exercise fails to maintain blood glucose targets during a period of 1-2 weeks. If there is any evidence of fetal macrosomia therapy should be initiated immediately. Treatment should be tailored to the individual women, but in general may include oral hypoglycaemics (metformin and glibenclamide) and insulin. There is insufficient evidence regarding long-acting insulin analogues, and isophane insulin therefore remains the first choice for long-acting insulin during pregnancy. Insulin aspart and lispro are safe rapid-acting analogues.

Women with insulin-treated gestational diabetes should be advised of the risk of hypoglycaemia (which they may be unaware of) and provided with a concentrated glucose solution.

During labour and birth, capillary blood glucose should be monitored on an hourly basis in patients with diabetes and maintained between 4 and 7mmol/litre. This may require the use of a sliding scale.

In this patient diet and exercise has not yet been trialled, and there is no mention of foetal macrosomia. Metformin can then be started if glycaemic control is not achieved within 1-2 weeks. Waiting another four weeks to instigate therapy exposes both mother and

foetus to potential harm. Insulin can be used if glycaemic control is not achieved with metformin. Glipizide is not used in pregnancy.

[Q: 2365] OnExamination 2012 - Endocrinology

A 30-year-old female presents with mild galactorrhoea.

Biochemistry reveals an elevated prolactin of 1200 mU/L (50-450) and an oestradiol concentration of 100 pmol/L (130-450).

Which of the following is the likely cause?

- 1- Addison's disease
- 2- Hyperthyroidism
- 3- Non-functioning pituitary tumour (NFPT)
- 4- Post-cranial irradiation for acute lymphocytic leukaemia as a child
- 5- Sheehan's syndrome

Answer & Comments

Answer: 3- Non-functioning pituitary tumour (NFPT)

Addison's may be associated with hypogonadism but prolactin (PRL) concentrations are usually normal.

Severe hypothyroidism is associated with hyperPRL hypogonadism.

An NFPT may cause hyperprolactinaemia through stalk compression.

Sheehan's syndrome is associated with a low prolactin concentration.

Cranial irradiation may initially cause hyperprolactinaemia but a low PRL is typical after a year.

[Q: 2366] OnExamination 2012 - Endocrinology

A 26-year-old woman presents with episodes of dizziness mainly on standing.

Her biochemical profile shows hyperkalaemic acidosis.

Which underlying condition is she most likely to have?

- 1- Addison's disease
- 2- Bulimia nervosa
- 3- Conn's syndrome
- 4- Cushing's syndrome
- 5- Type 1 renal tubular acidosis

Answer & Comments

Answer: 1- Addison's disease

Her symptoms are suggestive of postural hypotension, which together with hyperkalaemic (and hyponatraemia) acidosis would strongly indicate the presence of Addison's disease.

Cushing's and Conn's syndromes are associated with hypertension and hypokalaemia.

Hypokalaemia is the most frequent complication of bulimia which may cause cardiac arrhythmias, fits and paraesthesia.

Renal tubular acidosis (RTA) is due to inability of the renal tubules to maintain acid-base balance causing a hyperchloraemia and a normal anion-gap.

In type 1 (distal) RTA there is hypokalaemic acidosis with low urinary ammonium production. Patients present with hyperventilation/acidosis and muscular weakness from hypokalaemia.

In type 4 RTA (hyporeninaemic hypoaldosteronism) there is hyperkalaemic acidosis caused by chronic renal insufficiency from diabetes or tubulointerstitial disease.

[Q: 2367] OnExamination 2012 - Endocrinology

A 26-year-old female presents with a six week

history of galactorrhoea. She has no other symptoms but takes medication for contraception, dyspepsia and migraine.

Examination reveals slight galactorrhoea with expression from both breasts but is otherwise normal.

Investigations show:

Prolactin 915 mU/L(< 450)

Which one of the following drugs may be responsible?

- 1- Codeine phosphate
- 2- Metoclopramide
- 3- Omeprazole
- 4- Oral contraceptive pill
- 5- Sumatriptan

Answer & Comments

Answer: 2- Metoclopramide

Metoclopramide acts as a dopamine antagonist. Dopamine inhibits the release of prolactin from the anterior pituitary gland.

Therefore, metoclopramide can predispose to hyperprolactinaemia and consequent galactorrhoea.

[Q: 2368] OnExamination 2012 - Endocrinology

A 19-year-old female is concerned following exposure to meningococcal meningitis. Her flatmate contracted meningococcal meningitis and she now wants preventative treatment.

She is generally well without any past medical history. She takes Logynon as a contraceptive agent and uses a salbutamol inhaler infrequently.

Which prophylactic antimicrobial treatment would you select?

- 1- Augmentin
- 2- Ciprofloxacin
- 3- Clarithromycin

4- Doxycycline

5- Rifampicin

Answer & Comments

Answer: 2- Ciprofloxacin

Rifampicin is a reasonable choice as prophylaxis against meningococcal infection but in this 19-year-old sexually active student may be expected to reduce the efficacy of the oral contraceptive through liver enzyme induction.

Therefore Ciproxin would be the most appropriate agent from the above list as it does not induce cytochrome p450.

[Q: 2369] OnExamination 2012 - Endocrinology

A 58-year-old man presents with a history of indigestion which has been steadily worsening over the past few months. He tells you that he has lost 4 kg in weight in the past half a year.

There is no past medical history of note apart from smoking of 10 cigarettes / day. On examination his BP is 152/90 mmHg, pulse is 75 and regular. His BMI is 22.

Investigations show:

Haemoglobin 10.9 g/dl(13.5-17.7)

White cell count $7.5 \times 10^9/L$ (4-11)

Platelets $280 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Which of the following is the most appropriate course of action?

1- Barium swallow

2- Magnesium trisilicate

3- Omeprazole

4- Ranitidine

5- Upper GI endoscopy

Answer & Comments

Answer: 5- Upper GI endoscopy

Barium swallow is not the usual first line investigation, with upper gastrointestinal (GI) endoscopy preferred for the majority of patients.

Magnesium trisilicate is an antacid used for short term relief of symptoms only.

Ranitidine is predominantly used now as an over the counter indigestion relief tablet.

Omeprazole is standard pharmacological therapy for gastro-oesophageal reflux disease, although not until an endoscopy has excluded a serious underlying diagnosis in this case.

[Q: 2370] OnExamination 2012 - Endocrinology

A 42-year-old publican who has a significant problem with excess alcohol consumption comes to the clinic for review.

He has had persistent diarrhoea which he says is difficult to flush away and intermittent upper abdominal pain.

On examination his BP is 125/72 mmHg, his pulse is 75 and his BMI is 21. He has signs of chronic liver disease.

Investigations show:

Haemoglobin 10.2 g/dl(13.5-17.7)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $198 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Calcium 2.1 mmol/l (2.2-2.61)

Alanine aminotransferase 92 U/l (5-40)

Albumin 25g/l (35-50)

You suspect malabsorption.

Which of the following is the most appropriate initial test as a pointer to the diagnosis?

- 1- Abdominal CT
- 2- Abdominal ultrasound
- 3- ERCP
- 4- Faecal elastase
- 5- Secretin stimulation test

Answer & Comments

Answer: 4- Faecal elastase

Abdominal ultrasound, CT and ERCP may all indicate structural changes consistent with chronic pancreatitis, but do not provide the link to function and thus the cause of the diarrhoea.

As such faecal elastase is the preferred answer.

The secretin stimulation test is also a test of exocrine function but is invasive and therefore not a preferred investigation.

[Q: 2371] OnExamination 2012 - Endocrinology

A 41-year-old woman presents with palpitations and weight loss to the endocrine clinic. She has lost over two stone over the last four months and is increasingly anxious.

On examination her BMI is 20, her BP is 135/72 mmHg, and her pulse is 90 and regular. She has a fine tremor. A TSH is measured at <0.05.

Which of the following would you expect to find on further questioning or clinical examination?

- 1- Constipation
- 2- Decreased libido
- 3- Dry skin
- 4- Menorrhagia
- 5- Weight gain

Answer & Comments

Answer: 2- Decreased libido

Constipation, dry skin, menorrhagia and weight gain are more commonly described as being associated with hypothyroidism.

More rarely patients may gain weight in hyperthyroidism however, when they succeed in eating more food than is required to compensate for their increased basal metabolic rate.

[Q: 2372] OnExamination 2012 - Endocrinology

A 45-year-old man is referred to the endocrine clinic by his GP.

He has been found on routine new patient screening to have an isolated elevated calcium of 2.9 mmol/l. There is no past medical history of note, and clinical examination is entirely normal.

On further questioning you understand that his father and uncle have been reported to have high calcium levels but had no other significant problems.

Investigations show:

Haemoglobin 13.7 g/dl (13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $202 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 117 $\mu\text{mol/l}$ (79-118)

Calcium 2.89 mmol/l (2.20-2.62)

What is the diagnosis?

- 1- Familial isolated hyperparathyroidism (FIHP)
- 2- Hyperparathyroidism jaw tumour syndrome
- 3- MEN 1
- 4- MEN 2a
- 5- MEN 2b

Answer & Comments

Answer: 1- Familial isolated hyperparathyroidism (FIHP)

Hyperparathyroidism jaw tumour syndrome is a syndrome of hyperparathyroidism and fibro-osseous tumours of the jaw. It is described as having increased incidence in Romany families.

MEN 1 is associated with hyperparathyroidism in 80%, pancreatic tumours and pituitary adenomas.

MEN 2a is associated with parathyroid hyperplasia, medullary carcinoma of the thyroid, and pheochromocytoma.

Parathyroid hyperplasia is not a usual feature of MEN 2b.

[Q: 2373] OnExamination 2012 - Endocrinology

A 16-year-old boy with short stature, bony aches and pains, and learning difficulties comes to the clinic for review.

The most marked abnormality on examination is a short fifth digit on each hand.

Investigations reveal a calcium of 2.05 mmol/l (2.20-2.61), and a phosphate of 1.8 mmol/l (0.8-1.5).

Which of the following abnormalities is most likely to be present?

- 1- Alpha subunit G protein mutation
- 2- Beta subunit G protein mutation
- 3- Gamma subunit G protein mutation
- 4- Renal tubular disorder
- 5- Vitamin D receptor mutation

Answer & Comments

Answer: 1- Alpha subunit G protein mutation

Mutations in the other G protein subunits do not occur in pseudohypoparathyroidism, so B and C are incorrect.

Whilst a renal tubular disorder or vitamin D receptor mutation could in theory lead to hypocalcaemia, the short digit seen in this patient is characteristic of pseudohypoparathyroidism.

[Q: 2374] OnExamination 2012 - Endocrinology

A 25-year-old woman presents with sickness and lethargy some 10 weeks into her first pregnancy.

She was previously fit and well with no significant medical history. On examination her BMI is 22, her BP is 95/60 mmHg, pulse is 75. There are no abnormal findings on examination.

Investigations show:

Haemoglobin 10.4 g/dl(11.5-16.0)

White cell count $4.9 \times 10^9/l$ (4-11)

Platelets $177 \times 10^9/l$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 3.2 mmol/l (3.5-5)

Creatinine 90 micromol/l (79-118)

TSH 0.2(0.5-4.5)

Which of the following is the most likely diagnosis?

- 1- De Quervain's thyroiditis
- 2- Graves' disease
- 3- Hashimoto's disease
- 4- Hyperemesis gravidarum
- 5- Riedel's thyroiditis

Answer & Comments

Answer: 4- Hyperemesis gravidarum

We are told that this patient has significant problems with sickness, which may be driven by high levels of beta-human chorionic gonadotropin (HCG).

Beta-HCG has a degree of thyroid stimulating activity. In the circumstances it is likely that this has driven thyroid-stimulating hormone (TSH) down to below the lower limit of normal. No intervention is necessary, and there is no value in using anti-thyroid drugs in this situation.

De Quervain's thyroiditis follows symptoms of a viral illness and is usually associated with pain over the gland. It may be associated with transient hypo- or hyperthyroidism.

Graves' disease is associated with a goitre and thyrotoxicosis.

Hashimoto's is associated with hypothyroidism.

Riedel's is associated with a woody feel to the gland.

[Q: 2375] OnExamination 2012 - Endocrinology

A 16-year-old boy comes to the endocrine clinic with his father; he is tall and thin but is most concerned because his voice has not properly broken and he has not started to go through puberty.

Other past history of note is that he has complained to his GP on a number of occasions that he has no sense of smell, and that food tastes bland.

On examination he is 184 cm in height. His BMI is 21, his BP is 125/80 mmHg. He has very sparse sexual hair, small testes and an underdeveloped phallus.

Investigations show:

Haemoglobin 13.4 g/dl(11.5-16.5)

White cells $7.4 \times 10^9/L$ (4-11)

Platelet $205 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 92 $\mu\text{mol/l}$ (79-118)

Serum testosterone 4 nmol/l (9-42)

Which of the following is the most likely diagnosis?

1- Kallmann's syndrome

2- Klinefelter's syndrome

3- Noonan's syndrome

4- Pituitary apoplexy

5- Testicular feminisation

Answer & Comments

Answer: 1- Kallmann's syndrome

A number of genes including KAL-1 and FGFR-1 are involved in the formation of the olfactory bulb area of the brain, which as well as being responsible for sense of smell, is also involved in the production of gonadotropin-releasing hormone (GnRH).

Failure of this area of the brain to develop leads to an absent sense of smell and either not entering or partial puberty.

GnRH or gonadotrophin-based preparations can be used to restore fertility, or testosterone can be used to drive development of secondary sexual characteristics.

A. Kallmann's syndrome is the correct answer because anosmia, failure to enter puberty, and low testosterone are typical of the condition.

B. Klinefelter's syndrome is incorrect because the lack of sense of smell should point you towards Kallman's as the alternative diagnosis.

C. Noonan's syndrome is incorrect because it is associated with short stature, webbing of the neck, scoliosis, ligamentous laxity, and pectus excavatum.

D. Pituitary apoplexy is incorrect because it is associated with deficiency of multiple pituitary hormones.

E. Testicular feminisation is incorrect because it is associated with androgen insensitivity and subjects look externally female.

[Q: 2376] OnExamination 2012 - Endocrinology

A 43-year-old woman presents with a lump on the left side of her neck.

There is no evidence of hypo- or hyperthyroidism on symptom check and there is no history of recent weight change. The only medication of note is the progesterone only pill.

On examination her BP is 135/80 mmHg, her pulse is 68 and regular. Her BMI is 24, she has a left sided thyroid nodule approximately 0.8 cm in diameter. Her TSH is normal at 3.6 mU/L.

Which of the following is the most appropriate initial investigation?

- 1- CT scan neck
- 2- Fine needle aspiration
- 3- Free T3/T4
- 4- Radionucleotide scan
- 5- Ultrasound scan neck

Answer & Comments

Answer: 5- Ultrasound scan neck

Ultrasound is the initial investigation of choice for thyroid nodules; it can visualise cystic lesions 2 mm or more in diameter, and solid lesions 3 mm or more in diameter.

It is far more sensitive than palpation alone, with less than 10% of nodules detected by ultrasound being clinically palpable. Ultrasound is used to inform progression to fine needle aspiration.

Option A is not correct because CT scanning is usually only performed to examine for local spread of malignant disease or for degree of compression of other structures in the neck.

Option B is not correct because fine needle aspiration follows on from ultrasound scanning.

Option C is not correct because in view of a normal thyroid-stimulating hormone (TSH), tri-iodothyronine/thyroxine (T3/T4) are unlikely to be abnormal or contribute to the underlying diagnosis.

Option D is not correct because radionucleotide scanning is used for the investigation of thyroiditis or a toxic adenoma.

Option E is the correct initial investigation for thyroid nodules.

[Q: 2377] OnExamination 2012 - Endocrinology

A 48-year-old patient presents to the clinic with a gradual change in her facial appearance, swelling of her fingers so that her rings no longer fit, sweating, hypertension and worsening problems with sleep apnoea. You understand she has recently had surgery for bilateral carpal tunnel syndrome.

On examination she is hypertensive at 150/90 mmHg. She has coarsening of facial features with prognathism which is obvious when you look at old photos from her album; her hands and feet look enlarged.

Investigations show

Haemoglobin 14.1 g/dl (11.5-16.5)

White cell count $6.8 \times 10^9/L$ (4-11)

Platelets $183 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 102 $\mu\text{mol/l}$ (79-118)

TSH 3.1 mU/l (0.5-5.0)

Free thyroxine 13.2 pmol/l (10-25)

Glucose 4.6 mmol/l (4.5-5.6)

Which of the following is the investigation most likely to elucidate the underlying diagnosis?

- 1- Glucose tolerance test with growth hormone monitoring
- 2- Growth hormone releasing hormone
- 3- Insulin tolerance test with growth hormone monitoring
- 4- Prolactin
- 5- Random growth hormone level

Answer & Comments

Answer: 1- Glucose tolerance test with growth hormone monitoring

This patient's features are consistent with a diagnosis of acromegaly.

A glucose tolerance test with growth hormone measurement is useful with respect to screening as growth hormone is usually suppressed by hyperglycaemia to a level below 0.3 mcg/l.

Serum IGF1 is also particularly useful as it has a long half life and is elevated in conjunction with acromegaly.

MRI is useful for tumour localisation.

Prolactin may of course be elevated because of local pressure effect from a growth hormone producing adenoma.

[Q: 2378] OnExamination 2012 - Endocrinology

On routine screening of a 50-year-old woman who complained of tiredness, she is found to be hypercalcaemic.

She is being treated for manic depression, and cardiac failure.

Which of the following is most likely to be the cause of the raised calcium?

- 1- ACE inhibitor therapy
- 2- Furosemide therapy
- 3- Lithium therapy
- 4- Seroxat treatment

- 5- Vitamin D deficiency

Answer & Comments

Answer: 3- Lithium therapy

Lithium can produce diabetes insipidus and also raise calcium.

Neither Seroxat nor angiotensin-converting enzyme (ACE) inhibitors are related to hypercalcaemia.

Excess of vitamin D causes elevated calcium.

Furosemide lowers calcium but thiazides reduce excretion and so can exacerbate hypercalcaemia.

[Q: 2379] OnExamination 2012 - Endocrinology

A 58-year-old woman is admitted with a collapse and palpitations, having passed out in front of her husband whilst coming out of the bathroom. She has a history of severe diarrhoea over the past few days.

Medical history of note includes ketoconazole for a fungal infection, and bendroflumethiazide for hypertension.

On examination her BP is 100/60 mmHg, her pulse is 80. She looks dehydrated. Whilst you are watching her monitor she feels unwell again and you notice a run of torsades de pointes VT.

Which of the following electrolyte abnormalities is likely to be contributing to her risk of VT?

- 1- Hyperkalaemia
- 2- Hypernatraemia
- 3- Hyperuricaemia
- 4- Hypocalcaemia
- 5- Hypomagnesaemia

Answer & Comments

Answer: 5- Hypomagnesaemia

This woman is taking ketoconazole, which is known to lead to possible QT prolongation and increase the risk of torsades de pointes VT.

Additionally, she has been suffering from severe diarrhoea which will lead to GI magnesium loss, and is taking bendroflumethiazide which in itself contributes to low magnesium levels.

She should have her magnesium levels measured early, and be considered for IV magnesium supplementation if she is found to be hypomagnesaemic.

Of course it is also vitally important to stop her ketoconazole.

[Q: 2380] OnExamination 2012 - Endocrinology

A 32-year-old lady presented with episodes of polydipsia and polyuria for the last six months.

Investigations revealed:

Serum Urea 8.1 mmol/L(2.5-7.5)

Serum Creatinine 92 µmol/L(60-110)

Serum corrected Calcium 2.85 mmol/L(2.2-2.6)

Serum phosphate 0.75 mmol/L(0.8-1.4)

Plasma parathyroid hormone 6.2 pmol/L(0.9-5.4)

Which of the following is directly responsible for her increased reabsorption of calcium in the distal tubule of the kidney?

- 1- 1,25 Dihydroxy vitamin D
- 2- 25 Hydroxy vitamin D
- 3- Calcitonin
- 4- Hypophosphataemia
- 5- Parathyroid hormone

Answer & Comments

Answer: 5- Parathyroid hormone

This patient has hypercalcaemia due to hyperparathyroidism.

Parathyroid hormone has a number of direct effects, enhancing:

The release of calcium from bones by binding to osteoblasts which stimulates the formation of osteoclasts, and

Reabsorption of calcium in the distal tubules.

[Q: 2381] OnExamination 2012 - Endocrinology

A 44-year-old man presents with new onset bilateral gynaecomastia.

He has been diagnosed with Zollinger-Ellison syndrome in the last year.

He underwent normal puberty at age 14.

Which of the following drugs would be most likely to cause gynaecomastia?

- 1- Cimetidine
- 2- Famotidine
- 3- Lansoprazole
- 4- Rabeprazole sodium
- 5- Ranitidine

Answer & Comments

Answer: 1- Cimetidine

The answer to this question is cimetidine which is an H2 receptor antagonist. Blockade of androgen-responsive receptors in the target organ appears to be the most likely mechanism involved.

Research has shown that the other drugs listed above, which may also be used as part of the treatment of Zollinger-Ellison syndrome, have a much lower - almost insignificant - risk in the development of gynaecomastia.

Other drugs that can cause gynaecomastia include:

Spironolactone

Digoxin

Methyldopa

Gonadotrophins

Cyproterone acetate.

Zollinger-Ellison syndrome:

The association of peptic ulcer with a gastrin-secreting pancreatic adenoma; 50-60% are malignant.

It occurs in approximately 0.1% of patients with duodenal ulcer disease and is to be suspected in those with multiple peptic ulcers that are resistant to drugs.

[Q: 2382] OnExamination 2012 - Endocrinology

A 33-year-old female presents with a one year history of galactorrhoea and amenorrhoea. She informs you that she does not want to become pregnant.

On examination there is galactorrhoea to expression and visual fields are normal to confrontation.

Investigations confirm the diagnosis of a macroprolactinoma, with a prolactin concentration of 10,500 mu/l (50-500) and MRI of the pituitary revealing a 1.5 cm tumour with some suprasellar extension.

What is the most appropriate treatment for this woman?

- 1- Cabergoline therapy
- 2- Combined oral contraceptive
- 3- Pituitary surgery
- 4- Somatostatin analogue therapy
- 5- Stereotactic pituitary irradiation

Answer & Comments

Answer: 1- Cabergoline therapy

This young woman has a macroprolactinoma and these are exquisitely sensitive to dopamine agonist therapy and rapid tumour reduction with restoration of menses and cessation of galactorrhoea expected.

Pituitary surgery is rarely required in prolactinomas and is generally reserved for patients intolerant of or resistant to dopamine agonist therapy.

Even with large tumours that compress the chiasm, these can be treated with dopamine agonists with rapid reduction in size and relief of pressure.

The fact that she does not want to become pregnant is a bit of an irrelevance. One would still treat her with dopamine agonist therapy and suggest use of appropriate contraception which could include the OCP.

[Q: 2383] OnExamination 2012 - Endocrinology

A 26-year-old female with no previous history of diabetes presents with a first episode of diabetic ketoacidosis. There is no evidence of infection but she has recently commenced a new medication.

Which of the following drugs is implicated in precipitating diabetic ketoacidosis?

- 1- Olanzapine
- 2- Omeprazole
- 3- Progestogen only contraceptive pill
- 4- Sodium valproate
- 5- Venlafaxine

Answer & Comments

Answer: 1- Olanzapine

The atypical antipsychotics such as olanzapine have been implicated in precipitating diabetes as well as diabetic ketoacidosis.

Other drugs implicated include thiazide diuretics, beta sympathomimetics and steroids.

[Q: 2384] OnExamination 2012 - Endocrinology

A 17-year-old boy was brought to clinic as his parents were concerned regarding possible delayed puberty.

He was otherwise well, played sports regularly and academic performance was good. His height was 1.7 m and weight was 70 kg.

On examination he had small penis and testes, absent pubic hair, but no other abnormalities.

Investigations revealed:

Serum testosterone 4 nmol/l (9-35)

Plasma follicle stimulating hormone (FSH) 1 U/l (1-7)

Plasma luteinising hormone (LH) 1 U/l (1-10)

Plasma prolactin 300 mU/l (<450)

Plasma TSH 2 mU/l (0.5-5)

Which one of the following is the most likely cause?

- 1- Constitutional delay
- 2- Hypopituitarism
- 3- Hypothyroidism
- 4- Kallman's syndrome
- 5- Klinefelter's syndrome

Answer & Comments

Answer: 4- Kallman's syndrome

The low follicle-stimulating hormone (FSH) and luteinising hormone (LH), together with the low testosterone, suggests a hypogonadotrophic hypogonadism.

We know that there is no mental retardation, and we are told that physical examination is normal and sense of smell would usually not be tested.

Consequently a diagnosis of Kallman's is suggested.

We are not told of a family history of growth delay, thus this is unlikely to be constitutional delay.

The thyroid-stimulating hormone (TSH) is normal, making hypothyroidism unlikely and this together with the normal prolactin make hypopituitarism most unlikely.

[Q: 2385] OnExamination 2012 - Endocrinology

Which of the following is a characteristic feature of familial hypercholesterolaemia?

- 1- Autosomal dominant inheritance
- 2- Elevated chylomicrons
- 3- Hypertriglyceridaemia
- 4- Increased expression of LDL receptors
- 5- Palmar xanthomas

Answer & Comments

Answer: 1- Autosomal dominant inheritance

Familial hypercholesterolaemia is an autosomal dominant condition manifest by increased low density lipoprotein (LDL) concentrations (not chylomicrons) due to constitutional abnormalities and reduced numbers of the LDL receptor.

Hypertriglyceridaemia is not characteristic and high density lipoprotein (HDL) concentrations are usually decreased.

Tendon xanthomata are characteristic and the condition is associated with a premature cardiovascular mortality.

[Q: 2386] OnExamination 2012 - Endocrinology

An asymptomatic 56-year-old man with a family history of type 2 diabetes was found to have a fasting venous glucose of 6.5 mmol/l.

Which of the following relating to his further investigation is correct?

- 1- He has impaired glucose tolerance
- 2- He should be investigated further by another fasting venous sampling
- 3- He should be treated with oral hypoglycaemics in the first instance
- 4- He should undergo a 75 gm oral glucose tolerance test
- 5- This does not need further investigation

Answer & Comments

Answer: 4- He should undergo a 75 gm oral glucose tolerance test

According to the new revised criteria for the diagnosis of diabetes, venous plasma glucose (VPG) of 6.1 - 6.9 is categorised as impaired fasting glycaemia and requires further assessment with a 75 gram oral glucose tolerance test (OGT) which is still the gold standard.

A two hour value of equal to or over 11.1 mmol/l is diagnostic of diabetes.

Impaired glucose tolerance is a two hour VPG of 7.8 - 11.1 during an OGT.

Initial treatment of type 2 diabetes is patient education, diet and lifestyle changes.

[Q: 2387] OnExamination 2012 - Endocrinology

Causes of hypoadrenalism include which of the following?

- 1- Hughes' syndrome (antiphospholipid antibody)
- 2- McArdle's syndrome
- 3- MEN type 2a
- 4- Pendred's syndrome
- 5- von Hippel-Lindau

Answer & Comments

Answer: 1- Hughes' syndrome (antiphospholipid antibody)

The antiphospholipid syndrome is one of the more common causes of hypoadrenalism and may precipitate adrenal infarction and haemorrhage through adrenal vein thrombosis.

[Q: 2388] OnExamination 2012 - Endocrinology

A 36-year-old male presents with lethargy. He takes no medication and has generally been otherwise well. Examination reveals that he is obese with a BMI of 36.4 kg/m² and a blood pressure of 120/72 mmHg.

There are no abnormalities of the cardiovascular, respiratory or abdominal systems.

Investigations reveal:

Sodium 141 mmol/l (137-144)

Potassium 2.8 mmol/l (3.5-4.9)

Urea 5.6 mmol/l (2.5-7.5)

Creatinine 76 µmol/l (60-110)

What is the most likely diagnosis?

- 1- Apparent mineralocorticoid excess
- 2- Bartter's syndrome
- 3- Conn's syndrome
- 4- Cushing's syndrome
- 5- Hypokalaemic periodic paralysis

Answer & Comments

Answer: 2- Bartter's syndrome

Bartter's syndrome is a mixed bag of disorders but most frequently characterised by an autosomal recessive condition consisting of juxtaglomerular cell hyperplasia and secondary hyperaldosteronism.

A normal or low blood pressure is typical.

It may present in childhood with weakness and failure to thrive, but may present coincidentally in adulthood.

[Q: 2389] OnExamination 2012 - Endocrinology

A 60-year-old woman diagnosed with giant cell arteritis was commenced on high dose prednisolone therapy.

What is the most appropriate treatment for the prevention of steroid-induced osteoporosis?

- 1- Bisphosphonate therapy
- 2- Calcium and vitamin D
- 3- Hormone replacement therapy (HRT)
- 4- Raloxifene
- 5- Salmon calcitonin

Answer & Comments

Answer: 1- Bisphosphonate therapy

The most appropriate therapy advocated by the National Osteoporosis Society for the prevention of steroid-induced osteoporosis would be bisphosphonate therapy such as Didronel or alendronate.

These are the only class of drug shown to offer osteoprotection with steroid therapy.

Patients taking 7.5 mg or more of prednisolone daily for three months or longer should be offered osteoprotection.

HRT would not really be appropriate for this subject who is ten years past the menopause and likely to be free of all menopausal symptoms.

[Q: 2390] OnExamination 2012 - Endocrinology

Osteomalacia may be expected in which of the following?

- 1- Auto-immune adrenalitis

- 2- Mercury poisoning
- 3- Pernicious anaemia
- 4- Pseudo-hypoparathyroidism
- 5- Sarcoidosis

Answer & Comments

Answer: 2- Mercury poisoning

Osteomalacia may occur with vitamin D deficiency.

Mercury poisoning or any heavy metal poisoning causes an acquired Fanconi syndrome with proximal (type 2) renal tubular acidosis.

[Q: 2391] OnExamination 2012 - Endocrinology

A 21-year-old woman is taking vasopressin replacement after developing cranial diabetes insipidus after a road traffic accident. You are concerned that she may be using excess amounts of vasopressin.

Which of the following is a recognised effect of vasopressin?

- 1- Decreased factor VIII production
- 2- GI smooth muscle relaxation
- 3- Increased coronary artery blood flow
- 4- Increased platelet aggregation
- 5- Uterine smooth muscle relaxation

Answer & Comments

Answer: 4- Increased platelet aggregation

Antidiuretic hormone (ADH) actually leads to increased factor VIII production, and as such may be of utility in treating some patients with haemophilia A.

It leads to uterine and GI smooth muscle contraction and indirectly leads to a reduction in coronary artery blood flow.

[Q: 2392] OnExamination 2012 -
Endocrinology

A 32-year-old man is referred to the clinic with hypertension.

He is currently taking amlodipine, ramipril and bendroflumethiazide but his blood pressure in the clinic is 160/90 mmHg. Clinical examination is unremarkable and a range of investigations are arranged.

Investigations show:

Haemoglobin 11.4 g/dl(13.5-17.7)

White cell count $6.3 \times 10^9/l$ (4-11)

Platelets $193 \times 10^9/l$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.6 mmol/l (3.5-5)

Creatinine 140 micromol/l (79-118)

Ultrasound: Right kidney 6.9 cm, left kidney 10.5 cm.

Which of the following most accurately reflects the likely findings on renin/aldosterone testing?

- 1- Levels are not likely to be linked to any pathology seen here
- 2- Renin and aldosterone will be low
- 3- Renin will be high and aldosterone will be high
- 4- Renin will be high and aldosterone will be low
- 5- Renin will be low and aldosterone will be high

Answer & Comments

Answer: 3- Renin will be high and aldosterone will be high

This man's hypertension is significant, bearing in mind he has elevated blood pressure even after three anti-hypertensive medications.

The differential size on renal ultrasound scan raises the possibility of renal artery stenosis,

which would result in elevated renin and aldosterone levels.

Even in essential hypertension, renin and aldosterone may be elevated. As such the stems suggesting that both will be low, or that the levels are not linked to any pathology here must be incorrect.

Hyporeninaemic hyperaldosteronism is consistent with adrenal hyperplasia or a Conn's adenoma.

Hyperreninaemic hypoaldosteronism is linked to aldosterone deficiency which may be genetic in origin and would not result in hypertension.

It is also important to note that ideally antihypertensives should be stopped prior to measuring renin and aldosterone, if possible safely. In this case the gentleman is still severely hypertensive and therefore the renin and aldosterone are likely to still be raised. The effect of antihypertensives on renin and aldosterone levels (and the renin:aldosterone ratio) is shown below:

Medication Renin Aldosterone Overall Effect

Non-dihydropyridine CCB

(nifedipine, verapamil) Minimal Minimal No effect

Dihydropyridine CCB

(amlodipine) Minimal Decreased

(minimal) No effect

α -blockers Nil Nil No effect

Hydralazine Minimal Minimal No effect

ACE inhibitors Increased Decreased False negative

Diuretics Increased markedly Increased False negative

Minoxidil Increased Minimal False negative

Angiotensin receptor

blockers Increased Decreased False negative
 B-blockers Decreased Minimal False positive
 Methyl dopa Decreased Minimal False positive

[Q: 2393] OnExamination 2012 - Endocrinology

You are reviewing new potential targets for the treatment of type 2 diabetes.

When thinking about targets, which of the following is true?

- 1- GIP has a more potent effect on insulin release than GLP-1
- 2- Glucokinase activators should not cause hypoglycaemia
- 3- Metformin non-response is not usually genetic
- 4- PPAR gamma agonists increase bone mineral density
- 5- TCF7L2 mutations may be associated with a reduced incretin response

Answer & Comments

Answer: 5- TCF7L2 mutations may be associated with a reduced incretin response

Infusion of glucagon-like peptide 1 (GLP-1) leads to a more potent incretin effect than gastric inhibitory polypeptide (GIP), as such it is GLP-1 based therapies that have been the first incretin agents to be developed.

Glucokinase activators may lead to both enhanced insulin release and glycogen storage in the liver, as such they are known to cause hypoglycaemia. No glucokinase activators have yet made it to the clinic.

Mutations in organic cation transporters are known to be associated with differences in metformin response, and peroxisome proliferator activated receptor (PPAR) gamma agonists have been shown to reduce bone mineral density.

[Q: 2394] OnExamination 2012 - Endocrinology

A 26-year-old woman presents with concern about her weight gain and excessive hairiness. She has hair around her nipples and extending up from her groin, and is concerned that it is significantly affecting her self confidence.

She also finds it difficult to control her weight, having increased to over 16 stone in the past two to three years, and has periods only once every three to four months.

On examination she has a BP of 145/85 mmHg, a pulse of 75 and a BMI of 31 kg/m². She has midline hair spreading up to her navel, and around her areolae. She is obese, but otherwise there are no other abnormal findings.

Investigations show

Hb 13.0 g/dl (13.5-18)

WCC 6.0 x 10⁹/L (4-10)

PLT 193 x 10⁹/L (150-400)

Na 140 mmol/l (134-143)

K 4.4 mmol/l (3.5-5)

Gluc 6.1 g/dl (7.0-11.0)

Which of the following investigations would be most useful in supporting an underlying diagnosis of PCOS?

- 1- 17-OH progesterone
- 2- Abdominal ultrasound scan
- 3- LH:FSH ratio
- 4- Oral glucose tolerance test
- 5- Serum testosterone

Answer & Comments

Answer: 2- Abdominal ultrasound scan

Historically, a biochemical diagnosis of polycystic ovary syndrome (PCOS) was considered on the basis of a mild elevation of testosterone, and raised LH:FSH ratio.

It is recognised however that LH:FSH ratio is not always predictive of the presence of polycystic ovaries, so for this reason abdominal ultrasound scan is the investigation of choice.

Weight loss is the management of choice, and metformin has been used both to enhance weight loss and induce ovulation.

[Q: 2395] OnExamination 2012 - Endocrinology

You are visited by a 67-year-old woman who has a history of type 2 diabetes for the past six years, which was initially controlled with lifestyle and exercise, and then metformin 1 g twice daily. Her most recent HbA1c prior to clinic was 8.9%.

On examination she has a blood pressure of 145/89 mmHg, and a BMI of 29. You discuss options with her and come to the decision that insulin initiation would be the best option for her.

According to the ADA/EASD consensus, which of the following is the appropriate starting dose for intermediate acting insulin?

- 1- 0.1 U/kg
- 2- 0.2 U/kg
- 3- 0.7 U/kg
- 4- 1.0 U/kg
- 5- 1.5 U/kg

Answer & Comments

Answer: 2- 0.2 U/kg

0.2 U/kg or a flat dose of 10 U is the recommended starting dose for intermediate acting insulin.

A titration schedule based on fasting glucose levels is then recommended, with an increase of 2 U of insulin every three days until fasting glucose is in the target range of 3.9-7.2 mmol/l.

If the fasting plasma glucose is more than 10 mmol/l, then a more aggressive uptitration schedule of 4 U every three days can be considered.

[Q: 2396] OnExamination 2012 - Endocrinology

A 29-year-old female with Turner syndrome is referred by the GP concerned about her blood pressure which he has found to be persistently elevated at between 140-160/90 mmHg.

On examination she is noted to have a blood pressure of 148/92 mmHg, with no radio-femoral delay and no murmur audible.

Which of the following is the most likely cause of her hypertension?

- 1- Coarctation of the aorta
- 2- Essential hypertension
- 3- Primary hyperaldosteronism
- 4- Renal artery stenosis
- 5- Single horseshoe kidney

Answer & Comments

Answer: 2- Essential hypertension

Hypertension is quite common in Turner syndrome (10%) and is typically idiopathic - essential.

In a small proportion causes can include coarctation of the aorta and renal dysfunction due to horseshoe kidney.

In this case, essential hypertension is the most likely cause, and in the absence of specific features of coarctation this would again be the most appropriate option.

[Q: 2397] OnExamination 2012 - Endocrinology

A 18-year-old girl presents with anxiety and palpitations.

Her mother had been treated for an overactive thyroid gland having received radioiodine and was now on thyroxine replacement therapy.

On examination she had a pulse of 104 bpm with a fine tremor and lid lag. There was no goitre palpable.

Investigations revealed:

Serum Free T₄ 33 pmol/L (10-22)

Plasma thyroid stimulating hormone (TSH) <0.05 (0.4-5)

Serum antithyroid peroxidase (anti TPO) titre 40 U/L (<50)

What is the most likely cause of her symptoms?

- 1- Factitious thyrotoxicosis
- 2- Familial hyperthyroglobulinaemia
- 3- Graves' disease
- 4- Hashitoxicosis
- 5- Riedel's thyroiditis

Answer & Comments

Answer: 3- Graves' disease

Although the lead-in might make you think that this patient could gain access to thyroxine and so a diagnosis of factitious hyperthyroidism is possible, in practice this is extremely unlikely.

A strong family history of thyrotoxicosis is typical for Graves' disease and the absence of a goitre with the absence of TPO antibodies (found in 80% of Graves' cases) again is compatible with a diagnosis of Graves'.

[Q: 2398] OnExamination 2012 - Endocrinology

A 17-year-old female is referred following a visit to the dentist where marked erosion of her teeth was noted. She was entirely asymptomatic and her only medication was the oral contraceptive pill.

On examination her blood pressure was 110/70 mmHg and her body mass index was 21.5 kg/m² (18-25).

Investigations reveal:

Sodium 135 mmol/L(137-144)

Potassium 2.1 mmol/L(3.5-4.9)

Bicarbonate 42 mmol/L(20-28)

Urea 2.6 mmol/L(2.5-7.5)

Corrected Calcium 2.08 mmol/L(2.2-2.6)

Alkaline phosphatase 201 U/L(45-105)

What is the most likely diagnosis?

- 1- Bulimia nervosa
- 2- Conn's syndrome
- 3- Laxative abuse
- 4- Pregnancy
- 5- Primary hypoparathyroidism

Answer & Comments

Answer: 1- Bulimia nervosa

This patient has tooth erosion associated with hypokalaemic metabolic alkalosis and hypocalcaemia. This suggests a diagnosis of bulimia which may cause a mild hypocalcaemia.

Hypoparathyroidism is a possible answer but the alkaline phosphatase would be expected to be normal/low with this condition.

Again tooth erosion and the like is typical of primary hypoparathyroidism.

Conn's is unlikely in this age group, is not associated with tooth erosion and hypertension would be expected.

Laxative abuse would be associated with hypokalaemia but the hypocalcaemia with raised alkaline phosphatase would not be expected.

Early pregnancy would not fit this picture.

[Q: 2399] OnExamination 2012 - Endocrinology

Which of the following has a known association with phenylketonuria?

- 1- Musty odour.
- 2- Normal development.
- 3- Presentation in the second year of life with absence seizures.
- 4- Response of some patients to piridoxine.
- 5- The association of red hair and brown eyes.

Answer & Comments

Answer: 1- Musty odour.

Phenylketonuria is a quarter as common as congenital hypothyroidism, with an incidence of 1:10,000 live births.

It is due either to phenylalanine hydroxylase deficiency or problems with synthesis or recycling of the bipterin co-factor.

The presentation is with infantile spasms or developmental delay between 6 and 12 months of age. Patients may be musty smelling, fair haired and blue eyed and may develop eczema.

Treatment is with restriction of dietary phenylalanine, while ensuring sufficient for physical and neurological growth.

Co-factor defects are treated with a diet low in phenylalanine and high in neurotransmitter precursors.

[Q: 2400] OnExamination 2012 - Endocrinology

Which of the following is not associated with hyponatraemia and hyperkalaemia?

- 1- Acute hypoadrenalism
- 2- Carbenoxolone therapy
- 3- Co-amilofruse therapy
- 4- Congestive cardiac failure.

5- Type IV renal tubular acidosis

Answer & Comments

Answer: 2- Carbenoxolone therapy

Carbenoxolone therapy may be associated with hypokalaemia and salt retention due to pseudohypoaldosteronism through inhibition of the enzyme 11 beta hydroxysteroid dehydrogenase.

Type IV renal tubular acidosis is associated with hyporeninaemic hypoaldosteronism and both hyponatraemia and hyperkalaemia can occur.

Hypoadrenalism is associated with hyperkalaemia and hyponatraemia as is cardiac failure, hepatic and renal failure.

Co-amilofruse the combination of amiloride and furosemide may also produce this biochemical picture.

[Q: 2401] OnExamination 2012 - Endocrinology

Which of the following is a cause of the syndrome of inappropriate ADH secretion?

- 1- Bumetanide
- 2- Carbenoxolone
- 3- Dexamethasone
- 4- Fluoxetine
- 5- Lithium

Answer & Comments

Answer: 4- Fluoxetine

Selective serotonin reuptake inhibitors (SSRIs) are a recognised cause of syndrome of inappropriate antidiuretic hormone (SIADH).

Bumetanide would cause excess renal Na losses.

Carbenoxolone would cause apparent mineralocorticoid excess with hypokalaemia and salt retention as would dexamethasone.

Lithium causes diabetes insipidus.

[Q: 2402] OnExamination 2012 - Endocrinology

You are investigating a range of new agents for the treatment of inflammatory disorders, and are hoping to achieve steroid-like anti-inflammatory efficacy, without some of the known adverse effects.

Which of the following is the most important effect of corticosteroid therapy leading to increased risk of bone fracture?

- 1- Increased bone mineralisation
- 2- Increased osteoblast activity
- 3- Increased osteoblast apoptosis
- 4- Increased osteoclast activity
- 5- Increased osteoclast apoptosis

Answer & Comments

Answer: 3- Increased osteoblast apoptosis

Corticosteroids do not increase bone mineralisation, if anything they impact negatively on bone mineralisation.

They reduce osteoblast activity rather than increasing it.

Whilst corticosteroids do increase osteoclast activity, it is thought to be their effect on osteoblast activity which has a greater impact on bone mineral density.

[Q: 2403] OnExamination 2012 - Endocrinology

A 23-year-old woman presents to the hospital with a third attack of anxiety, abdominal pain and hypertension in the last six months.

On examination in the Emergency department her BP is 150/80 mmHg, pulse is 95 and

regular. She has generalised abdominal pain but her abdomen is soft and she has active bowel sounds.

Investigations show:

Haemoglobin 11.9 g/dl(11.5-16.0)

White cell count $10.9 \times 10^9/L$ (4-11)

Platelets $181 \times 10^9/L$ (150-400)

Sodium 131 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely cause of her hyponatraemia?

- 1- Addison's disease
- 2- Dehydration
- 3- Glomerulonephritis
- 4- Psychogenic polydipsia
- 5- Syndrome of inappropriate ADH

Answer & Comments

Answer: 5- Syndrome of inappropriate ADH

SIADH is associated with acute intermittent porphyria, the most likely diagnosis here. Hyponatraemia may contribute to a worsening of confusion and agitation and even convulsions where the sodium falls precipitously low.

Addison's seems unlikely in the absence of any elevation in potassium and no signs of hypovolaemia.

Similarly both dehydration and psychogenic polydipsia are not appropriate answers because the BP is not low and there are no signs of dehydration, and we have no history of polyuria.

Given that we are not presented with the results of urine testing, glomerulonephritis is not a correct option.

[Q: 2404] OnExamination 2012 - Endocrinology

A 51-year-old man presents with abdominal pain, stiffness and muscle spasms.

You understand that a few days earlier he injured himself when he stabbed a fork through his foot. He cleaned and dressed it himself, but refused to attend the Emergency Department for a check up.

On examination he is pyrexial 37.8°C, his pulse is 95 and his BP is 105/70 mmHg. He has obvious jaw and neck stiffness on examination and his abdominal muscles are held rigid. His left foot is erythematous with signs of local infection.

Investigations show:

Haemoglobin 12.9 g/dl(13.5-17.7)

White cell count 13.6 x 10(9)/l (4-11)

Platelets 180 x 10(9)/l (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 120 µmol/l (79-118)

Which of the following is the most appropriate next intervention?

- 1- Human tetanus immunoglobulin IV
- 2- Immediate debridement of the wound
- 3- Local application of tetanus toxoid
- 4- Metronidazole IV
- 5- Penicillin IV

Answer & Comments

Answer: 1- Human tetanus immunoglobulin IV

Debridement is incorrect because it should be delayed until a few hours after immunoglobulin has been administered.

Systemic antibiotics are largely disappointing. Whilst penicillin has been the traditional first choice, evidence suggests that where there is sensitivity to metronidazole, this is a better option.

Local application of human tetanus immunoglobulin has no value.

[Q: 2405] OnExamination 2012 - Endocrinology

A 62-year-old man with a 40 year history of type 1 diabetes comes to the renal clinic for review.

He has been referred by his GP because of a deteriorating GFR which has now fallen to 42 ml/min. His BP is actually well controlled at 115/72 mmHg on three oral agents and a recent HbA1c was measured at 7.2% (55 mmol/mol). He has 2+ proteinuria on dipstick testing.

Which of the following most accurately represents the average time his GFR will take to fall below 30 ml/min?

- 1- 1 year
- 2- 3 years
- 3- 5 years
- 4- 7 years
- 5- 9 years

Answer & Comments

Answer: 2- 3 years

Given that the progression of glomerular filtration rate (GFR) in patients with well controlled glucose and BP is established at 4 ml/min/year, all the other options apart from B must be incorrect.

More elevated glucose and BP would be associated with more rapid progression of GFR.

[Q: 2406] OnExamination 2012 - Endocrinology

A 23-year-old man is referred to the clinical pharmacology clinic with resistant hypertension. He is taking maximal ramipril

and amlodipine, yet his blood pressure is raised at 160/95 mmHg.

Further questioning reveals that his father and uncle both suffer from hypertension and have suffered haemorrhagic strokes in the past few years.

General clinical examination is unremarkable.

Investigations show:

Haemoglobin 13.9 g/dl(13.5-17.7)

White cell count $7.0 \times 10^9/L$ (4-11)

Platelets $180 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.2 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Renal ultrasound scan bilateral normal sized kidneys

He is given a trial of hydrocortisone and his blood pressure falls over a few weeks to 140/82 mmHg.

Which of the following is the most likely diagnosis?

- 1- Adrenal adenoma
- 2- Bilateral adrenal hyperplasia
- 3- Essential hypertension
- 4- Familial glucocorticoid remediable aldosteronism
- 5- Renal artery stenosis

Answer & Comments

Answer: 4- Familial glucocorticoid remediable aldosteronism

An adrenal adenoma or bilateral adrenal hyperplasia should not be responsive to corticosteroid therapy, ruling these out as possible scenarios.

Equally, essential hypertension is highly unlikely given hypokalaemia in the presence of maximal angiotensin-converting enzyme (ACE) inhibitor dose.

Finally, normal kidney size with no differential, and no bruits on clinical examination, whilst not ruling out renal artery stenosis, certainly diminishes the chances of this being the potential problem.

[Q: 2407] OnExamination 2012 - Endocrinology

A 62-year-old man with a history of type 2 diabetes comes to the nephrology clinic for review; he complains of increasing bony aches over the past few months.

His diabetes is managed with gliclazide, and he also takes ramipril, amlodipine, indapamide, atorvastatin and aspirin.

On examination his BP is 155/88 mmHg, his pulse is 82 and regular, his BMI is 29.

Investigations show:

Haemoglobin 10.4 g/dl(11.5-16.5)

White cells $8.4 \times 10^9/L$ (4-11)

Platelet $183 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 5.3 mmol/l (3.5-5)

Creatinine 187 $\mu\text{mol/l}$ (79-118)

Calcium 2.15 mmol/l (2.20-2.60)

Phosphate 1.9 mmol/l (0.8-1.5)

PTH 14.2 pmol/l (1-6.1)

PTH was 8.5 1 year earlier.

Which of the following is the most likely diagnosis?

- 1- Osteomalacia
- 2- Osteoporosis
- 3- Primary hyperparathyroidism
- 4- Secondary hyperparathyroidism
- 5- Tertiary hyperparathyroidism

Answer & Comments

Answer: 4- Secondary hyperparathyroidism

Phosphate retention and a lack of hydroxylated vitamin D drives increased levels of parathyroid hormone (PTH) as the body strives to retain calcium.

Patients with renal disease however are not treated for hyperparathyroidism until the PTH level breaches twice the upper limit of the normal range.

This is because of the risk of precipitating adynamic bone disease.

Usual first line therapy is weekly 1-alpha-calcidol.

A. Whilst decreased levels of hydroxylated vitamin D drive an increase in PTH, low vitamin D levels are not the primary pathology, so this answer is incorrect.

B. Osteoporosis is incorrect because the bloods we are provided with are consistent with metabolic bone disease.

C. Primary hyperparathyroidism is incorrect because the hyperparathyroidism is driven by chronic renal impairment.

D. Secondary hyperparathyroidism is the correct answer; the raised creatinine, borderline low calcium, raised phosphate are consistent with the condition.

E. Tertiary hyperparathyroidism is incorrect because of the relatively short duration of his bone and joint pains, and as yet uncorrected calcium and phosphate.

[Q: 2408] OnExamination 2012 - Endocrinology

A 33-year-old male with type 1 diabetes presents with a two day history of pain, swelling and redness in his left middle finger. This began after he pricked his finger in the garden whilst pruning a bush.

His diabetic control has been quite reasonable with a HbA1c of 7.1% (3.8-6.4) on basal bolus insulin consisting of Lispro tds and Humulin I in the evenings.

On examination he has a painful, red and swollen middle finger with the redness extending to the metacarpophalangeal joint. He is diagnosed with cellulitis.

What is the most appropriate treatment for this patient?

- 1- Admit to hospital for IV antibiotics
- 2- Oral flucloxacillin only
- 3- Oral metronidazole only
- 4- Oral penicillin V only
- 5- Oral penicillin V and flucloxacillin

Answer & Comments

Answer: 5- Oral penicillin V and flucloxacillin

The patient has digital cellulitis and the most likely organisms responsible are Strep. pyogenes or Staph. aureus.

The most appropriate treatment is penicillin V and flucloxacillin which should result in a rapid improvement.

If there is a deterioration then admission for IV antibiotics may be required but this should be unnecessary with appropriate antibiotic selection.

[Q: 2409] OnExamination 2012 - Endocrinology

A 38-year-old male presents with concerns relating to obesity.

What is the average daily energy used by a male of this age?

- 1- 1500 kcal
- 2- 2000 kcal
- 3- 2500 kcal
- 4- 3000 kcal
- 5- 3500 kcal

Answer & Comments

Answer: 3- 2500 kcal

The average daily energy consumption of a male is 2500 kcal and 2000 kcal for a female.

These values are important when determining the dietary calorie restriction.

[Q: 2410] OnExamination 2012 - Endocrinology

A 32-year-old female presents with a two month history of agitation, menstrual irregularity and weight loss.

Examination reveals a tremor and a palpable goitre with a bruit.

Which of the following would most likely be present in this patient?

- 1- Anti-thyroglobulin antibody
- 2- Thyroid microsomal antibodies
- 3- Thyroid peroxidase antibodies
- 4- TSH receptor inhibiting antibodies
- 5- TSH receptor stimulating antibodies

Answer & Comments

Answer: 5- TSH receptor stimulating antibodies

This patient is most likely to have Graves' disease as revealed by the thyroid bruit.

Thyroid-stimulating hormone (TSH) receptor stimulating antibody is specific for Graves' disease and is present in the vast majority of cases.

[Q: 2411] OnExamination 2012 - Endocrinology

A 64-year-old female is diagnosed with osteoporosis and is receiving treatment with raloxifene.

What is raloxifene?

- 1- A bisphosphonate
- 2- A selective androgen receptor modulator (SARM)

3- A selective oestrogen receptor modulator (SERM)

4- A synthetic oestrogen

5- An androgenic steroid

Answer & Comments

Answer: 3- A selective oestrogen receptor modulator (SERM)

Raloxifene, like tamoxifen is a SERM, with oestrogen-like activity at sites like bone but anti-oestrogen-like effects on breast/endometrium.

[Q: 2412] OnExamination 2012 - Endocrinology

A 37-year-old female presents with galactorrhoea.

She has a history of dyspepsia for which she receives omeprazole.

Examination reveals a BMI of 23.5 kg/m² and a small amount of galactorrhoea to expression.

Investigations show:

Prolactin 850 mU/L (50-500)

Oestradiol 88 pmol/L (130-500)

LH 3.2 mU/L (3.5-8)

FSH 2.8 mU/L (3-8)

What disorder should be considered?

- 1- Addison's disease
- 2- Drug-induced hyperprolactinaemia
- 3- Hyperthyroidism
- 4- Hypothyroidism
- 5- MEN type 1

Answer & Comments

Answer: 5- MEN type 1

The presence of hyperprolactinaemia with hypogonadotrophic hypogonadism suggests a diagnosis of a microprolactinoma and in combination with the recurrent dyspepsia a

diagnosis of multiple endocrine neoplasia (MEN) type 1 should be considered.

All the findings cannot be explained by omeprazole for which there are some case reports only of hyperprolactinaemia.

Addison's disease does not cause hyperprolactinaemia and neither hypothyroidism nor hyperthyroidism would fit this clinical scenario.

[Q: 2413] OnExamination 2012 - Endocrinology

A 23-year old woman with a history of type 1 diabetes, hypothyroidism and coeliac disease comes to the clinic complaining of increased tiredness and lethargy over the course of the past few months.

She is generally compliant with her insulin, thyroid medication and coeliac diet.

On examination her BP is 115/72 mmHg, pulse is 62 and regular, her BMI is 21. Apart from looking pale, her general physical examination is unremarkable.

Investigations show:

Haemoglobin 10.4 g/dl(11.5-16.0)

MCV 105 fL(80-96)

White cell count $5.1 \times 10^9/L$ (4-11)

Platelets $158 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.7 mmol/l (3.5-5)

Creatinine 110 micromol/l (79-118)

HbA1c 7.4%(<5.5)

Which of the following is the most likely diagnosis?

- 1- Addison's disease
- 2- Pernicious anaemia
- 3- Poor compliance with coeliac diet
- 4- Poor compliance with thyroid hormone replacement
- 5- Thyroid hormone resistance

Answer & Comments

Answer: 2- Pernicious anaemia

Given this patient is already suffering from three autoimmune conditions it is quite possible for her to acquire a fourth.

The picture of tiredness and lethargy, with a raised mean corpuscular volume (MCV) anaemia against a background of well controlled diabetes fits well with this. Her relatively good HbA1c gives us no reason to suspect poor compliance either with her insulin, coeliac diet or her thyroid medication.

Her electrolytes which are in the normal range make Addison's unlikely.

If she were poorly compliant with coeliac diet or thyroid hormone replacement, we would expect poor compliance with diabetes therapies and we have no evidence of that.

Thyroid hormone resistance would be associated with weight gain and symptoms of hypothyroidism.

[Q: 2414] OnExamination 2012 - Endocrinology

A 17-year-old woman presents with symptoms of severe lethargy and depression. According to her mother she eats minimal amounts and she suspects that her daughter is vomiting to reduce her calorie intake.

On examination her BMI is 16.5. She looks emaciated and there are scars on her knuckles consistent with induced vomiting. She has fine hairs covering her arms and legs.

Which of the following would you most expect to find on laboratory screening?

- 1- Decreased cortisol
- 2- Decreased potassium
- 3- Decreased TSH
- 4- Elevated sodium
- 5- Elevated TSH

Answer & Comments

Answer: 2- Decreased potassium

Cortisol levels if anything are increased, consistent with a stress response.

Thyroid-stimulating hormone (TSH) levels are not affected by anorexia and elevated sodium would only be expected in circumstances of severe dehydration.

[Q: 2415] OnExamination 2012 - Endocrinology

A 45-year-old man presents with joint pains and a flu-like illness a few weeks after returning from a walking holiday in the Austrian alps. He feels absolutely wretched and is unable to work because of fatigue.

On examination he is pyrexial 37.6°C, his pulse is 75 and his BP is 125/70 mmHg. He has arthralgia with limitation of movement affecting both knees and elbows. There is a circular rash on his left lower leg, he tells you he does not know how he got it.

Investigations show:

Haemoglobin 12.8 g/dl(13.5-17.7)

White cell count $10.9 \times 10^9/L$ (4-11)

Platelets $125 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

ESR 65 mm/hr(<10)

ALT 180 U/l (5-40)

Which of the following is the most likely diagnosis?

- 1- CMV infection
- 2- Hepatitis B
- 3- Lyme disease
- 4- Reactive arthritis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 3- Lyme disease

The raised alanine aminotransferase (ALT) may be indicative of a hepatic picture, but there is no pharyngitis to suggest a link to cytomegalovirus (CMV), nor is there any history of possible blood-borne transfer of hepatitis B.

Reactive arthritis follows either gastrointestinal or sexually transmitted infection, and the acute picture, coupled with features suggestive of infection, would not fit exactly with a diagnosis of rheumatoid.

[Q: 2416] OnExamination 2012 - Endocrinology

A 42-year-old man presents with severe hypertension and headaches. An adrenal tumour is identified on ultrasound scan and you are suspicious that this is a pheochromocytoma.

On further questioning it transpires his father died at an early age, and that his sister presented in a similar way with hypertension and was found to have an underlying tumour. You suspect MEN-2.

Which of the manifestations of MEN-2 has the most malignant potential?

- 1- C cell hyperplasia
- 2- Mucosal neuromas
- 3- Parathyroid hyperplasia
- 4- Pheochromocytoma
- 5- Renal disease

Answer & Comments

Answer: 1- C cell hyperplasia

Renal disease in multiple endocrine neoplasia type 2 (MEN-2) is characterised by stone, rather than tumour formation.

Mucosal neuromas and pheochromocytomas are generally not malignant, and parathyroid

hyperplasia, rather than adenoma formation tends to occur.

[Q: 2417] OnExamination 2012 - Endocrinology

A 64-year-old woman is taking long term amiodarone therapy for the management of paroxysmal atrial fibrillation.

She reports that over the past few months she has had mental slowing, weight gain and hair loss.

On examination her BP is 139/80 mmHg, her pulse is 48, and her BMI is 30. She has obviously thinning, dry hair. You measure her TSH which is elevated at 12 IU/l (0.5-4.5).

Which of the following is the most likely pathophysiological explanation for her hypothyroidism?

- 1- Desethylamiodarone driven inhibition of T3
- 2- Inhibition of type 1 5-deiodinase activity in peripheral tissues
- 3- Inhibition of type 2 5-deiodinase activity in the pituitary
- 4- Inhibition of T3 uptake into peripheral tissues
- 5- Iodine driven inhibition of thyroid hormone synthesis

Answer & Comments

Answer: 5- Iodine driven inhibition of thyroid hormone synthesis

Options A and B are known to precipitate an increase in thyroid hormone levels. A rise of between 20% and 40% is seen in patients between one and four months after starting amiodarone therapy.

As this may not necessarily constitute the development of thyrotoxicosis, treatment is not usually indicated without clinical symptoms of hyperthyroidism.

Inhibition of the entry of tri-iodothyronine (T3) into peripheral tissues also leads to a rise in thyroid hormones during the first few months after treatment.

Inhibition of type 2 5-deiodinase activity leads to a rise in thyroid-stimulating hormone (TSH) during the first one to two months after starting amiodarone, but levels usually return to normal about three to four months after starting therapy, and no intervention is required.

[Q: 2418] OnExamination 2012 - Endocrinology

Whilst hospitalised after a hip replacement, a patient with acute intermittent porphyria has a tonic clonic seizure. The seizure was thought to have been due to alcohol withdrawal. The patient required large amounts of analgesia. Six days post-operatively she suffers a porphyric attack.

Which of the following drugs on her prescription is likely to have been responsible?

- 1- Aspirin
- 2- Augmentin
- 3- Oramorph
- 4- Paracetamol
- 5- Sodium valproate

Answer & Comments

Answer: 5- Sodium valproate

AIP is an autosomal dominant disease resulting from defects in production or activity of the enzyme porphobilinogen (PBG) deaminase. Attacks may be precipitated by fasting, and by many drugs, such as phenobarbitone, alcohol, sulphonylureas and oestrogens. Amoxicillin and opiates are thought to be safe in porphyria.

More reading

[Q: 2419] OnExamination 2012 - Endocrinology

A 35-year-old woman with a five year history of treated hypothyroidism presented following an episode of vomiting and collapse. There was a short history of weight loss.

On examination she had a temperature of 37.7°C, a blood pressure of 80/40 mmHg and vitiligo.

Which one of the following, given intravenously, would be the most appropriate initial management?

- 1- 10% dextrose infusion
- 2- Cefotaxime
- 3- Fludrocortisone
- 4- Hydrocortisone
- 5- Tri-iodothyronine

Answer & Comments

Answer: 4- Hydrocortisone

This patient is likely to have Addison's disease based upon her history, autoimmune disease, and presentation.

She requires treatment with intravenous hydrocortisone which can be a lifesaving manoeuvre in acute hypoadrenalism.

[Q: 2420] OnExamination 2012 - Endocrinology

A 20-year-old man with asthma was found to be hypertensive.

Investigations revealed:

Serum Sodium 144 mmol/L (137-144)

Serum potassium 2.4 mmol/L (3.5-4.9)

Serum bicarbonate 30 mmol/L (20-28).

Which one of the following is the most likely diagnosis?

- 1- Bartter's syndrome
- 2- Coarctation of the aorta

- 3- Congenital adrenal hyperplasia
- 4- Conn's syndrome
- 5- Inhaled salbutamol therapy

Answer & Comments

Answer: 4- Conn's syndrome

This is a tough question as a number of answers are possible.

This young asthmatic has a hypokalaemic hypertension and it is assumed that his hypertension is sustained.

This would therefore suggest a secondary cause which may be either hyperaldosteronism or pseudohyperaldosteronism.

A rare CAH (11-beta hydroxysteroid dehydrogenase [11-BHSD] deficiency) may be responsible for hypokalaemic hypertension and the presentation is variable ranging from birth to adulthood but typically birth.

Bartter's syndrome is not associated with hypertension.

Conn's syndrome is usually found in middle aged patients and would be unusual in a patient of this age but even so is probably the best answer here.

Liquorice ingestion could fit this picture but would again be somewhat unusual in this patient.

Salbutamol may cause hypokalaemia particularly when given via nebuliser or particularly intravenously but should not produce hypertension.

[Q: 2421] OnExamination 2012 - Endocrinology

Which of the following is true of IGF-1 concentrations?

- 1- Concentrations are elevated in diabetes mellitus

- 2- Concentrations are elevated in hepatic cirrhosis
- 3- Concentrations are reduced in pregnancy
- 4- Concentrations are reduced in starvation
- 5- Concentrations are usually elevated in adult growth hormone deficiency (GHD)

Answer & Comments

Answer: 4- Concentrations are reduced in starvation

IGF-1 concentrations are often increased in pregnancy.

Reduced IGF-1 is typically found in adult GHD.

Reduced synthesis can be due to cirrhosis of the liver, diabetes mellitus or starvation.

[Q: 2422] OnExamination 2012 - Endocrinology

Which of the following is correct regarding the peroxisome proliferator activated receptor gamma (PPAR gamma)?

- 1- Is a G-protein coupled receptor
- 2- Is a member of the cytokine receptor superfamily
- 3- Is activated by free fatty acid as the endogenous ligand
- 4- Is antagonised by low density lipoprotein (LDL).
- 5- Is antagonised by thiazolidinediones

Answer & Comments

Answer: 3- Is activated by free fatty acid as the endogenous ligand

PPAR gamma is an intracellular receptor that is activated by free fatty acids (which are the natural endogenous ligands) and the thiazolidinediones such as pioglitazone.

On ligand binding it associates with the retinoid X receptor and couples with DNA

producing downstream gene activation with protein synthesis that controls adipocyte differentiation and function and is also related to cellular anti-inflammatory effects.

Two licensed medications existed in the thiazolidinedione class, rosiglitazone and pioglitazone, but rosiglitazone has been suspended from the European market due to concerns about its benefit:risk ratio.

[Q: 2423] OnExamination 2012 - Endocrinology

Which of the following techniques would be most useful in the differential diagnosis between ectopic Cushing's syndrome and pituitary dependent Cushing's disease?

- 1- ACTH concentrations
- 2- CRF test
- 3- High dose dexamethasone suppression test
- 4- Inferior petrosal sinus sampling
- 5- Urine free cortisol

Answer & Comments

Answer: 4- Inferior petrosal sinus sampling

Inferior petrosal sinus sampling with an elevated central adrenocorticotrophic hormone (ACTH) concentration compared with the peripheral value is the most valuable test in the differential diagnosis of either Cushing's disease or ectopic Cushing's syndrome.

The other tests are far less useful in comparison.

[Q: 2424] OnExamination 2012 - Endocrinology

A 33-year-old woman with a history of Graves' disease is referred for thyroidectomy as she has young children, plans further additions to her family and therefore does not want radioiodine therapy.

You are counselling her as to the risks of surgery.

Which of the following is the most likely post-operative complication?

- 1- Bleeding
- 2- Infection
- 3- Recurrent laryngeal nerve palsy
- 4- Superior laryngeal nerve palsy
- 5- Transient hypoparathyroidism

Answer & Comments

Answer: 5- Transient hypoparathyroidism

Infection is seen in 1-2% of patients undergoing thyroidectomy.

Bleeding is less common, seen in around 0.5% or less of patients undergoing the operation. Bleeding risks have fallen significantly due to improvements in surgical technique.

Permanent recurrent laryngeal nerve palsy occurs in 1% of patients; superior laryngeal nerve palsy affects more patients (3-4% in case series).

[Q: 2425] OnExamination 2012 - Endocrinology

A 45-year-old woman comes to the clinic for review.

She takes long term risperidone for schizophrenia. There is also a history of hypertension for which she takes bendroflumethiazide, ramipril and amlodipine. She also uses ranitidine for gastro-oesophageal reflux disease.

On examination her BP is 155/92 mmHg, her pulse is 68 and regular. Her BMI is 33. Unfortunately a fasting plasma glucose is elevated, measured at 9.2 mmol/l.

Which of the following agents is most likely to have contributed to her presentation with diabetes?

- 1- Amlodipine

- 2- Bendroflumethiazide

- 3- Ramipril

- 4- Ranitidine

- 5- Risperidone

Answer & Comments

Answer: 5- Risperidone

Both typical antipsychotics and antihypertensives, (thiazides and beta blockers), have been shown in meta-analyses to be associated with impaired glucose tolerance and increased risk of type 2 diabetes.

The risk is relatively larger for risperidone than thiazides however, so it is risperidone which is the correct answer here.

One epidemiology study suggested a relative risk for development of diabetes of 1.6, versus controls not taking risperidone.

Amlodipine, ramipril and ranitidine are not thought to be associated with increased risk of impaired glucose tolerance or type 2 diabetes.

Bendroflumethiazide and atenolol were shown in a meta-analysis of blood pressure lowering to be associated with impaired glucose tolerance, although on an individual patient basis, this risk is less than that for risperidone.

[Q: 2426] OnExamination 2012 - Endocrinology

A 70-year-old woman is referred by her GP with a breast lump.

She was asymptomatic but her investigations reveal:

Corrected Calcium 2.72 mmol/L(2.2-2.6)

Phosphate 0.80 mmol/L(0.8-1.4)

Alkaline phosphatase 110 U/L(45-105)

PTH concentration 5.1 pmol/L(0.9-5.4)

What is the most likely diagnosis?

- 1- Bony metastases
- 2- Chronic vitamin D excess
- 3- Ectopic PTH related peptide (PTHrp) secretion
- 4- Multiple myeloma
- 5- Primary hyperparathyroidism

Answer & Comments

Answer: 5- Primary hyperparathyroidism

This patient has hypercalcaemia with a borderline low phosphate concentration but an inappropriately normal parathyroid hormone (PTH) concentration.

In primary hyperparathyroidism the PTH may be normal or high because the feedback loop in which calcium drives down PTH production is lost.

This suggests hyperparathyroidism, which is a relatively common disorder amongst elderly females.

The story of the breast lump in this case is endeavouring to mislead the candidate.

Vitamin D excess would be expected to cause an elevated phosphate.

[Q: 2427] OnExamination 2012 - Endocrinology

A 47-year-old female of Asian origin presents with a long history of deteriorating weakness and fatigue. Of late, she has difficulty ascending stairs at home and needs to crawl up them.

She has a six year history of type 2 diabetes mellitus and is treated with metformin and gliclazide. Initial x rays reveal healing clavicular fractures, and a superior pubic rami fracture.

Her investigations show:

Calcium 2.2 mmol/l (2.2-2.5)

Phosphate 0.7 mmol/l (0.8-1.5)

Alkaline phosphatase 212 U/L(50-110)

AST 30 U/L(5-40)

Urea 12 mmol/l (3-8)

Creatinine 67 mol/l (50-100)

HbA1c 11.0%(4-6%)

What is the likely diagnosis?

- 1- Advanced diabetic renal disease
- 2- Diabetic amyotrophy
- 3- Hypoparathyroidism
- 4- Osteoporosis
- 5- Vitamin D deficiency

Answer & Comments

Answer: 5- Vitamin D deficiency

This patient has vitamin D deficiency.

It classically presents in the female Asian population whose clothing offers little exposure to sunlight. The phosphate and calcium are usually low normal, and the alkaline phosphatase is high.

Bone deformity or rickets may develop in children. Fractures can occur due to bone demineralisation with osteoporosis on DEXA.

Proximal myopathy is often a presenting feature of osteomalacia as is probably the case with this patient.

[Q: 2428] OnExamination 2012 - Endocrinology

A 21-year-old male is referred to the endocrine clinic with poorly developed secondary sexual characteristics. The only relevant finding on history is that he has a very poor sense of smell.

On examination he has no axillary or pubertal hair, a 3 cm penis and testicular volumes of approximately 5 ml bilaterally. Smell test reveals that he is unable to distinguish acetone and coffee.

Investigations reveal:

Testosterone 4 nmol/l (10-30)

Prolactin 380 mU/l (<450)

FSH 2.1 IU/l (1-7)

LH 1.5 IU/l (1-10)

What is the most likely diagnosis?

- 1- 5-alpha reductase deficiency
- 2- Craniopharyngioma
- 3- Kallman's syndrome
- 4- Klinefelter's syndrome
- 5- Microdeletion of the Y chromosome

Answer & Comments

Answer: 3- Kallman's syndrome

This patient has evidence of hypogonadotrophic hypogonadism with a low testosterone and a low follicle-stimulating hormone (FSH) and luteinising hormone (LH). In this case, there is isolated gonadotrophic deficiency as evidenced by a normal prolactin. This is seen in Kallman's syndrome, which is often associated with anosmia.

In Klinefelter's syndrome an elevated LH/FSH would be expected, as this is due to testicular failure as would be the case in 5-alpha reductase deficiency.

Craniopharyngioma is a possibility as it does cause hypogonadotrophic hypogonadism but abnormalities in sense of smell would not be expected.

[Q: 2429] OnExamination 2012 - Endocrinology

Which of the following hormones acts through cyclic AMP as the second messenger?

- 1- Insulin
- 2- Oestradiol
- 3- PTH
- 4- TRH

5- Triiodothyronine

Answer & Comments

Answer: 3- PTH

Unlike steroids (progesterone, testosterone, oestradiol and cortisol) other ionic hormones such as:

Adrenaline

Growth hormone-releasing hormone (GHRH)

Glucagon

Luteinising hormone (LH)

Follicle stimulating hormone (FSH)

Parathyroid hormone (PTH)

Thyroid-stimulating hormone (TSH)

are unable to pass the plasma membrane acting upon cell surface receptors and then through cyclic adenosine monophosphate (cAMP) as the second messenger.

Insulin acts through mitogen-activated protein (MAP) kinase pathway, as does growth hormone (GH) and prolactin.

Thyroid releasing hormone (TRH)

Gonadotrophin-releasing hormone (GnRH)

Antidiuretic hormone (ADH)

act through calcium/phosphoinositide.

Nitric oxide and atrial natriuretic peptide (ANP) act through cyclic guanosine monophosphate (cGMP).

Triiodothyronine (T3) acts by binding to intracellular receptors.

[Q: 2430] OnExamination 2012 - Endocrinology

A 60-year-old woman with a two year history of diet-controlled type 2 diabetes was admitted with an acute myocardial infarction (MI). She received thrombolysis together with

an insulin infusion and has done well. Discharge medication includes ramipril and furosemide for mild biventricular failure post infarct.

Investigations revealed a fasting glucose of 12 mmol/l (3.0-6.0) together with a cholesterol of 6.6 mmol/l (<5.2). Her HbA1c was 7.6%.

Which of the following is the most appropriate treatment for her subsequent glycaemic control?

- 1- Continue diet alone
- 2- Gliclazide modified release
- 3- Metformin
- 4- Pioglitazone
- 5- Subcutaneous insulin

Answer & Comments

Answer: 5- Subcutaneous insulin

Following DIGAMI 1 study it was assumed that three months of insulin was appropriate post-MI.

However, DIGAMI 2, which specifically looked at mortality, found no differences between control with oral hypoglycaemic agents (OHAs), insulin or routine metabolic management.

Her mild cardiac failure would count against use of pioglitazone.

In the BNF, metformin is listed as contraindicated within six weeks of MI. Therefore, in this patient we should aim for tighter glycaemic control and probably subcutaneous insulin would be most appropriate here in the first instance, with an early review of glycaemic control at six weeks.

The option then would be to switch to metformin.

[Q: 2431] OnExamination 2012 - Endocrinology

A 51-year-old man is found to have bilateral

breast enlargement.

He says that this is normal for him and that he has not noted any change in years. He shaves infrequently and has scant pubic hair.

Which of the following is most likely to be present?

- 1- 47, XXY karyotype
- 2- History of antidepressant drug therapy
- 3- Increased risk for breast carcinoma
- 4- Increased testosterone levels
- 5- Seminoma of the testis

Answer & Comments

Answer: 1- 47, XXY karyotype

Gynaecomastia is common with Klinefelter's syndrome.

Male breast cancer is rare and is more often associated with advanced age.

There is an association between gynaecomastia and some functioning testicular tumours such as Leydig cell tumours (or rarely, Sertoli cell tumours).

Gynaecomastia is related to conditions of high oestrogens, and one of the most common causes for this is cirrhosis of the liver in chronic alcoholics.

[Q: 2432] OnExamination 2012 - Endocrinology

A previously fit 47-year-old male presents with lower back pain from a vertebral collapse due to osteoporosis.

Which of the following investigations would be the most appropriate for this man?

- 1- Oestrogen concentration
- 2- Prolactin concentration
- 3- Prostate-specific antigen concentration
- 4- Testosterone concentration
- 5- Thyroid function tests

Answer & Comments

Answer: 4- Testosterone concentration

Osteoporosis in a young male would be unusual.

Any symptoms or features of hypogonadism or hypercalcaemia should be elicited.

Hyperprolactinaemia causes hypogonadism so a testosterone concentration would be far more relevant.

Hyperthyroidism would need to be present for a considerable length of time before producing osteoporosis.

Hypogonadism often goes unnoticed.

Prostate malignancy does not cause osteoporosis.

[Q: 2433] OnExamination 2012 - Endocrinology

In randomised clinical studies which of the following is correct regarding post-menopausal hormone replacement therapy (HRT)?

- 1- Causes regression of coronary plaques.
- 2- Increases plasma LDL concentrations.
- 3- Increases plasma triglycerides
- 4- Reduces cardiovascular mortality.
- 5- Reduces the incidence of stroke

Answer & Comments

Answer: 3- Increases plasma triglycerides

In randomised controlled trials (RCTs), HRT has not been shown to reduce cardiovascular (CV) mortality or the incidence of stroke (heart [o]estrogen replacement study - HERS), nor does it cause regression of coronary plaques ([o]estrogen replacement and angiography study - ERA).

In fact HRT has been shown to have an increased CV morbidity in the WHI study.

It does not produce a raised low density lipoprotein (LDL) but may increase high density lipoprotein (HDL) concentrations. Similarly it frequently produces a rise in triglyceride concentrations.

[Q: 2434] OnExamination 2012 - Endocrinology

Adult growth hormone deficiency (GHD) is confirmed by which of the following?

- 1- A low IGF-1 concentration
- 2- A low IGF binding protein-3 (IGFBP3) concentration
- 3- A peak growth hormone concentration of 6 mU/l (2 microg/l) with insulin-induced hypoglycaemia
- 4- An undetectable random growth hormone concentration.
- 5- Suppression of GH below 2 mU/l (1.3 microg/l) with an oral glucose tolerance test

Answer & Comments

Answer: 3- A peak growth hormone concentration of 6 mU/l (2 microg/l) with insulin-induced hypoglycaemia

The diagnosis of adult GHD depends on a peak GH response of less than 9 mU/l to insulin-induced hypoglycaemia.

[Q: 2435] OnExamination 2012 - Endocrinology

A 54-year-old woman comes to visit her daughter who is a student in London. She currently lives in central Africa and has had problems with lethargy and tiredness for some time.

On examination in the clinic her BP is 145/89 mmHg, pulse is 62 and regular. She has a large diffuse goitre on examination of her neck.

Investigations show:

Haemoglobin 12.0 g/dl(11.5-16.0)

White cell count $7.1 \times 10^9/L$ (4-11)

Platelets $207 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 112 $\mu\text{mol/l}$ (79-118)

TSH 12 IU/l (0.5-4.5)

Which of the following is the most likely diagnosis?

- 1- Graves' disease
- 2- Hashimoto's thyroiditis
- 3- Iodine deficiency
- 4- Non-toxic multinodular goitre
- 5- Toxic multinodular goitre

Answer & Comments

Answer: 3- Iodine deficiency

Graves' disease is associated with thyrotoxicosis.

Hashimoto's would have been an alternative diagnosis, but the history of inhabiting central Africa is the pointer to iodine deficiency.

Toxic multinodular goitre is associated with thyrotoxicosis, and the fact she is hypothyroid rules out non-toxic multinodular goitre.

[Q: 2436] OnExamination 2012 - Endocrinology

A 51-year-old man with hypertension, morbid obesity and type 2 diabetes is diagnosed with pituitary-dependent Cushing's.

He is managed with three antihypertensives, metformin and gliclazide, yet his pre-operative BP is elevated at 175/100 mmHg, his BMI is 32 and his fasting glucose is 11.2 mmol/l.

Which of the following is most appropriate to improve his metabolic parameters prior to surgery?

- 1- Insulin

2- Metyrapone

3- Mitotane

4- Octreotide

5- Somatotrophin

Answer & Comments

Answer: 2- Metyrapone

Insulin may be an option to improve glycaemic control pre-surgery but it is likely to result in further weight gain and may therefore exacerbate hypertension.

Mitotane has a more delayed onset of action and as such it is less appropriate for pre-surgical use.

Cushing's has no response to octreotide in the majority of patients and somatotrophin, growth hormone, has no value.

[Q: 2437] OnExamination 2012 - Endocrinology

A 32-year-old woman with a history of type 1 diabetes for many years comes to the clinic with rapidly worsening lethargy and nausea.

She takes a basal bolus insulin regime and her most recent HbA1c demonstrated good control.

On examination she looks tanned, her BP is 95/60 mmHg. Her BMI is 19.

Investigations show:

Haemoglobin 11.0 g/dl (11.5-16.5)

White cell count $6.9 \times 10^9/L$ (4-11)

Platelets $162 \times 10^9/L$ (150-400)

Sodium 128 mmol/l (135-146)

Potassium 4.5 mmol/l (3.5-5)

Creatinine 145 $\mu\text{mol/l}$ (79-118)

Urea 8.2 mmol/l (2.5-6.7)

Glucose 5.9 mmol/l (<7.0)

Morning cortisol 100 nmol/l (>140)

Which of the following is true of her underlying condition?

- 1- 75% of patients have circulating anti-adrenal antibodies
- 2- Fludrocortisone replacement is guided by serum electrolytes and postural blood pressure
- 3- It is likely to be related to pituitary failure
- 4- Pernicious anaemia occurs less commonly in patients with this diagnosis
- 5- Two-thirds of hydrocortisone replacement should be taken in the evening

Answer & Comments

Answer: 2- Fludrocortisone replacement is guided by serum electrolytes and postural blood pressure

Replacement of hydrocortisone is skewed so that 2/3rds of the dose is given in the morning with 1/3rd given in the evening.

Given that increased skin colouration is related to high circulating levels of adrenocorticotrophic hormone (ACTH), autoimmune adrenal failure is the most likely cause. Autoimmune adrenal failure is a primary T cell disease, although 50% of patients have circulating anti-adrenal antibodies.

Other autoimmune conditions such as pernicious anaemia and thyroid disease occur more commonly in association with Addison's.

[Q: 2438] OnExamination 2012 - Endocrinology

A 46-year-old man presents passing 4-5 litres of urine per day after commencing a new drug.

Tests show:

Serum Sodium 142 mmol/l (137-144)

Plasma osmolality 295 mosmol/l (275-290)

Urine osmolality 280 mosmol/l (350-1000)

What drug was prescribed?

- 1- Carbamazepine
- 2- Chlorpropamide
- 3- Fluoxetine
- 4- Furosemide
- 5- Lithium

Answer & Comments

Answer: 5- Lithium

The patient appears to have a drug-induced diabetes insipidus based upon the high urine output, low urine osmolality and the high plasma osmolality.

The most likely cause is lithium.

Chlorpropamide causes a SIADH as does carbamazepine and fluoxetine.

Furosemide is another possibility but if it had dried the patient out the plasma sodium would be expected to be higher.

It is most likely that the patient has started lithium for a psychiatric disorder.

A 46-year-old man would be unlikely to be receiving high doses of furosemide.

[Q: 2439] OnExamination 2012 - Endocrinology

A 62-year-old female with a six year history of type 2 diabetes attends for annual review.

Her HbA1c is 10% (3.8-6.4).

Into what average plasma glucose concentration does her HbA1c translate?

- 1- 7.5 mmol/l
- 2- 10 mmol/l
- 3- 12.5 mmol/l
- 4- 15.5 mmol/l
- 5- 19 mmol/l

Answer & Comments

Answer: 4- 15.5 mmol/l

The HbA1c is an important reflection of control over a three month period (life expectancy of the erythrocyte).

There is a good relationship between the rise in glucose and its ability to glycosylate the Hb molecule (there is a difference between average plasma glucose and blood glucose).

Thus a HbA1c of 7% would translate into an average plasma (higher than value of blood glucose) glucose of 9.5 mmol/l and a HbA1c of 10% into 15.5 mmol/l.

This is the reason why so much emphasis is placed on controlling HbA1c rather than the specific glucose measurements, as these vary so much throughout the day.

This is a difficult question and it is very unlikely that you would be asked to translate average blood glucose into an exact HbA1c figure without being provided with a conversion calculator; however, the learning point here is that you realise that the numerical values are not the same.

[Q: 2440] OnExamination 2012 - Endocrinology

Which of the following is true of radioactive iodine (¹³¹I) therapy?

- 1- Causes hypothyroidism in 90% of treated patients within three months
- 2- Causes a deterioration in ophthalmopathy in patients with Graves' disease
- 3- Is associated with a subsequently increased risk of infertility
- 4- Is associated with an increased risk of thyroid lymphoma
- 5- Is the preferred treatment in amiodarone induced thyrotoxicosis

Answer & Comments

Answer: 2- Causes a deterioration in ophthalmopathy in patients with Graves' disease

RAI is associated with the induction of hypothyroidism in the majority of subjects by three months (70%) with 10% failing at the first dose at about 18 months.

It may precipitate deterioration in ophthalmopathy in patients with Graves'.

There is no evidence of either increased risk of infertility or lymphoma after RAI with evidence suggesting that it is quite safe.

Withdrawing amiodarone is the preferred treatment in amiodarone induced thyrotoxicosis and often the iodine uptake would be low in these patients making ¹³¹I therapy unhelpful.

[Q: 2441] OnExamination 2012 - Endocrinology

A 50-year-old man presents with a diagnosis of acromegaly but has normal visual fields.

Which of the following is the most appropriate treatment for this patient?

- 1- Bromocriptine
- 2- Cabergoline
- 3- Radiotherapy
- 4- Somatostatin analogue therapy
- 5- Trans-sphenoidal hypophysectomy

Answer & Comments

Answer: 5- Trans-sphenoidal hypophysectomy

The most appropriate treatment for acromegaly in this middle aged man which may prove curative is surgery.

Somatostatin therapy, although frequently effective in reducing growth hormone (GH), would not be advocated in a young patient who would require lifelong therapy.

[Q: 2442] OnExamination 2012 - Endocrinology

Which of the following may be responsible for a hypokalaemic hypertension?

- 1- Bartter's syndrome
- 2- Diabetic nephropathy
- 3- Liddle's syndrome
- 4- Non-classical congenital adrenal hyperplasia
- 5- Type IV renal tubular acidosis (RTA)

Answer & Comments

Answer: 3- Liddle's syndrome

Liddle's syndrome is typically associated with hypokalaemic hypertension and low renin and aldosterone concentrations - the so-called pseudo-hyperaldosteronism.

Bartter's syndrome is associated with hypokalaemia, though hypertension is not a feature.

In type IV RTA, there is a hyporeninaemic hypoaldosteronism, which may also be produced with diabetic nephropathy, hence hyperkalaemia is more typical.

[Q: 2443] OnExamination 2012 - Endocrinology

Which of the following is true concerning testosterone?

- 1- Acts via cell surface receptors
- 2- Acts via G protein second messengers
- 3- In the circulation is mostly bound to albumin
- 4- Is a steroid hormone
- 5- Is manufactured through the breakdown of oestradiol

Answer & Comments

Answer: 4- Is a steroid hormone

Testosterone is a steroid hormone receptor and can be converted to oestradiol.

It binds to intracellular receptors and is mostly bound to sex-hormone binding globulin.

[Q: 2444] OnExamination 2012 - Endocrinology

A patient is receiving treatment with recombinant human growth hormone (GH).

Which of the following is a recognised side effect of GH therapy?

- 1- Benign intra-cranial hypertension (BIH)
- 2- Melanoma
- 3- Osteoporosis
- 4- Prolongation of the QT interval
- 5- Prostatic hypertrophy

Answer & Comments

Answer: 1- Benign intra-cranial hypertension (BIH)

GH is rarely associated with BIH, the mechanism probably is related to fluid retention.

The commonest side effect of GH therapy is fluid retention, though other side effects include gynaecomastia, hypertension and atrial fibrillation.

Benign prostatic hyperplasia (BPH) has not been reported.

[Q: 2445] OnExamination 2012 - Endocrinology

A 22-year-old woman presented with hirsutism and oligomenorrhea for the last five years.

She is an accountancy trainee and does not want to conceive at least for the next couple of years. She is very anxious about her irregular menses and is especially worried as

her mother was diagnosed with uterine cancer recently.

Examination is essentially normal apart from coarse dark hair being noticed under her chin and over her lower back.

Investigations during the follicular phase:

Serum androstenedione 10.1 nmol/l (0.6-8.8)

Serum dehydroepiandrosterone sulphate 11.6 µmol/l (2-10)

Serum 17-hydroxyprogesterone 5.6 nmol/l (1-10)

Serum oestradiol 220 pmol/l (200-400)

Serum testosterone 3.6 nmol/l (0.5-3)

Serum sex hormone binding protein 32 nmol/l (40-137)

Plasma luteinising hormone 3.3 U/l (2.5-10)

Plasma follicle-stimulating hormone 3.6 U/l (2.5-10)

What is the most appropriate treatment?

- 1- Combined OCP
- 2- Finasteride
- 3- Metformin
- 4- Progesterone only pill
- 5- Spironolactone

Answer & Comments

Answer: 1- Combined OCP

This young woman has typical features of polycystic ovary syndrome (PCOS), with supportive biochemistry elevated androstenedione, normal oestradiol and 17OHP.

She wants treatment of her hirsutism, does not want to fall pregnant and the most appropriate therapy would be the combined oral contraceptive pill (OCP) such as Dianette.

[Q: 2446] OnExamination 2012 - Endocrinology

A 39-year-old male presents with gynaecomastia.

Which of the following is the most likely cause of his gynaecomastia?

- 1- Congenital adrenal hyperplasia (CAH)
- 2- Hypopituitarism
- 3- Hypothyroidism
- 4- Prolactinoma
- 5- Seminoma

Answer & Comments

Answer: 5- Seminoma

Gynaecomastia is due to a perturbation in the testosterone to oestradiol ratio.

Neither hyperprolactinaemia nor hypopituitarism disturb this ratio and are rarely associated with gynaecomastia.

Unlike hyperthyroidism, hypothyroidism is not a cause.

CAH is not a cause.

However, gynaecomastia may be a presenting symptom of a seminoma and may arise due to human chorionic gonadotropin (HCG) secretion.

[Q: 2447] OnExamination 2012 - Endocrinology

A 31-year-old man presents to the clinic with decreased libido and problems maintaining his erection.

At first he consulted his GP and was told that his problems were most likely to be psychological.

Clinical examination is unremarkable with a BP of 122/80 mmHg and a pulse of 65 and regular. His prolactin level is elevated at 2900 mU/l.

Which of the following is the most likely cause?

- 1- Drug induced hyperprolactinaemia
- 2- Hypothyroidism
- 3- Incidental finding
- 4- Macroprolactinoma
- 5- Microprolactinoma

Answer & Comments

Answer: 5- Microprolactinoma

Drug induced hyperprolactinaemia tends to be associated with levels less than 1000, as does hypothyroidism.

Given his symptoms and the degree of elevation, the prolactin level could not be considered incidental.

Macroprolactinomas tend to be associated with prolactin levels above 3000.

[Q: 2448] OnExamination 2012 - Endocrinology

A 49-year-old city worker attends the clinic for review because of gynaecomastia and erectile dysfunction.

He has mild hypertension for which he takes amlodipine 5 mg daily, but no other past medical history of note. He admits to working long hours and spends a great deal of time entertaining clients.

On examination his BP is 145/82 mmHg, his pulse is 70 and regular and his BMI is 31. He has obvious bilateral gynaecomastia.

Investigations show:

Haemoglobin 10.5 g/dl(13.5-17.7)

White cell count $6.8 \times 10^9/L$ (4-11)

Platelets $197 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 117 $\mu\text{mol/l}$ (79-118)

Alkaline phosphatase 130 U/l (39-117)

Alanine aminotransferase 160 U/l (5-40)

Which of the following is the most likely diagnosis?

- 1- Chronic alcoholism
- 2- Cushing's syndrome
- 3- Haemochromatosis
- 4- Klinefelter's syndrome
- 5- Simple obesity

Answer & Comments

Answer: 1- Chronic alcoholism

Given the history we are provided with, and the fact this patient only has mild obesity and controlled hypertension, Cushing's is unlikely.

Haemochromatosis could be considered if when challenged, this patient denied excess alcohol consumption.

Klinefelter's would not fit well with this phenotype and earlier presentation would be expected.

Simple obesity should not be associated with other medical conditions.

[Q: 2449] OnExamination 2012 - Endocrinology

A 28-year-old woman with a history of hypothyroidism comes to the clinic for review. She is happy to tell you that she is ten weeks pregnant with her first child.

She normally takes 100 mcg of thyroxine daily, and her TSH has been stable at 1.2 for the past two to three years.

Which of the following represents the correct advice with respect to managing her thyroxine dose in pregnancy?

- 1- She should reduce the dose to 75 mcg for fear of inducing foetal hyperthyroidism
- 2- She will probably be able to remain on 100 mcg for the duration of the pregnancy

- 3- She will probably need to increase the dose to 150 mcg during the pregnancy
- 4- She will probably need to increase the dose to 150 mcg immediately post-partum to cope with feeding the child
- 5- She will probably need to increase the dose to 200 mcg during the pregnancy

Answer & Comments

Answer: 2- She will probably be able to remain on 100 mcg for the duration of the pregnancy

Hypothyroidism is the commonest pre-existing endocrine disorders in pregnancy, with an incidence of 9 in 1000 pregnancies. It is most commonly caused by Hashimoto's thyroiditis.

Hypothyroidism has significant consequences for both the mother and foetus. Women can develop congestive cardiac failure, megacolon, adrenal crisis, psychosis, myxoedema coma and hyponatraemia.

For the foetus, there is a small increase in the stillbirth rate and there is a need to therefore monitor the pregnancy more closely. Untreated maternal hypothyroidism can lead to pre-eclampsia, low birth weight, placental abruption and miscarriage. Foetal thyroid development begins at 10-12 weeks gestation, with T4 secretion beginning at 18-20 weeks. T4 is critical for neural development, and is especially important during the second trimester. Maternal thyroid hormone is needed for neuronal development until 12-13 weeks, and recent research has shown children of mothers with hypothyroidism may have a lower IQ than those born to women with normal thyroid function.

Prognosis for mother and foetus is however excellent with appropriate treatment.

Thyroid function tests should be measured every 8-12 weeks if stable, and 4-6 weeks if medication is changed. Thyroxine treatment should be altered according to the free T4

levels as thyroid-stimulating hormone (TSH) may remain elevated even with appropriate treatment (especially in the third trimester). If the patient is stable with regard to thyroxine dose pre-pregnancy then they are likely to remain stable without any dose adjustment during the pregnancy.

Reducing the dose of thyroxine is inappropriate as it runs the risk of inducing maternal hypothyroidism, and the complications associated with this.

Increasing the dose without monitoring the TSH runs the risk of inducing maternal thyrotoxicosis which is potentially damaging to the viability of the pregnancy.

There is no evidence that increasing the dose of thyroxine in the immediate post-partum period is required.

[Q: 2450] OnExamination 2012 - Endocrinology

A 42-year-old alcoholic presents to the clinic with symptoms of lethargy and muscle pains. He also reports intermittent tingling and loss of sensation in his hands and feet. He admits to drinking six to eight pints of lager per day.

On examination his BP is 116/72 mmHg, his pulse is 65 and regular. There are signs of chronic liver disease.

Investigations show:

Haemoglobin 10.8 g/dl(13.5-17.7)

White cell count $5.2 \times 10^9/L$ (4-11)

Platelets $180 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.6 mmol/l (3.5-5)

Creatinine 100 $\mu\text{mol/l}$ (79-118)

Urea 5.2 mmol/l (2.5-6.7)

Glucose 5.8 mmol/l (<7.0)

Calcium 2.02 mmol/l (2.20-2.61)

Phosphate 1.6 mmol/l (0.8-1.5)

Alkaline phosphatase 82 U/l (39-117)

Which of the following is the most likely diagnosis?

- 1- Hyperparathyroidism
- 2- Hypoparathyroidism
- 3- Hypothyroidism
- 4- Osteomalacia
- 5- Pseudopseudohypoparathyroidism

Answer & Comments

Answer: 2- Hypoparathyroidism

The biochemical abnormalities automatically preclude pseudopseudohypoparathyroidism, as both the calcium and phosphate are abnormal.

Pseudohypoparathyroidism may fit with this picture, but only if the PTH is elevated.

In osteomalacia it would be expected to see a raised alkaline phosphatase.

Hypothyroidism is not associated with abnormalities in calcium metabolism.

[Q: 2451] OnExamination 2012 - Endocrinology

A 38-year-old man with type 2 diabetes comes to the clinic for review. He was diagnosed three years ago after changing his general practitioner, and has been treated for the past few years with metformin 1 g twice daily.

On examination he is morbidly obese with a BMI of 41.

Investigations show:

Haemoglobin 13.0 g/dl (13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $149 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

HbA1c 8.1% (<5.5)

According to the ADA/EASD consensus, which of the following is the most appropriate additional therapy for him?

- 1- Exenatide
- 2- Gliclazide
- 3- Pioglitazone
- 4- Sitagliptin
- 5- Vildagliptin

Answer & Comments

Answer: 1- Exenatide

The preferred pathway for glucose management according to the consensus is to add either sulphonylurea (SU) or insulin to metformin therapy.

However, where weight is of particular concern, exenatide may be considered as an alternative.

This patient's age and weight make weight a particular consideration and as such, exenatide would be the preferred option.

Concerns about limited data and potential impact on immune function are mentioned as potential reasons not to choose dipeptidyl peptidase IV (DPPIV) inhibition and pioglitazone is likely to lead to weight gain.

[Q: 2452] OnExamination 2012 - Endocrinology

A 56-year-old man presented to the Emergency department with an episode of collapse at home. He had been feeling increasingly tired with polyuria for the last two months and also reported a loss of libido.

He had undergone a transsphenoidal surgery two years ago, followed by external beam radiation for a non-functional pituitary adenoma. He took ramipril 10 mg every day for hypertension.

On examination, his pulse was 102 beats per minute and regular, and blood pressure measured 104/66 mmHg in the lying position, dropping to 80/40 mmHg on standing. Heart sounds were normal. There was no galactorrhoea to expression and testicular volume was normal.

Investigations showed:

12 lead ECG Normal

Fasting plasma glucose 4.9 mmol/L (3.0-6.0)

Serum Sodium 129 mmol/L (137-144)

Serum Potassium 4.8 mmol/L (3.5-4.9)

Serum Urea 7.2 mmol/L (2.5-7.5)

Serum creatinine 88 mol/L (60-110)

Serum testosterone 4.5 nmol/L (9-35)

Plasma luteinising hormone 0.3 U/L (1-10)

Plasma thyroid-stimulating hormone 0.1 mU/L (0.4-5)

Plasma Free T₄ 7 pmol/L (10-22)

Insulin-like growth factor 15.2 nmol/L (5.6-23.3)

Which is the most appropriate immediate treatment for this man?

- 1- Desmopressin
- 2- Growth hormone
- 3- Hydrocortisone
- 4- Testosterone
- 5- Thyroxine

Answer & Comments

Answer: 3- Hydrocortisone

This patient is likely to have secondary hypoadrenalism following his pituitary surgery or his radiotherapy.

Hypopituitarism may develop indolently after radiotherapy and patients should be monitored closely for this potential complication.

He requires hydrocortisone replacement therapy at a physiological dose - 10 mg/5 mg/5 mg, mimicking the diurnal cortisol profile.

This diagnosis should not be missed as the consequences may be catastrophic. Hydrocortisone replacement is an urgent measure which may be life-saving, testosterone and thyroxine replacement should then be considered.

[Q: 2453] OnExamination 2012 - Endocrinology

Which one of the following statements applies to an infant with undiagnosed congenital hypothyroidism?

- 1- Gastrointestinal disturbances, especially diarrhoea may develop
- 2- Haemolytic jaundice occurs
- 3- Tachyarrhythmias may occur.
- 4- They may be asymptomatic
- 5- They may later have early acceleration of bone age and short stature at maturity

Answer & Comments

Answer: 4- They may be asymptomatic

Lack of symptoms may be a feature.

Prolonged conjugated hyperbilirubinaemia is seen with this condition.

Bone age and growth will be delayed.

Constipation rather than diarrhoea is observed.

Bradycardia may occur but tachyarrhythmias are not associated.

[Q: 2454] OnExamination 2012 - Endocrinology

An overweight, 60-year-old female with an eight year history of type 2 diabetes mellitus presents with deteriorating glycaemic control.

She takes gliclazide 160 mg twice daily.
Investigations reveal:

Sodium and potassium Normal

Serum Urea 10 mmol/l (2.5-7.5)

Serum Creatinine 160 µmol/l (60-110)

Serum alanine transaminase 31 U/l (5-35)

Serum aspartate transferase 30 U/l (1-31)

HbA1C 8.8% (3.8-6.4)

Which of the following would be the most appropriate additional therapy for improved glycaemic control?

- 1- Acarbose
- 2- Guar gum
- 3- Metformin
- 4- Pioglitazone
- 5- Repaglinide

Answer & Comments

Answer: 4- Pioglitazone

This woman with diabetes has poor glycaemic control with renal impairment.

With creatinine concentrations above 150 µmol/l, metformin is not recommended due to the small risk of lactic acidosis. Therefore, the most appropriate treatment would be pioglitazone, as liver function tests are normal and there is no suggestion of heart failure. It should be noted however, that given her renal impairment she should be closely monitored for fluid retention, and if this occurs, insulin is the other realistic option for her.

Acarbose is poorly tolerated and is now rarely prescribed.

Guar gum has little place in the treatment of diabetes.

Repaglinide the non-sulphonylurea insulin secretagogue would have little benefit in conjunction with a traditional SU such as gliclazide.

[Q: 2455] OnExamination 2012 - Endocrinology

With which of the following is hyperprolactinaemia associated?

- 1- Cabergoline therapy
- 2- Depression
- 3- Fluoxetine therapy
- 4- Hyperthyroidism
- 5- Sheehan's syndrome

Answer & Comments

Answer: 3- Fluoxetine therapy

Hyperprolactinaemia may manifest as a milky discharge from the breasts.

The causes include:

Prolactinoma

Hypothyroidism (far increased thyrotropin-releasing hormone [TRH])

Non-functional tumour with stalk compression and

Drugs, in particular dopamine antagonists such as chlorpromazine, haloperidol and domperidone.

Pregnancy is a particularly common cause of hyperprolactinaemia.

Other drugs that are occasionally reported include selective serotonin reuptake inhibitors (SSRIs).

Polycystic ovary syndrome (PCOs) is often associated with idiopathic hyperprolactinaemia.

[Q: 2456] OnExamination 2012 - Endocrinology

Primary hyperparathyroidism may occur in association with which of the following conditions?

- 1- Autoimmune polyendocrine syndrome

- 2- Chronic renal failure (CRF)
- 3- Gastrinoma
- 4- Sjogren's syndrome
- 5- Vitamin D deficiency

Answer & Comments

Answer: 3- Gastrinoma

The association of primary hyperparathyroidism and a gastrinoma would suggest a diagnosis of multiple endocrine neoplasia type 1.

CRF causes secondary or tertiary hyperparathyroidism, with vitamin D deficiency causing secondary hyperparathyroidism.

There is no association with Sjogren's.

[Q: 2457] OnExamination 2012 - Endocrinology

Which of the following is typically found in Pendred's syndrome?

- 1- Cataract
- 2- Mental retardation
- 3- Sensorineural deafness
- 4- Thyroid agenesis
- 5- Thyrotoxicosis

Answer & Comments

Answer: 3- Sensorineural deafness

Pendred's syndrome is an autosomal recessive condition which includes nerve deafness with goitre due to a defect of iodine binding.

Patients are usually euthyroid.

[Q: 2458] OnExamination 2012 - Endocrinology

You are trialling a new dipeptidyl peptidase IV (DPP-IV) inhibitor which you believe may have greater specificity for the DPP-IV enzyme than

other members of the class and therefore offer advantages for treatment of type 2 diabetes.

Which of the following correctly reflects one aspect of the mode of action of DPP-IV inhibition?

- 1- Glucose dependent glucagon suppression
- 2- Glucose dependent insulin suppression
- 3- Increased GI motility
- 4- Increased release of GIP
- 5- Increased release of GLP-1

Answer & Comments

Answer: 1- Glucose dependent glucagon suppression

DPP-IV inhibitors enhance the incretin effect which is a peak of insulin release associated with an oral glucose load; as such they are associated with glucose dependent insulin stimulation.

They are associated with reduced gastrointestinal motility; they are weight neutral when used in the treatment of type 2 diabetes.

DPP-IV inhibitors do not increase the release of incretins, merely interfere with their breakdown.

[Q: 2459] OnExamination 2012 - Endocrinology

A 45-year-old man who has undergone bilateral adrenalectomy for Cushing's returns to the clinic for his yearly follow up appointment.

Over the course of the past few months he has begun to feel increasingly tired and has given up driving after suffering a road traffic accident where he did not see a car coming from the side.

On examination his BP is 132/72 mmHg, his pulse is 70 and regular. His BMI is 28. You notice that his skin appears tanned.

Investigations show:

Haemoglobin 13.2 g/dl(13.5-17.7)

White cell count $5.9 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 112 $\mu\text{mol/l}$ (79-118)

Urea 5.2 mmol/l (2.5-6.7)

Glucose 5.2 mmol/l (<7.0)

TSH 0.1 (0.5-4.5)

Which of the following is the most appropriate intervention?

- 1- Carbimazole
- 2- Increased hydrocortisone replacement
- 3- Octreotide
- 4- Referral to a pituitary surgeon
- 5- Thyroxine replacement

Answer & Comments

Answer: 4- Referral to a pituitary surgeon

Carbimazole is incorrect as this patient actually has pituitary dependent hypothyroidism as a result of his tumour.

Increased hydrocortisone treatment will also not suppress the pituitary adenoma.

Octreotide has shown some success in clinical trials but is inferior to surgical intervention, and thyroxine replacement, whilst correcting hypothyroidism will not resolve the underlying adenoma.

[Q: 2460] OnExamination 2012 - Endocrinology

A 58-year-old man who has a history of type 2 diabetes comes to the clinic because he has severe pins and needles and pains in his lower

legs and feet, particularly in the early hours of the morning, which are affecting his sleep almost every night.

He takes BD 30/70 mixed insulin for control of his blood sugar, has had an inferior MI previously and treated hypertension. Medication apart from insulin includes ramipril, atorvastatin, amlodipine, tamsulosin and aspirin.

On examination his BP is 149/78 mmHg, his pulse is 82. His chest is clear and his abdomen is soft and non-tender. He has sensory loss to the mid shin bilaterally.

Investigations show:

Haemoglobin 12.8 g/dl(11.5-16.5)

White cells $5.2 \times 10^9/L$ (4-11)

Platelet $188 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.9 mmol/l (3.5-5)

Creatinine 133 $\mu\text{mol/l}$ (79-118)

HbA1c 7.6%(<5.5)

Which of the following is the most appropriate initial therapy for his neuropathy?

- 1- Amitriptyline
- 2- Carbamazepine
- 3- Duloxetine
- 4- Gabapentin
- 5- Valproate

Answer & Comments

Answer: 3- Duloxetine

Duloxetine is recommended in NICE guidelines for the management of peripheral neuropathy. The starting dose is 60 mg daily although this may be increased up to 120 mg/day. It cannot be used in patients with a history of acute narrow angle glaucoma.

Opioid based agents should be avoided unless there has been previous recommendation/assessment by a specialist.

Amitriptyline is incorrect because it is an alternative option to duloxetine if it is contraindicated; a dose of 10-75 mg/day is recommended.

Carbamazepine is incorrect because it is not featured in the NICE guidelines for the management of peripheral neuropathy.

Duloxetine is correct because it is the standard first line therapy for neuropathy.

Gabapentin is incorrect because it may be used in the management of neuropathy, but more usually pregabalin is recommended either as a second line agent or in combination with amitriptyline.

Valproate is incorrect because it is not featured in the NICE guidelines for the management of peripheral neuropathy.

Neuropathic pain - pharmacological management

[Q: 2461] OnExamination 2012 - Endocrinology

A 60-year-old woman with a history of type 2 diabetes comes to the clinic for review.

She is currently managed with gliclazide 160 mg BD as she failed to tolerate metformin, but she is finding it difficult to manage her blood sugar control. Her morning finger prick testing glucoses approaches 10 mmol/l glucose.

On examination her BMI is 36, her BP is 155/90 mmHg, her pulse is 86 and regular. Apart from her obesity, physical examination is unremarkable.

Investigations

Haemoglobin 12.2 g/dl (11.5-16.5)

White cell count $5.1 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 210 $\mu\text{mol/l}$ (79-118)

HbA1C 8.8% (<5.5)

Which of the following is the next most appropriate step in managing her blood glucose control?

1- Exenatide

2- Metformin slow release

3- Pioglitazone

4- Sitagliptin

5- Switch to insulin

Answer & Comments

Answer: 5- Switch to insulin

This woman has significant renal impairment, as illustrated by a creatinine of 210. As such, options are limited; both sitagliptin and exenatide are not recommended in patients with this degree of renal impairment, and metformin is contraindicated.

While glitazones are effective in lowering blood glucose, in this patient type they are likely to lead to significant fluid retention.

This leaves insulin switch as the most appropriate option, despite the fact it is likely to result in further weight gain.

[Q: 2462] OnExamination 2012 - Endocrinology

A 45-year-old male presents concerned about his risk of developing diabetes.

His family history reveals that his mother and maternal uncle both have diabetes. He has central obesity with a waist measurement of 110 cm. On examination, his blood pressure is 130/82 mmHg, his BMI is 30.2 kg/m^2 .

His investigations reveal:

Fasting cholesterol 5.2 mmol/l (<5.2)

Triglycerides 1.4 mmol/l (0.45-1.69)

HDL cholesterol 1.1 mmol/l (>1.55)

Fasting glucose 6.2 mmol/l (3.0-6.0)

In addition to his waist measurement which of this man's observations fulfills the criteria for the diagnosis of the metabolic syndrome?

- 1- Blood pressure of 130/82 mmHg
- 2- BMI of 30.2 kg/m²
- 3- Fasting plasma glucose of 6.2 mmol/l
- 4- HDL concentration of 1.1 mmol/l
- 5- Triglyceride concentration of 1.4 mmol/l

Answer & Comments

Answer: 3- Fasting plasma glucose of 6.2 mmol/l

The metabolic syndrome is becoming hugely important as a cluster of features associated with increased cardiovascular and diabetes risk.

The condition is defined by various criteria the latest of which is the global definition for the IDF as central obesity (≥94 cm for men, ≥80 cm for women) plus any two of the following:

Hypertriglyceridaemia >1.7 mmol/l

Low HDL concentration <1.03 mmol/l male, <1.29 mmol/l female

BP ≥ 130/85 mmHg, or on treatment for hypertension

Fasting glucose ≥5.6 mmol/l, or known to have type 2 diabetes.

Thus, in our patients case the elevated fasting glucose of 6.2 mmol/l fulfils this diagnostic criterion.

The BMI is not a function of the diagnostic criterion as the waist circumference appears to be a far more powerful predictor of risk.

[Q: 2463] OnExamination 2012 - Endocrinology

A patient with type 2 diabetes being treated with gliclazide presents with sweating and dizziness. Blood glucose was 1.9 mmol/L (3.0-6.0).

He is on long-standing treatment for hypertension, atrial fibrillation, joint pain and indigestion. These treatments have not changed recently.

You understand that he has recently been prescribed an agent for balanitis by his GP.

Which of the following drugs may be responsible for increasing the likelihood of hypoglycaemia in this situation?

- 1- Aspirin
- 2- Atenolol
- 3- Digoxin
- 4- Fluconazole
- 5- Ranitidine

Answer & Comments

Answer: 4- Fluconazole

As a result of drug interaction hypoglycaemia may be potentiated when a sulphonylurea is used concurrently with agents such as

Long-acting sulfonamides

Tuberculostatics

Phenylbutazone

Clofibrate

Monoamine oxidase (MAO) inhibitors

Coumarin derivatives

Salicylates

Probenecid

Propranolol

Cimetidine

Disopyramide

Angiotensin converting enzyme inhibitors.

Gliclazide is a sulphonylurea drug with an intermediate half life of around 11 hours. It is extensively metabolised within the liver by CYP2C9. Within the circulation, gliclazide is

highly bound to plasma proteins, about 94%. Renal clearance accounts for only 4% of total drug clearance.

Therefore gliclazide action can be potentiated predominantly by two mechanisms:

- 1: Displacement of the drug from plasma proteins to give more free (unbound) drug - some agents such as aspirin can do this.
- 2: Interference with the hepatic metabolism of the drug.

The only change in this patient's treatment recently has been the addition of an antimicrobial agent.

Fluconazole has a low level of plasma protein binding and it is excreted by the kidney. However, it is also a potent inhibitor of CYP2C8 and CYP2C9 and can thus interact with gliclazide and other sulphonylureas (for example, glimepiride, glibenclamide, tolbutamide and glipizide).

Thus the best answer in this scenario would be likely to be fluconazole.

[Q: 2464] OnExamination 2012 - Endocrinology

An 18-year-old female with polycystic ovary syndrome was prescribed metformin.

What is the most important pharmacological action of metformin in this situation?

- 1- Increasing gluconeogenesis
- 2- Increasing insulin levels
- 3- Increasing luteinising hormone levels
- 4- Increasing oestradiol levels
- 5- Increasing peripheral glucose uptake

Answer & Comments

Answer: 5- Increasing peripheral glucose uptake

Lowering serum insulin concentrations with metformin ameliorates hyperandrogenism, by

reduction of ovarian enzyme activity that results in ovarian androgen production.

Clinical studies have shown that metformin reduces insulin resistance, and have demonstrated a fall in serum androgens, luteinising hormone and weight.

The reduced insulin resistance is associated with reduced insulin drive to the insulin sensitive ovary in polycystic ovarian syndrome and hence reduces androgen production.

[Q: 2465] OnExamination 2012 - Endocrinology

A 33-year-old woman with an 18 year history of type I diabetes mellitus presents with proteinuria. She is a smoker of 20 cigarettes daily.

Examination reveals a blood pressure of 155/95 mmHg.

Investigations reveal:

Serum cholesterol 7.6 mmol/L(<5.2)

HbA1c 8.3%(3.8-6.4)

24 hour urinary protein excretion 1.5 g(<0.2)

Which intervention is most likely to retard the development of renal failure?

- 1- Bendroflumethiazide
- 2- Improve glycaemic control with HbA1c less than 7%
- 3- Lisinopril
- 4- Simvastatin
- 5- Stop smoking

Answer & Comments

Answer: 3- Lisinopril

This patient has diabetic nephropathy with marked proteinuria.

To attenuate the progression towards end stage renal disease, stringent blood pressure control should be employed maintaining a BP less than 130/80 mmHg and an angiotensin-

converting enzyme (ACE) inhibitor would probably offer even greater reno-protection than any other anti-hypertensive.

Simvastatin has no proven benefit on renal disease and improved glycaemic control although of benefit would be of less benefit than BP control (UKPDS/DCCT trials).

Again stopping smoking would probably be of greatest benefit to her with regard to reducing cardiovascular risk but would not itself offer any reno-protective effect.

[Q: 2466] OnExamination 2012 - Endocrinology

A 55-year-old female who received radioactive iodine over five years ago presents for annual thyroid function assessment. She is well and takes no medication.

Her results reveal:

Free Thyroxine 13.2 pmol/L (10-22)

TSH 16 mU/L (0.4-5)

Total cholesterol 6.8 mmol/L (<5.2)

Plasma triglycerides 2.2 mmol/L (0.45-1.69)

What is the most appropriate treatment for this patient's dyslipidaemia?

- 1- Cholestyramine
- 2- Fibrate therapy
- 3- Hormone replacement therapy
- 4- Statin therapy
- 5- Thyroxine

Answer & Comments

Answer: 5- Thyroxine

This patient has subclinical hypothyroidism as reflected by the normal thyroxine (T4) but elevated thyroid-stimulating hormone (TSH).

A hypercholesterolaemia with hypertriglyceridaemia is frequently associated due to impaired lipoprotein lipase function.

The dyslipidaemia may well resolve following the appropriate replacement with thyroxine.

[Q: 2467] OnExamination 2012 - Endocrinology

A 42-year-old man is referred to the endocrine clinic for investigation of a thyroid mass.

He tells you that his mother and brother both suffered from thyroid cancer, but he has not responded to multiple invitations from the local endocrine clinic to attend for review.

He has been attending his GP who is finding his blood pressure difficult to manage. He is currently taking ramipril 10 mg daily and amlodipine 10 mg.

On examination in the clinic his BP is 155/100 mmHg, his pulse is 85 and regular. There is a firm left sided thyroid mass, around 3 cm in diameter.

Investigations show:

Haemoglobin 13.5 g/dl (11.5-16.5)

White cells $6.5 \times 10^9/L$ (4-11)

Platelet $359 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 92 $\mu\text{mol/l}$ (79-118)

TSH 3.1 (0.5-5.0)

Calcium 2.91 mmol/l (2.2-2.60)

Which of the following is the next step?

- 1- Abdominal MRI
- 2- Excision biopsy of the thyroid
- 3- Growth hormone suppression test
- 4- MRI pituitary
- 5- Pentagastrin suppression test

Answer & Comments

Answer: 1- Abdominal MRI

The history of thyroid carcinoma in two first degree relatives raises the possibility of a familial thyroid cancer syndrome.

The hypercalcaemia further increases suspicion that this is medullary carcinoma of the thyroid.

If there is any suggestion of phaeochromocytoma, and the hypertension raises that possibility here, adequate investigation and possible removal of adenoma before thyroidectomy is crucial.

In the event of a phaeochromocytoma, alpha blockade with phenoxybenzamine is the primary strategy for blood pressure control.

A. Abdominal MRI is the correct answer because exclusion of phaeochromocytoma is crucial before considering thyroidectomy.

B. Excision biopsy is incorrect, because surgery should not be attempted prior to excluding phaeochromocytoma, and thyroidectomy is the treatment of choice.

C. Growth hormone suppression test is incorrect; pituitary adenomas are a feature of multiple endocrine neoplasia-1 (MEN-1).

D. MRI pituitary is incorrect; pituitary adenomas are a feature of MEN-1.

E. Pentagastrin suppression test is incorrect because there is an obvious thyroid tumour, and this should not delay progression to surgery.

[Q: 2468] OnExamination 2012 - Endocrinology

A 55-year-old man presents with gynaecomastia. He is receiving treatment for heart failure and gastro-oesophageal reflux.

Which of the following drug he takes is most likely to be responsible for his gynaecomastia?

1- Amitriptyline

2- Carvedilol

3- Furosemide

4- Spironolactone

5- Ramipril

Answer & Comments

Answer: 4- Spironolactone

Spironolactone is associated with gynaecomastia.

Other agents causing of gynaecomastia include:

amiloride

to a lesser extent eplerenone

digoxin

luteinising hormone-releasing hormone (LHRH) analogues

finasteride.

[Q: 2469] OnExamination 2012 - Endocrinology

Which of the following is a likely presenting feature of Cushing's syndrome?

1- Diabetes insipidus

2- Lichen planus

3- Mononeuritis multiplex

4- Necrosis of the femoral head

5- Polymyositis

Answer & Comments

Answer: 4- Necrosis of the femoral head

Cases of Cushing's syndrome have presented with necrosis of the femoral head due to osteoporosis.

Diabetes insipidus would be very unusual, whereas diabetes mellitus may occur in 30%.

Lichen planus is treated with corticosteroids, as is polymyositis.

Mononeuritis multiplex is not a feature.

[Q: 2470] OnExamination 2012 - Endocrinology

A 62-year-old man with extensive metastases from ileal carcinoid is admitted to the Emergency department with deteriorating health.

He has become increasingly confused with worsening symptoms of diarrhoea over the past few weeks. You find that he has impaired short term memory and increased skin pigmentation.

Deficiency of which vitamin is a potential problem?

- 1- Ascorbic acid
- 2- Folate
- 3- Niacin
- 4- Riboflavin
- 5- Thiamine

Answer & Comments

Answer: 3- Niacin

Extensive metastases from carcinoid can lead to metabolism of very large amounts of tryptophan. This then leads to a pellagra-like picture.

In normal patients, only 1% of dietary tryptophan is converted to serotonin, in patients with carcinoid syndrome this value may increase to 70%.

The diversion of tryptophan to making serotonin in patients with metastatic tumors can result in tryptophan deficiency. Carcinoid syndrome can then lead to niacin deficiency, and clinical manifestations of pellagra.

None of the other vitamins listed are deficient in patients with metastatic carcinoid, so niacin is the only possible correct answer.

Thiamine deficiency is associated with memory loss, but is also associated with peripheral neuropathy and tends to occur in alcoholic individuals.

[Q: 2471] OnExamination 2012 - Endocrinology

Which of the following statements is true of type 2 diabetes mellitus?

- 1- 20% of patients develop macrovascular complications within 10 years of diagnosis
- 2- A single fasting plasma glucose above 8 mmol/l is diagnostic of diabetes.
- 3- Drug treatment is associated with a 25% reduction in microvascular complications compared with diet alone.
- 4- Metformin is the preferable treatment in the obese patient with type 2 diabetes
- 5- Type 2 diabetes is associated with being underweight

Answer & Comments

Answer: 4- Metformin is the preferable treatment in the obese patient with type 2 diabetes

The diagnosis of type 2 diabetes is made by demonstrating a fasting plasma glucose >6.9 on two separate occasions and is associated with being overweight.

Drug treatment of type 2 diabetes is associated with a linear reduction in mortality related to level of glycaemic lowering.

The rate of macrovascular complications within 10 years of diagnosis is much higher than 20%.

UKPDS (United Kingdom Prospective Diabetes Study) has shown that metformin is the preferable first line therapy in type 2 diabetes.

Sulphonylureas are associated with marginally higher cardiovascular mortality and weight gain.

[Q: 2472] OnExamination 2012 - Endocrinology

An 18-year-old man develops thirst, weight loss and polyuria.

Investigations confirm that he has type 1 diabetes and is treated with basal bolus insulin.

He is keen to know what limitations this diagnosis imposes on career opportunities.

Which of the following professions would he not be able to pursue?

- 1- Ambulance control centre worker
- 2- Civil engineer
- 3- Milkman
- 4- Physical education instructor
- 5- Police advanced driver

Answer & Comments

Answer: 5- Police advanced driver

Most police forces have their own policies with regard to applications from diabetic people. Provided their diabetes is stable and well controlled, they may be considered for the police force but most forces have a blanket ban on any advanced driving duties.

The armed forces, working offshore or aboard ships, air pilot, HGV/PSV licence, fire or driving in the post office are career paths closed to subjects with insulin dependent diabetes.

Some local authorities do permit licences to taxi drivers with insulin treated diabetes whilst others do not.

[Q: 2473] OnExamination 2012 - Endocrinology

A 19-year-old female with type 1 diabetes is admitted with diabetic ketoacidosis.

Which of the following is most appropriate concerning the use of a bicarbonate infusion?

- 1- Bicarbonate infusion should be considered at pH less than 7
- 2- Commence a bicarbonate infusion with a ketone concentration above 5 mmol/l (NR less than 1)

- 3- Commence bicarbonate infusion with a potassium concentration above 6 mmol/l
- 4- Commence a bicarbonate infusion with a standard bicarbonate concentration below 5 mmol/l (NR 22-26)
- 5- No benefit from using a bicarbonate infusion

Answer & Comments

Answer: 1- Bicarbonate infusion should be considered at pH less than 7

The use of bicarbonate in DKA is controversial (pdf).

However, most authorities agree that a bicarbonate infusion may be used in subjects with a severe metabolic acidosis (pH less than 7).

[Q: 2474] OnExamination 2012 - Endocrinology

A 23-year-old woman presents to the clinic with lethargy and recurrent fainting attacks.

She is usually fit and well and her only medication of note is the progesterone only pill.

On examination her BP is 110/70 mmHg, she has a postural drop of 20 mmHg on standing. Her BMI is 19. Respiratory and abdominal examination is normal.

Investigations show:

Haemoglobin 10.9 g/dl(11.5-16.0)

White cell count $7.1 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 131 mmol/l (135-146)

Potassium 5.1 mmol/l (3.5-5)

Creatinine 125 $\mu\text{mol/l}$ (79-118)

Which of the following investigations would be most likely to elucidate the underlying diagnosis?

- 1- Abdominal x ray

- 2- Adrenal autoantibodies
- 3- Chest x ray
- 4- Random cortisol
- 5- Short Synacthen test

Answer & Comments

Answer: 5- Short Synacthen test

Abdominal x ray may be useful if adrenal calcification is suspected, and a chest x ray may reveal underlying TB, but both of these are investigations to be performed after the initial diagnosis is made.

Equally, adrenal antibodies may establish if the cause is autoimmune.

Random cortisol is less useful than a short Synacthen test as cortisol production varies during the course of a day.

[Q: 2475] OnExamination 2012 - Endocrinology

A 35-year-old man comes to the clinic for review after referral from his GP. He was admitted to the intensive care unit after a motorbike accident and has only recently been discharged from hospital.

He complains of lethargy and tiredness.

His thyroid function testing is described below:

TSH 0.3 IU/l (0.5-4.5)

Free T₄ 8 pmol/l (9-25)

Free T₃ 3.1 pmol/l (3.4-7.2)

Which of the following is the most likely diagnosis?

- 1- Hashimoto's thyroiditis
- 2- Graves' disease
- 3- Secondary thyroid failure
- 4- Sick euthyroid syndrome
- 5- Subacute thyroiditis

Answer & Comments

Answer: 4- Sick euthyroid syndrome

Hashimoto's thyroiditis would be associated with a raised thyroid-stimulating hormone (TSH) and decreased tri-iodothyronine (T₃) and thyroxine (T₄).

Graves' would be associated with a raised T₃ and T₄ and a decreased TSH.

Subacute thyroiditis is associated with transient hyperthyroidism and pain over the gland.

Secondary thyroid failure would be a differential, but measurement of reverse T₃ would help differentiate between this and sick euthyroid syndrome.

[Q: 2476] OnExamination 2012 - Endocrinology

A 42-year-old woman presents to the endocrine clinic with weight gain, hypertension and impaired glucose tolerance. Over the past year she has gained 8 kg in weight.

Other symptoms include heightened libido and increased hair growth on the lower abdomen and upper chest.

On examination her BP is 162/95 mmHg, pulse is 68 and regular. She has a BMI of 32 and abdominal striae.

Investigations show:

Haemoglobin 10.5 g/dl (11.5-16.0)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $205 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 123 $\mu\text{mol/l}$ (79-118)

Alkaline phosphatase 240 U/l (39-117)

Alanine aminotransferase 190 U/l (5-40)

Overnight dexamethasone suppression test positive

Which of the following is the most likely diagnosis?

- 1- Adrenal adenoma
- 2- Adrenal carcinoma
- 3- Pituitary adenoma
- 4- Pseudo-Cushing's
- 5- Simple obesity

Answer & Comments

Answer: 2- Adrenal carcinoma

The features of virilisation, whilst not invariably associated with adrenal carcinoma, favour this as the diagnosis, rather than an adenoma. The abnormal liver function tests (LFTs) also suggest metastases which would not be seen with an adenoma.

Pituitary disease would not be expected to be associated with virilisation or abnormal LFTs.

Pseudo-Cushing's and simple obesity are ruled out by the abnormal clinical findings seen here.

[Q: 2477] OnExamination 2012 - Endocrinology

According to the new revised criteria for diagnosing diabetes in an asymptomatic patient:

- 1- A fasting venous plasma concentration of < 6.9 can be ignored
- 2- A single fasting venous plasma glucose concentration of > 7 mmol/l can be used to diagnose diabetes
- 3- Impaired glucose tolerance is signified by a venous glucose concentration of < 7 mmol and > 11.1 mmol
- 4- 75 gm oral glucose test is mandatory for diagnosing diabetes
- 5- Two separate fasting venous plasma glucose concentration of > 7 mmol/l is diagnostic of diabetes

Answer & Comments

Answer: 5- Two separate fasting venous plasma glucose concentration of > 7 mmol/l is diagnostic of diabetes

In an asymptomatic individual, a single sample alone is not sufficient for diagnosis.

Diabetes can be diagnosed if separate fasting samples show above 7 mmol/l.

75 gram oral glucose test (OGT) is still the gold standard for diagnosing diabetes, although fasting glucose can be used, provided adequate fast is ensured.

Fasting glucose of above 6.1 but below 6.9 is classed as impaired fasting glycaemia, which is a new category of glycaemia. IGT = 7.8 - 11.1

[Q: 2478] OnExamination 2012 - Endocrinology

A 25-year-old female presents with weight gain, oligomenorrhoea and primary infertility. She has a history of bipolar disorder for which she takes lithium.

On examination she has a BMI of 32 kg/m².

Investigations reveal:

Free T₄ 6.4 pmol/l (10-22)

TSH 42 mU/l (0.4-5)

Prolactin 980 mU/l (50-450)

What is the most appropriate treatment for this patient?

- 1- Cabergoline
- 2- Cabergoline plus thyroxine
- 3- Metformin
- 4- Stop lithium
- 5- Thyroxine

Answer & Comments

Answer: 5- Thyroxine

This patient has primary hypothyroidism which would explain the increasing weight and the associated hyperprolactinaemia.

The latter occurs as a consequence of reduced dopaminergic tone.

Lithium may be the cause of this but stopping it is not usually attempted since it may dangerously exacerbate the psychiatric illness. There is an excellent review by John Lazarus on this topic¹ where he says, "The common clinical side effects of the drug are goitre in up to 40% and hypothyroidism in about 20%. Lithium increases thyroid autoimmunity if present before therapy. Treatment with levothyroxine is effective and lithium therapy should not be stopped."

The most appropriate treatment for her would be thyroxine which would, through euthyroidism, be expected to normalise prolactin concentration.

In turn this may improve weight, menstrual function and fertility.

Reference:

Lazarus JH. Lithium and thyroid. *Best Pract. Res. Clin. Endocrinol. Metab.* 2009;23(6):723-733.

[Q: 2479] OnExamination 2012 - Endocrinology

A 70-year-old male was receiving amiodarone 200 mg daily for intermittent atrial fibrillation. However, he was aware of tiredness and lethargy. He appeared clinically euthyroid with no palpable goitre.

Investigations revealed:

Serum Free T₄ 23pmol/l (9-26)

Serum total T₃ 0.8 nmol/l (0.9-2.8)

Serum TSH 8.2 mU/l (<5)

Which of the following statements would explain these results?

- 1- Abnormal thyroxine binding globulin
- 2- Amiodarone-induced hypothyroidism

- 3- 'Sick euthyroid' syndrome
- 4- Spontaneous hypothyroidism
- 5- TSH secreting pituitary adenoma

Answer & Comments

Answer: 2- Amiodarone-induced hypothyroidism

The results show normal thyroxine (T₄), low triiodothyronine (T₃) with elevated thyroid-stimulating hormone (TSH).

These results are typical of amiodarone-induced hypothyroidism which inhibits the peripheral conversion of T₄ to T₃.

[Q: 2480] OnExamination 2012 - Endocrinology

A 16-year-old female patient is referred with primary amenorrhoea.

Investigations reveal a 46 XY karyotype.

Which of the following concerning the condition is true?

- 1- A diagnosis of Turner's syndrome is likely
- 2- It is likely that her mother received carbimazole for thyrotoxicosis during pregnancy
- 3- Low testosterone and oestradiol concentrations would be expected
- 4- The diagnosis is likely to be androgen insensitivity syndrome
- 5- The diagnosis is Noonan's syndrome

Answer & Comments

Answer: 4- The diagnosis is likely to be androgen insensitivity syndrome

A female phenotype can occur in androgen insensitivity syndrome, due to an androgen receptor defect. This was previously referred to as testicular feminisation syndrome.

Stilboestrol therapy has been associated with the induction of latent tumours and with

influencing sexual behaviour, but is not associated with abnormalities of sexual identity.

In Noonan's syndrome, infants are males but physical features resemble those found in Turner's syndrome.

Neither prednisolone nor maternal thyrotoxicosis would cause gender malassignment problems.

[Q: 2481] OnExamination 2012 - Endocrinology

A 40-year-old man with diabetes presents with deteriorating thirst and nocturia.

He had been diagnosed with diabetes mellitus five years ago and is now taking maximal metformin and gliclazide yet his HbA1c is 10.9% (3.8-6.4).

You want to change him to insulin but he informs you that he is employed as a lorry driver.

What would be the impact of converting him to insulin on his heavy goods vehicle (HGV) licence?

- 1- Can keep his HGV licence
- 2- Can regain his HGV licence after one year without hypoglycaemic episodes
- 3- Can regain his HGV licence if after six months he does not have any hypoglycaemic episodes
- 4- Temporary suspension of his HGV licence until established on stable doses of insulin
- 5- Will lose his HGV licence indefinitely whilst treated with insulin

Answer & Comments

Answer: 5- Will lose his HGV licence indefinitely whilst treated with insulin

Switching patients to insulin does have a major impact on their ability to pursue certain careers and/or vehicle licensing.

Insulin treated diabetics are unable to hold a HGV or PSV licence and in some councils are unable to have a taxi licence.

For further reading on employment restrictions and diabetes read here.

[Q: 2482] OnExamination 2012 - Endocrinology

A 54-year-old woman presents to the clinic for review.

Unfortunately she has carcinoid with extensive hepatic metastases and still has significant diarrhoea and flushing.

Which of the following is the initial medical therapy of choice for her?

- 1- Bromocriptine
- 2- Cabergoline
- 3- Interferon alpha
- 4- Octreotide
- 5- Somatotrophin

Answer & Comments

Answer: 4- Octreotide

Bromocriptine and cabergoline are dopamine agonists used in the treatment of prolactinomas.

Somatotrophin is a growth hormone analogue and as such its use may actually worsen the symptoms of carcinoid syndrome.

Interferon alpha can be used as an adjunct to octreotide in patients with resistant symptoms of carcinoid.

[Q: 2483] OnExamination 2012 - Endocrinology

Which one of the following concerning insulin is correct?

- 1- Acts via a similar mechanism to steroid receptors
- 2- Can be detected in the lymph

- 3- Causes an increased glucose-protein transport on the endoplasmic reticulum
- 4- Interacts with the nuclear membrane
- 5- Is synthesised in the alpha cells of islets of Langerhans

Answer & Comments

Answer: 2- Can be detected in the lymph

Insulin acts via cell surface receptors.

Insulin binding to its receptor results in receptor autophosphorylation on tyrosine residues and the tyrosine phosphorylation of insulin receptor substrates (IRS-1, IRS-2 and IRS-3) by the insulin receptor tyrosine kinase.

Insulin is synthesised in the beta cells of the islets of Langerhans not the alpha cells.

[Q: 2484] OnExamination 2012 - Endocrinology

Which of the following percentages most accurately reflects the mortality associated with the modern management of diabetic ketoacidosis?

- 1- 0.5%
- 2- 1%
- 3- 2-3%
- 4- 5-6%
- 5- 8-10%

Answer & Comments

Answer: 3- 2-3%

Despite the advances in the management of diabetes in general and the improvements in intensive care, studies reveal that the mortality associated with diabetic ketoacidosis remains stubbornly around the 2-5% since the 1970s.

Specifically, mortality relates to cerebral oedema.

[Q: 2485] OnExamination 2012 - Endocrinology

A 56-year-old male presents with a five year history of increased sweats and change in shoe size.

Examination reveals prognathism and macroglossia, with large hands.

Blood pressure is 180/94 mmHg but visual field examination is full to confrontation.

Which of the following tests would be diagnostic?

- 1- IGF-1 concentration
- 2- Insulin tolerance test
- 3- Oral glucose tolerance test
- 4- Pituitary MRI
- 5- TRH test

Answer & Comments

Answer: 3- Oral glucose tolerance test

The diagnosis of acromegaly is confirmed with a failure of growth hormone suppression during an oral glucose tolerance test.

Though a pituitary adenoma may be present it is not diagnostic of acromegaly.

[Q: 2486] OnExamination 2012 - Endocrinology

A 35-year-old man presents with weakness and tiredness.

He is noted to be hypertensive.

Electrolytes show a hypokalaemia and hypomagnesaemia.

What investigation would you select for this patient?

- 1- Colonoscopy
- 2- Oral glucose tolerance test
- 3- Plasma renin to aldosterone ratio
- 4- Serum amylase
- 5- Serum calcium

Answer & Comments

Answer: 3- Plasma renin to aldosterone ratio

This scenario illustrates that young patients with hypertension may have underlying secondary causes.

This patient has primary hyperaldosteronism, which is thought to be a reasonably common cause of hypertension.

Primary hyperaldosteronism is associated with high aldosterone, suppressed renin, alkalosis, low potassium, low magnesium and normal/high sodium.

An important differential diagnosis here is renal artery stenosis.

Causes of primary hyperaldosteronism include:

Conn's syndrome (adrenal adenoma) causes over 50%.

Adrenal hyperplasia

Adrenal carcinoma (rare)

Glucocorticoid deficiency - also called glucocorticoid-remediable aldosteronism. Note that this is isolated glucocorticoid (cortisol) deficiency driving high ACTH levels and increased aldosterone production. Addison's disease is different as it involves both glucocorticoid and mineralocorticoid deficiencies.

[Q: 2487] OnExamination 2012 - Endocrinology

Which of the following is true concerning oral hypoglycaemic agents?

- 1- Acarbose promotes insulin secretion in response to meals
- 2- Chlorpropamide induces liver enzymes
- 3- Glibenclamide is excreted unchanged by the kidney
- 4- Gliclazide inhibits gluconeogenesis

5- Metformin inhibits hepatic gluconeogenesis

Answer & Comments

Answer: 5- Metformin inhibits hepatic gluconeogenesis

Chlorpropamide, like all the other sulfonylureas, stimulates pancreatic insulin secretion.

They are not liver enzyme inducers but are affected by liver enzyme inducers and inhibitors. They undergo hepatic metabolism then renal excretion.

Acarbose is an alpha glucosidase inhibitor which inhibits the splitting of disaccharides into glucose and so inhibits glucose absorption from the gut.

Metformin is an insulin sensitiser and although its actions are not fully understood its main role appears to be through inhibition of hepatic gluconeogenesis.

[Q: 2488] OnExamination 2012 - Endocrinology

Which of the following is associated with congenital adrenal hyperplasia (CAH)?

- 1- Delayed puberty
- 2- Hypopigmentation
- 3- Hyporeninaemia
- 4- Persistent wolffian duct
- 5- Premature epiphyseal closure

Answer & Comments

Answer: 5- Premature epiphyseal closure

Premature epiphyseal closure is a classical feature of CAH and is secondary to high levels of sex steroids.

Under, and over treatment of CAH puts patients at risk of short stature, over treatment because of the glucocorticoid induced inhibition of the growth axis.

CAH is associated with precocious puberty caused by long term exposure to androgens, which activate the hypothalamic-pituitary-gonadal axis.

Similarly, CAH is associated with hyperpigmentation, and hyperreninaemia due to sodium loss and hypovolaemia.

The wolffian duct is never formed in CAH.

[Q: 2489] OnExamination 2012 - Endocrinology

A 30-year-old female presents with a one year history of galactorrhoea. She has been receiving treatment for hay fever, depression, obesity and dyspepsia.

Her investigations reveal:

Full blood count Normal

Urea and electrolytes Normal

Prolactin 820 mU/l (<360)

Free thyroxine (T4) 18.3 pmol/l (10-22)

TSH concentration 2.1 mU/l (0.4-5)

Which one of the following drugs is most likely to explain these findings?

- 1- Astemizole
- 2- Metoclopramide
- 3- Orlistat
- 4- Paroxetine
- 5- Ranitidine

Answer & Comments

Answer: 2- Metoclopramide

Although the selective serotonin reuptake inhibitors (SSRIs) are also rarely associated with hyperprolactinaemia, the answer has to be metoclopramide, which is a dopamine antagonist that is typically associated with hyperprolactinaemia.

[Q: 2490] OnExamination 2012 - Endocrinology

Which one of the following measurements is a test for exocrine pancreatic insufficiency?

- 1- Faecal amylase
- 2- Faecal elastase
- 3- Faecal fat
- 4- Faecal lipase
- 5- Serum lipase

Answer & Comments

Answer: 2- Faecal elastase

Even the secretin stimulation test, which is the most sensitive method of assessing pancreatic exocrine function, is probably abnormal only when more than 60% of exocrine function has been lost.

Non-invasive, indirect tests of pancreatic exocrine function (faecal elastase, serum trypsinogen) are much more likely to give abnormal results in patients with obvious pancreatic disease (for example, pancreatic calcification, steatorrhea, or diabetes mellitus), than in patients with occult disease.

[Q: 2491] OnExamination 2012 - Endocrinology

You are treating a 48-year-old man for acromegaly.

Unfortunately despite adenomectomy, he continues to have an elevated growth hormone. You decide to start a long acting somatostatin analogue, Somatoline LA.

Which of the following correctly describes one aspect of its mode of action?

- 1- High affinity for human somatostatin receptor (HSSR) 3
- 2- Increased prolactin
- 3- Low affinity for human somatostatin receptor (HSSR) 2

- 4- Reduced fasting gastrin secretion
- 5- Reduced meal time superior mesenteric artery blood flow

Answer & Comments

Answer: 5- Reduced meal time superior mesenteric artery blood flow

Somatuline, like most other synthetic somatostatin analogues, has high affinity for HSSR-2 and 5, and low affinity for 1,3, and 4.

It is activity at the 2 and 5 receptors which is thought to be primarily the reason why growth hormone secretion falls.

There is no significant effect of Somatuline on fasting gastrin or secretin secretion.

Prolactin levels are generally reduced by somatostatin use.

[Q: 2492] OnExamination 2012 - Endocrinology

A 54-year-old man who has gained significant amounts of weight over the past six months is referred to the endocrine clinic with suspected Cushing's disease.

He has hypertension and impaired glucose tolerance. On examination his BP is 165/90 mmHg, pulse is 80 and regular and his BMI is 33. As part of the routine work up, a discrete mass is discovered on chest x ray.

When considering further work up, which of the following is the most appropriate option to rule out/in ectopic ACTH production as a cause of Cushing's?

- 1- 24 hour urinary free cortisol
- 2- High dose dexamethasone suppression test
- 3- Low dose dexamethasone suppression test
- 4- Midnight cortisol
- 5- Plasma ACTH

Answer & Comments

Answer: 2- High dose dexamethasone suppression test

All of the other options are possibilities for determining whether there are excess circulating corticosteroids, or there is excess adrenocorticotrophic hormone (ACTH) production.

They are not useful, however, in determining the origin of excess ACTH.

[Q: 2493] OnExamination 2012 - Endocrinology

A 54-year-old woman presents to the clinic with tiredness and a yellow tinge to her skin.

She has increased in weight by a few kg over the past six months.

On examination her BP is 139/70 mmHg, pulse is 64 and regular. Her BMI is 29.

Investigations show:

Haemoglobin 10.9 g/dl (11.5-16.0)

White cell count $7.9 \times 10^9/L$ (4-11)

Platelets $171 \times 10^9/L$ (150-400)

Sodium 133 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Bilirubin 21 $\mu\text{mol/l}$ (<17)

Which of the following is the most likely diagnosis?

- 1- Anorexia nervosa
- 2- Chronic liver disease
- 3- Diabetes mellitus
- 4- Dietary carotene excess
- 5- Hypothyroidism

Answer & Comments

Answer: 5- Hypothyroidism

Anorexia nervosa is associated with hypercarotenaemia but does not fit here with the history of weight gain and elevated BMI.

Diabetes mellitus is also associated with hypercarotenaemia, but the sodium at the lower end of normal is a better pointer towards hypothyroidism as the alternative diagnosis.

Dietary carotene excess is unlikely, and occurs more frequently in children. The normal bilirubin rules this out as a cause of the pigmentation.

[Q: 2494] OnExamination 2012 - Endocrinology

A 37-year-old woman presents with sudden onset painful visual loss in her left eye.

She has a history of previous mononeuritis affecting her left and right common peroneal nerves on separate occasions over the past three years. She has 6/36 vision in her left eye with loss of colour sensitivity.

Which of the following would you be most likely to see on visual evoked potential (VEP) examination of her right eye?

- 1- Delayed latency
- 2- Increased amplitude of the positive peak
- 3- Reduction in the amplitude of the first negative peak
- 4- Reduction in the amplitude of the second negative peak
- 5- Reduction in the amplitude of the positive peak

Answer & Comments

Answer: 1- Delayed latency

Amplitude reduction is seen against a background of retinal disease which interferes with signal transduction.

Amplitude reduction is also seen against a background of refractory errors, but the

question asks about VEP examination of the right eye, where there is no reported loss in visual acuity, so it is purely delayed latency that should be seen.

[Q: 2495] OnExamination 2012 - Endocrinology

A 24-year-old woman presents to the genetics clinic for pre-conception advice. She has a family history of thyroid hormone dysmorphogenesis and wonders what exactly the disorder is.

Which of the following stems best characterises the defect responsible for thyroid hormone dysmorphogenesis?

- 1- Defect in iodine organification
- 2- Defect in thyroid hormone release
- 3- Thyroid hormone releasing hormone receptor mutation
- 4- Thyroxine receptor mutation
- 5- TSH receptor mutation

Answer & Comments

Answer: 1- Defect in iodine organification

Thyroid-stimulating hormone (TSH) receptor mutations occur more commonly in association with other G protein receptor mutations such as those involved in the pathogenesis of pseudohypoparathyroidism.

Other abnormalities leading to congenital hypoparathyroidism include abnormal migration or formation of the gland, not the other stems described in the question.

[Q: 2496] OnExamination 2012 - Endocrinology

A 32-year-old man who is a non-smoker and only occasionally drinks alcohol presents to the outpatient endoscopy unit with worsening symptoms of indigestion.

He was scoped only five months earlier, where multiple gastric ulcers were found and he was started on high dose omeprazole. Helicobacter biopsy was negative. Repeat endoscopy showed further evidence of ulceration.

Investigations showed:

Haemoglobin 10.2 g/dl(13.5-17.7)

White cell count $7.9 \times 10^9/L$ (4-11)

Platelets $210 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 114 $\mu\text{mol/l}$ (79-118)

Glucose 5.2 mmol/l (<7.0)

Calcium 2.98 mmol/l (2.2-2.61)

Which of the following is the most likely diagnosis?

- 1- Gastric carcinoma
- 2- MEN-1
- 3- MEN-2a
- 4- MEN-2b
- 5- Missed Helicobacter infection

Answer & Comments

Answer: 2- MEN-1

There is no evidence of obstruction or a mass on endoscopy which would support a diagnosis of gastric carcinoma.

Equally, negative Helicobacter biopsies, when in fact infection has occurred are highly unlikely.

With respect to MEN-2, it is associated with pheochromocytoma, parathyroid adenoma, and medullary carcinoma of the thyroid.

[Q: 2497] OnExamination 2012 - Endocrinology

A 23-year-old student from central Africa brings her 29-year-old sister who is visiting on

holiday to see the GP because she is concerned about a fullness in her neck.

There is also a history of fatigue, a dry cough and a change in the quality of her voice over the past few months. She has no other past medical history of note; you ask about her diet, she tells you she eats mainly local food and they cannot get access to fresh fish.

On examination her BP is 135/70 mmHg, her pulse is 65 and her BMI is 28. There is a large, diffuse multinodular goitre.

Investigations show:

Haemoglobin 10.8 g/dl (11.5-16.5)

White cells $7.5 \times 10^9/L$ (4-11)

Platelet $179 \times 10^9/L$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 99 $\mu\text{mol/l}$ (79-118)

TSH 6.0 (0.5-5.0)

Which of the following is the most likely diagnosis?

- 1- Graves' disease
- 2- Hashimoto's disease
- 3- Idiopathic hypothyroidism
- 4- Iodine deficiency
- 5- Non-toxic multinodular goitre

Answer & Comments

Answer: 4- Iodine deficiency

Iodine deficiency occurs more commonly in central Africa.

It may present in a euthyroid state, or with severe deficiency, symptoms of hypothyroidism.

Diffuse goitre becomes nodular over time with prolonged deficiency.

Symptoms of extrinsic compression due to goitre size, including shortness of breath and difficulty swallowing may exist.

The presentation here with mild hypothyroidism (thyroid-stimulating hormone [TSH] just outside the normal range) is entirely consistent with this picture.

- A. Graves' is associated with symptoms of thyrotoxicosis so is incorrect.
- B. Hashimoto's would be an alternative consideration here, but the patient's location and relatively indolent course of her disease is designed to point you towards iodine deficiency.
- C. Again, the location should prompt you to consider iodine deficiency, so idiopathic hypothyroidism is the incorrect answer.
- D. Iodine deficiency and the large goitre, coupled with mild hypothyroidism in a patient from central Africa points you to this as the correct option.
- E. Non-toxic multinodular goitre is incorrect because of the clues that point you to iodine deficiency. It would be the default correct answer in another situation.

[Q: 2498] OnExamination 2012 - Endocrinology

A 43-year-old man comes to the clinic, he is known to have primary hypertriglyceridaemia and is managed with high dose statin and fibrate therapy.

He complains of episodes of upper abdominal pain, nausea and vomiting. He has had three or four attacks like this over the past six months. He denies significant alcohol consumption.

On examination his BP is 138/78 mmHg, his pulse is 78 and regular and his BMI is 22. Apart from eruptive xanthomata, there are no other significant findings.

Investigations show:

Haemoglobin 13.3 g/dl(13.5-17.7)

White cells $5.2 \times 10^9/L$ (4-11)

Platelet $244 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 112 $\mu\text{mol/l}$ (79-118)

HDL cholesterol 0.9 mmol/l (0.8-1.8)

LDL cholesterol 2.3 mmol/l (<4.0)

Triglycerides 5.8 mmol/l (0.7-2.1)

Glucose 5.2 mmol/l (<7.0)

Which of the following is the most likely underlying cause?

- 1- Acute pancreatitis
- 2- Chronic pancreatitis
- 3- Chronic stable angina
- 4- Chylomicronaemia syndrome
- 5- Gall bladder disease

Answer & Comments

Answer: 4- Chylomicronaemia syndrome

The answer is D, chylomicronaemia syndrome.

Chylomicronaemia syndrome is recognised in patients with severe hypertriglyceridaemia and causes recurrent episodes of abdominal pain, often accompanied by nausea and vomiting. It occasionally also causes chest or back pain and shortness of breath.

Amylase and lipase during an acute attack are within the normal range or mildly elevated, this helps differentiate an acute attack from acute pancreatitis. They are not shown here because this is a clinic follow up appointment.

He is of course also at risk of accelerated cardiovascular disease.

Yuan G, Al-Shali KZ, Hegele RA. Hypertriglyceridemia: its etiology, effects and treatment. CMAJ. 2007;176(8):1113-1120.

[Q: 2499] OnExamination 2012 - Endocrinology

A 73-year-old male with type 2 diabetes requires improved glycaemic control. He also

suffers from heart failure which is controlled with furosemide, ramipril, and bisoprolol.

Which of the following hypoglycaemic agents is contraindicated in this patient?

- 1- Acarbose
- 2- Glipizide
- 3- Nateglinide
- 4- Metformin
- 5- Pioglitazone

Answer & Comments

Answer: 5- Pioglitazone

Pioglitazone can result in fluid retention of unknown aetiology which may cause a mild dilutional anaemia (haemoglobin typically falls by 1 to 2 g/dL) and ankle oedema. It is contraindicated in congestive heart failure.

Sulphonylureas, acarbose, and nateglinide can be used in patients with heart failure.

To reduce the risk of lactic acidosis, metformin should be avoided in those at risk of tissue hypoxia or sudden deterioration in renal function, such as those with dehydration, severe infection, shock, sepsis, acute heart failure, respiratory failure, or hepatic impairment, or those who have recently had a myocardial infarction.

Although acute heart failure may increase the risk of lactic acidosis with metformin, this patient's heart failure appears to be controlled, and metformin may be used with caution.

[Q: 2500] OnExamination 2012 - Endocrinology

A 17-year-old girl presents with vomiting and her investigations show:

Sodium 120 mmol/L(137-144)

Potassium 3.0 mmol/L(3.5-4.9)

Urea 2.2 mmol/L(2.5-7.5)

Urine sodium 2 mmol/L

Urine osmolality 700 mosmol/kg(350-1000)

What is the most likely diagnosis?

- 1- Addison's disease
- 2- Bulimia nervosa
- 3- Diuretic abuse
- 4- Syndrome of inappropriate antidiuretic hormone secretion
- 5- Water intoxication

Answer & Comments

Answer: 2- Bulimia nervosa

This patient is likely to have bulimia - young girl with a likely low body mass contributing to the low urea, vomiting contributing to the hypokalaemia/hyponatraemia.

Her urine sodium is appropriately low and due to a relative dehydration she has appropriately concentrated urine.

This is not Addison's disease as urine sodium would be high with high urea and likely high potassium.

Similarly it is not SIADH due to the low urine sodium.

Diuretic abuse would cause high urine sodium.

Water intoxication would produce a dilute urine.

[Q: 2501] OnExamination 2012 - Endocrinology

A 40-year-old obese man with a BMI of 36 kg/m² was diagnosed with type 2 diabetes mellitus one year ago. He is now eating a healthy diet and getting sufficient exercise.

He did not report any osmotic symptoms and so far had been free from any micro- or macrovascular complications. He is currently not taking any medications.

Investigations at his annual diabetic follow-up were as follows:

Haemoglobin A_{1c} 7.4 % (3.8-6.4)

Fasting plasma glucose 9.8 mmol/l (3.0-6.0)

Serum Sodium 138 mmol/l (137-144)

Serum Potassium 4.7 mmol/l (3.5-4.9)

Serum urea 4.3 mmol/l (2.5-7.5)

Serum creatinine 88 µmol/l (60-110)

What would be the most appropriate management to optimise his glycaemic control?

- 1- Continue with lifestyle measures
- 2- Gliclazide therapy
- 3- Metformin therapy
- 4- Orlistat therapy
- 5- Pioglitazone therapy

Answer & Comments

Answer: 3- Metformin therapy

This obese male has sub-optimal control of his hyperglycaemia (HbA_{1c} 7.4%) despite diet.

One should aim for a HbA_{1c} below 7% and so the addition of metformin would be the most appropriate choice for this man.

[Q: 2502] OnExamination 2012 - Endocrinology

A 68-year-old woman presented to her general practitioner with a history of generalised tiredness.

She had recently been commenced on a water tablet to ease her swollen feet. She was also diagnosed with glaucoma for which she used topical eye drops.

Investigations showed:

Serum Sodium 138 mmol/L (137-144)

Serum potassium Haemolysed sample

Serum urea 4.3 mmol/L (2.5-7.5)

Serum creatinine 88 µmol/L (60-110)

Serum corrected Calcium 2.68 mmol/L (2.2-2.6)

Which diuretic was this lady most probably taking?

- 1- Acetazolamide
- 2- Amiloride
- 3- Bendroflumethiazide
- 4- Furosemide
- 5- Indapamide

Answer & Comments

Answer: 3- Bendroflumethiazide

Thiazide diuretics are associated with increased calcium concentrations as well as raised urate.

[Q: 2503] OnExamination 2012 - Endocrinology

A 54-year-old male who is a HGV driver and has a 10 year history of type 2 diabetes is seen on annual review.

His glycaemic control is poor with a HbA_{1c} of 10.5% on maximal oral hypoglycaemic therapy (3.8-6.4). You suggest switching to insulin but he refuses to do this as he would lose his HGV licence. He also refuses to inform the DVLA himself.

What is the most appropriate action in this case?

- 1- Continue to review patient in clinic and accept that he continues to drive
- 2- Discharge him from clinic as there is nothing more that you can do
- 3- Inform his employer that he must stop driving and suggest administrative work
- 4- Inform the DVLA even if the patient withholds his consent
- 5- Tell his next of kin that they should inform the DVLA that he is no longer fit to drive

Answer & Comments

Answer: 1- Continue to review patient in clinic and accept that he continues to drive

In this particular case, the patient has poor glycaemic control, but otherwise has no features whatsoever that preclude him from driving such as retinopathy, neuropathy or hypoglycaemic episodes. You cannot therefore force this patient to switch to insulin and neither can you stop him driving. He will continue to need a regular medical every three years for his continued HGV licence.

[Q: 2504] OnExamination 2012 - Endocrinology

A 70-year-old male with a history of syncope and hypertension is found to have runs of non-sustained ventricular tachycardia during telemetry.

Investigations show a serum magnesium of 0.4 mmol/l (0.75-1.05).

Which one of the following is most likely to be responsible for this biochemical abnormality?

- 1- Chronic renal failure
- 2- Diuretic therapy
- 3- Elevated PTH concentrations
- 4- Hyperphosphataemia
- 5- Treatment with antacids

Answer & Comments

Answer: 2- Diuretic therapy

Diuretic therapy is a common cause of hypomagnesaemia due to increased renal excretion. It is not seen in hyperparathyroidism.

Chronic renal failure and antacid therapy are both causes of hypermagnesaemia.

Hypophosphataemia is seen in association with hypomagnesaemia.

[Q: 2505] OnExamination 2012 - Endocrinology

A 44-year-old female presents with features suggestive of Cushing's syndrome.

Initial investigations reveal a 24 hour urine free cortisol concentration of 350 nmol/day (<250).

Which is the most appropriate investigation of this patient's suspected Cushing's syndrome?

- 1- 9 am and midnight cortisol
- 2- ACTH concentration
- 3- High dose dexamethasone suppression test
- 4- Low dose dexamethasone suppression test
- 5- Short Synacthen test

Answer & Comments

Answer: 4- Low dose dexamethasone suppression test

This patient is clinically suspected to have Cushing's syndrome with the diagnosis being supported by elevated urine free cortisol concentrations.

However, the diagnosis of hypercortisolism needs to be established and the best way of doing this is with a low dose dexamethasone suppression test (DXM 0.5 mg qds for two days). The high dose test (2 mg qds for two days) adds little diagnostic value over and above the low dose test.

9 am and midnight cortisol concentrations would not add much to the suspicion of hypercortisolism which is provided by the urine free cortisol.

Short Synacthen tests are used to assess for hypoadrenalism.

A CRF test is used occasionally to distinguish between ectopic and pituitary dependent Cushing's.

Adrenocorticotrophic hormone (ACTH) concentrations would also be valuable after

the diagnosis is confirmed to assess for ACTH dependency.

[Q: 2506] OnExamination 2012 - Endocrinology

An 18-year-old male presented with delayed pubertal development. He had always noted an impaired sense of smell.

Examination revealed that his height was on 90th centile and his weight on the 90th centile. His external genitalia showed a small penis with testicular volumes of 3 mL bilaterally and no pubic hair.

Investigations revealed:

LH concentration 1.0 U/L(1-10)

FSH concentration 1.0 U/L(1-7)

Serum testosterone 3.0 pmol/L(9-35)

Free T₄ 19 pmol/L(10-22)

TSH 3.0 mU/L(0.4-5)

CT scan reported as normal.

What is the most likely diagnosis?

- 1- Constitutional delay of puberty
- 2- Kallmann's syndrome.
- 3- Klinefelter's syndrome.
- 4- Noonan's syndrome.
- 5- Prader-Willi syndrome.

Answer & Comments

Answer: 2- Kallmann's syndrome.

The combination of hypogonadotrophic hypogonadism and anosmia would suggest a diagnosis of Kallmann's syndrome.

This is one of the commonest causes of isolated hypogonadotrophic hypogonadism and is due to a failure of migration of the olfactory neurones and gonadotropin-releasing hormone (GnRh) neurones during development.

[Q: 2507] OnExamination 2012 - Endocrinology

A 53-year-old male is suspected of having acromegaly.

Which of the following is the best investigation to confirm the diagnosis?

- 1- 9 am growth hormone (GH) concentrations
- 2- An insulin tolerance test with growth hormone concentrations
- 3- Glucose tolerance test with growth hormone concentrations
- 4- Growth hormone releasing hormone test
- 5- Insulin-like growth factor-1 (IGF-1)

Answer & Comments

Answer: 3- Glucose tolerance test with growth hormone concentrations

The diagnosis of acromegaly is confirmed by inadequate suppression of GH concentrations below 2 mU/l in an oral glucose tolerance test.

Although IGF-1 concentrations are elevated these are not diagnostic and may fall during illness.

[Q: 2508] OnExamination 2012 - Endocrinology

Which of the following is true of the thyroid hormone receptor?

- 1- A cell surface receptor
- 2- A cytoplasmic protein
- 3- A gated ion channel
- 4- A G protein coupled receptor
- 5- A nuclear receptor

Answer & Comments

Answer: 5- A nuclear receptor

The thyroid hormone receptor is a nuclear receptor.

When it binds tri-iodothyronine (T3) it is able to bind to the thyroid hormone response element (TRE) in the promoter region of thyroid hormone responsive genes and initiates transcription.

[Q: 2509] OnExamination 2012 - Endocrinology

A 64-year-old male presents with difficulty in micturition.

He is diagnosed with benign prostatic hyperplasia and elects to receive finasteride.

Production of which of the following hormones would be selectively inhibited?

- 1- Androstenedione
- 2- Dihydroepiandrosterone sulphate (DHEAS)
- 3- Dihydrotestosterone (DHT)
- 4- IGF-1
- 5- Testosterone

Answer & Comments

Answer: 3- Dihydrotestosterone (DHT)

Finasteride is a 5 alpha-reductase inhibitor and inhibits the conversion of testosterone to the active DHT.

[Q: 2510] OnExamination 2012 - Endocrinology

Leptin:

- 1- Acts upon the adipocyte
- 2- Is synthesised in the hypothalamus
- 3- Plasma concentrations correlate directly with lean body mass.
- 4- Produces satiety
- 5- Reduces basal metabolic rate

Answer & Comments

Answer: 4- Produces satiety

Leptin is synthesised within the adipocyte and plasma concentrations are directly related to adipocyte (fat) mass.

It acts on centres within the hypothalamus to produce satiety.

[Q: 2511] OnExamination 2012 - Endocrinology

In active acromegaly with associated diabetes mellitus which of the following findings would be expected?

- 1- Diabetes mellitus is due to an auto-immune process
- 2- Growth hormone concentrations are suppressed with hyperglycaemia
- 3- IGF-1 concentrations are low
- 4- There is insulin resistance
- 5- Treatment with a somatostatin analogue is contraindicated

Answer & Comments

Answer: 4- There is insulin resistance

Insulin resistance stems from the excessive growth hormone (GH) concentrations (anti-insulin effects) that of course fail to suppress with hyperglycaemia.

Acromegaly is often effectively treated with somatostatin analogues which may improve glycaemic control.

Many of the effects of GH are mediated through insulin-like growth factor-1 (IGF-1), concentrations of which are high in acromegaly.

Diabetes mellitus is due to the insulin resistance and is not due to auto-immune insulinitis.

[Q: 2512] OnExamination 2012 - Endocrinology

A 52-year-old female presents with tiredness.

There are no specific abnormalities noted on examination, but investigations reveal:

T₄ 21.1 pmol/L (10-22)

T₃ 5.2 pmol/L (5-10)

TSH 0.05 mU/L (0.4-5)

Thyroid autoantibody titres are all undetectable.

Of what do these results suggest a diagnosis?

- 1- DeQuervain's thyroiditis
- 2- Graves' disease
- 3- Hashimoto's thyroiditis
- 4- Sick euthyroid syndrome
- 5- Solitary toxic nodule

Answer & Comments

Answer: 5- Solitary toxic nodule

This patient has subclinical hyperthyroidism and, in the absence of thyroid auto-antibodies, the most probable explanation of these thyroid function abnormalities is a solitary toxic nodule.

[Q: 2513] OnExamination 2012 - Endocrinology

A 42-year-old woman who is known to have Hashimoto's thyroiditis presents to the clinic with muscle pains and fatigue, and pins and needles affecting her hands intermittently. She takes no regular medication apart from thyroxine replacement.

Clinical examination is unremarkable.

Investigations show:

Haemoglobin 12.2 g/dl(11.5-16.0)

White cell count $6.4 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (135-146)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 108 $\mu\text{mol/l}$ (79-118)

Calcium 2.05 mmol/l (2.20-2.61)

Phosphate 1.65 mmol/l (0.8-1.5)

Alkaline phosphatase 62 U/l (39-117)

Which of the following is the most appropriate way to manage her symptoms?

- 1- Calcitonin
- 2- Calcium and vitamin D3
- 3- Cinacalcet
- 4- PTH analogue
- 5- Risedronate

Answer & Comments

Answer: 2- Calcium and vitamin D3

The blood picture raises the possibility of osteomalacia, as such calcium and vitamin D are most appropriate.

Calcitonin is licensed for the treatment of osteoporosis and is therefore not appropriate here.

Cinacalcet is appropriate for the treatment of tertiary hyperparathyroidism where the patient cannot undergo surgery, such as occurs in chronic kidney disease.

Parathyroid hormone (PTH) analogues are used in the treatment of osteoporosis, as is risedronate.

[Q: 2514] OnExamination 2012 - Endocrinology

A 54-year-old woman presents to the clinic with hypercalcaemia detected at GP screening.

She has no significant medical history apart from mild hypertension for which she has been advised by the GP to lose weight.

On examination her BP is 150/90 mmHG, her BMI is 29. General physical examination is unremarkable.

Investigations show:

Haemoglobin 11.5 g/dl(11.5-16.0)

White cell count $5.6 \times 10^9/L$ (4-11)
 Platelets $168 \times 10^9/L$ (150-400)
 Sodium 139 mmol/l (135-146)
 Potassium 4.2 mmol/l (3.5-5)
 Creatinine 110 micromol/l (79-118)
 PTH 12.2 micromol/l
 Hip T score -2.7

Which of the following treatments should she be offered?

- 1- Cinacalcet
- 2- Furosemide
- 3- Risedronate
- 4- Surgical referral
- 5- Vitamin D

Answer & Comments

Answer: 4- Surgical referral

Guidelines from the NIH on the management of primary hyperparathyroidism suggest that this patient should be offered surgery.

Considerations for surgery include:

Serum albumin-adjusted calcium greater than 0.25 mmol/L above the upper limit of local laboratory reference range

Twenty four hour total urinary calcium excretion greater than 10 mmol (400 mg)

Creatinine clearance reduced by 30% or more

Bone mineral density T score less than -2.5 (at any site)

Age younger than 50 years

Patient request; adequate follow-up unlikely.

This woman fulfils the guidelines due to osteoporosis.

Risedronate is incorrect because this patient already fulfils the diagnosis of osteoporosis and as such should be offered surgery in the first instance.

Cinacalcet is incorrect because it should be only offered in patients with tertiary hyperparathyroidism who are unfit for surgery.

Furosemide may be useful in situations of acute hypercalcaemia, and vitamin D is a treatment for secondary hyperparathyroidism.

[Q: 2515] OnExamination 2012 - Endocrinology

An 18-year-old man comes to the endocrine clinic for review. He has been followed up since entering puberty at the age of 10. There are visible bony deformities and he walks slowly with a stick.

On examination his BP is 148/82 mmHg, pulse is 70 and regular. He has a number of café au lait spots. There are obvious multiple healed fractures.

Investigations show:

Haemoglobin 13.2 g/dl (13.5-17.7)

White cell count $7.3 \times 10^9/L$ (4-11)

Platelets $160 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 103 micromol/l (79-118)

TSH 0.3 IU (0.5-4.5)

Alkaline phosphatase 230 U/l (39-117)

Calcium 2.2 mmol/l (2.20-2.61)

Which of the following is the most likely diagnosis?

- 1- Autoimmune polyglandular syndrome
- 2- McCune-Albright syndrome
- 3- Neurofibromatosis type 2
- 4- Neurofibromatosis type 1
- 5- Osteomalacia

Answer & Comments

Answer: 2- McCune-Albright syndrome

The diagnosis of McCune-Albright is established on clinical grounds, with the presence of precocious puberty, bony fibromas leading to possible pathological fractures, thyrotoxicosis, and cafe au lait spots all supporting this as the underlying cause.

Autoimmune polyglandular syndrome leads to multiple hormone deficiencies, including Addison's, hypothyroidism, and hypoparathyroidism.

Whilst neurofibromatosis is a cause of cafe au lait spots, it is not usually a cause of precocious puberty and other endocrine abnormalities such as the thyrotoxicosis seen here.

Osteomalacia can occur as a consequence of McCune-Albright, but is not the primary diagnosis seen here.

[Q: 2516] OnExamination 2012 - Endocrinology

A 61-year-old woman comes to the clinic.

She currently takes metformin 1 g twice daily and gliclazide 160 mg twice daily. On examination her blood pressure is 155/90 mmHg, her BMI is 29.

Her general practitioner is concerned as he has noticed a rise in her creatinine to 138.

Investigations in clinic show:

Haemoglobin 11.9 g/dl(13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $193 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 5.0 mmol/l (3.5-5)

Creatinine 142 $\mu\text{mol/l}$ (60-120)

HbA1c 7.2%(<5.5)

Glomerular filtration rate 38 ml/min(>90)

Which of the following is the correct course of action with regard to her metformin?

- 1- Continue her metformin
- 2- Stop her metformin and consider acarbose
- 3- Stop her metformin and consider exenatide
- 4- Stop her metformin and consider insulin
- 5- Stop her metformin and continue the gliclazide

Answer & Comments

Answer: 1- Continue her metformin

Impaired renal function leads to decreased clearance of metformin, and an increased risk of lactic acidosis. NICE has therefore released guidelines regarding the use of metformin in patients with renal impairment.

Clinical circumstances should be reviewed when the eGFR falls below 45mL/min/1.73m² (or the serum creatinine exceeds 130 $\mu\text{mol/L}$). metformin should then be stopped if the serum creatinine exceeds 150 $\mu\text{mol/L}$ (or eGFR is below 30mL/min/1.73m²).

Metformin may be continued (or initiated) with an eGFR less than 60mL/min/1.73m², but renal function should be monitored closely (every 3-6 months).

The dose of metformin should be reviewed and reduced in those with an eGFR of less than 45mL/min/1.73m², and renal function should be monitored every three months. Metformin should not be initiated in patients as this stage however.

The drug should be stopped once eGFR falls to less than 30mL/min/1.73m² (creatinine more than 150 $\mu\text{mol/L}$).

Caution should be taken in patients with anticipated significant fluctuations in renal function, or those at risk of abrupt deterioration in function (based on history, co-morbidities, proteinuria and other medications).

In this case the eGFR is more than 30mL/min/1.73m², and the creatinine is less than 150μmol/L, therefore metformin can be continued (albeit at a reduced dose). Further review of her medication is likely to be needed due to her raised HbA1c, however this is not what the question asks.

[Q: 2517] OnExamination 2012 - Endocrinology

A 60-year-old woman with type 2 diabetes comes to the clinic three months after adding a daily injection of long-acting insulin to her regime.

She has had type 2 diabetes for some six years, and also takes metformin 1 g BD, ramipril 10 mg, aspirin 75 mg and atorvastatin 10 mg.

You review her results, and her average morning fasting sugar is 5.9 mmol/L. Unfortunately, her pre-lunch glucose is consistently out of range, at around 9.5 mmol/L.

Which of the following is the correct intervention according to the ADA/EASD consensus algorithm 2006?

- 1- Add a pre-breakfast injection of NPH insulin
- 2- Add a pre-breakfast injection of rapid acting insulin
- 3- Add a pre-lunch injection of NPH insulin
- 4- Add a pre-lunch injection of rapid acting insulin
- 5- Add a pre-dinner injection of NPH insulin

Answer & Comments

Answer: 2- Add a pre-breakfast injection of rapid acting insulin

This is the course of action recommended by the consensus.

It seems with a pre-lunch glucose level of 9.5, that there is a significant post-breakfast peak in glucose levels. As such, the best way to

manage this is with a breakfast time injection of rapid acting insulin.

The consensus does not recommend using BD pre-mixed preparations until the need for rapid acting insulin and any necessary dose titration has been adequately assessed.

[Q: 2518] OnExamination 2012 - Endocrinology

A 30-year-old woman who is 24 weeks pregnant presents with a blood pressure on three separate occasions of approximately 160/110 mmHg.

Her liver function tests (LFTs) show:

Aspartate transaminase 150 U/L (5-45)

Alkaline phosphatase 213 U/L (50-120)

Bilirubin 31 μmol/L (0-18)

Which antihypertensive is indicated?

- 1- Atenolol
- 2- Irbesartan
- 3- Labetalol
- 4- Methyldopa
- 5- Ramipril

Answer & Comments

Answer: 3- Labetalol

Angiotensin-converting enzyme inhibitors are contraindicated in pregnancy as they cause renal dysgenesis in the fetus. For this reason A2RBs are also not recommended for use in pregnancy.

There is a theoretical risk of intrauterine growth retardation with the use of atenolol in pregnancy although the studies which showed this effect were done with very large doses of atenolol.

One would not utilise methyldopa in a patient with abnormal LFTs.

[Q: 2519] OnExamination 2012 - Endocrinology

A 35-year-old woman presents with episodic sweats associated with hunger. She was otherwise well and had gained some weight recently.

Investigations reveal normal urea and electrolytes, liver function tests and full blood count. An overnight fasting plasma glucose is 3.8 mmol/l (3.0-6.0).

What is the most appropriate investigation for this patient?

- 1- 24 hour ECG recording
- 2- 72 hour fast
- 3- Fasting insulin and C peptide concentrations
- 4- MR scan of pancreas
- 5- Short Synacthen test

Answer & Comments

Answer: 2- 72 hour fast

This patient presents with features suggestive of spontaneous hypoglycaemia often due to an insulinoma. She requires confirmation of the suspected diagnosis and this should be undertaken with a 72 hour fast.

If the patient develops symptoms then a plasma glucose is measured and if low, insulin, and C peptide is then collected and the fast terminated.

We have been provided with a fasting plasma glucose on this patient which is normal.

Measuring insulin and C peptides with this normal glucose would provide no meaningful information. First we have to see whether she actually becomes hypoglycaemic.

[Q: 2520] OnExamination 2012 - Endocrinology

Which of the following suggests a diagnosis of familial combined hyperlipidaemia (FCHL)?

rather than heterozygous familial hypercholesterolaemia (FH)?

- 1- Absence of hyperuricaemia
- 2- Presence of arcus senilis
- 3- Presence of glucose intolerance
- 4- Strong family history of premature coronary artery disease
- 5- Tendon xanthomas

Answer & Comments

Answer: 3- Presence of glucose intolerance

The genetic dyslipidaemias occur in one third of patients who have suffered from their first myocardial infarction below the age of 50 years in men.

The commonest is familial combined hyperlipidaemia (two thirds), with a fifth due to familial hypercholesterolaemia. The former can be diagnosed only on family studies, and there is elevation of fasting plasma triglycerides not associated with hyperchylomicronaemia.

It is autosomal dominant, and some family members may have hyperchylomicronaemia.

Only 20% of children have elevated triglycerides before the age of 25.

Obesity, insulin resistance, hyperinsulinaemia, glucose intolerance, and hyperuricaemia are associated.

Heterozygous familial hypercholesterolaemia is dominantly inherited, and results from defects in the low-density lipoprotein (LDL) receptor. The most important clinical manifestation is premature coronary artery disease, particularly with onset between the third or fourth decade.

Tendon xanthomata and arcus cornea are rarely present in children, but are very important signs to identify.

[Q: 2521] OnExamination 2012 - Endocrinology

A 45-year-old male with type 1 diabetes and with a number of complex diabetic gastrointestinal complications is noted to have a PR interval of 0.18 s, a QRS duration of 0.1 s and a QT interval of 0.48 s on routine ECG.

Which of the following drugs may be responsible?

- 1- Cimetidine
- 2- Co-trimoxazole
- 3- Domperidone
- 4- Erythromycin
- 5- Octreotide

Answer & Comments

Answer: 4- Erythromycin

Erythromycin has been associated with prolonged QT interval and torsades de pointes and is used in diabetic gastropathy, although its benefits in the condition are not entirely understood.

Prolonged QT is defined as greater than 0.45 s.

Other agents include amitriptyline and phenothiazines yet metoclopramide and domperidone are not associated.

[Q: 2522] OnExamination 2012 - Endocrinology

A 16-year-old male presents with a day history of malaise, weakness and vomiting. He was diagnosed with insulin-dependent diabetes mellitus three years previously.

Which one of the following supports a diagnosis of diabetic ketoacidosis (DKA)?

- 1- Abdominal pain at onset
- 2- A serum standard bicarbonate of 10 mmol/l (NR 22-26)

- 3- A random serum glucose 14 mmol/l (NR 4.5-6-4)
- 4- Decreased appetite in the past few days
- 5- Shallow respirations

Answer & Comments

Answer: 2- A serum standard bicarbonate of 10 mmol/l (NR 22-26)

A. This is an unusual but recognised feature, particularly in children. However it does not support a diagnosis of DKA.

B. The low plasma bicarbonate is highly suggestive of a metabolic acidosis.

C. 'Normoglycaemic DKA' can occur and a glucose of 14 is compatible with a diagnosis, but is not suggestive as one might expect to find these sort of concentrations with diabetes per se.

D. Usually patients are unwell with infections and anorexia. Fasting is itself associated with the presence of ketones in the urine but not necessarily ketoacidosis.

E. Respiratory compensation leads to rapid deep (Kussmaul's) breathing.

[Q: 2523] OnExamination 2012 - Endocrinology

Growth hormone deficiency (GHD) is noted in which of the following?

- 1- Chronic renal failure (CRF)
- 2- Constitutional short stature
- 3- Laron's syndrome
- 4- Sheehan's syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 4- Sheehan's syndrome

Sheehan's syndrome is post-delivery infarction of the pituitary and GHD is typical.

Although GH therapy is used in CRF, Turner's syndrome and short stature subjects are not GH deficient.

Laron's syndrome is due to a GH receptor defect with impaired IGF-1 production.

[Q: 2524] OnExamination 2012 - Endocrinology

A 58-year-old man comes to the diabetes clinic for review. He has had type 2 diabetes for eight years and has troublesome neuropathy with pain and burning in both lower limbs for long periods of the night.

Current medication for his diabetes includes metformin 1 g BD and gliclazide 80 mg BD.

On examination his BP is 145/85 mmHg, his pulse is 80 and regular. He has glove and stocking neuropathy with sensory loss to the mid shin.

Investigations show:

Haemoglobin 12.3 g/dl(13.5-17.7)

White cell count $7.1 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

HbA1c 7.3%(<5.5)

Which of the following is the most appropriate way to manage his pain?

- 1- Amitriptyline
- 2- Axsain cream
- 3- Carbamazepine
- 4- Duloxetine
- 5- Gabapentin

Answer & Comments

Answer: 4- Duloxetine

Amitriptyline is first line therapy for diabetic neuropathy only if duloxetine is contraindicated.

Axsain cream, whilst an effective topical agent is not recommended by NICE.

Second line therapy of choice according to NICE is pregabalin, which may be used in combination with amitriptyline.

[Q: 2525] OnExamination 2012 - Endocrinology

A 52-year-old woman presents to the clinic complaining of intense paroxysms of pain affecting her left cheek, which can last anything from 30 seconds to several minutes. She says that these can come on at any time but may be triggered by activities like going out on a cold day or using her hair dryer.

She has no past medical history of note. Clinical examination is entirely normal.

Investigations show:

Haemoglobin 11.9 g/dl(11.5-16.0)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

Which of the following would be the most appropriate option to manage these episodes of pain?

- 1- Amitriptyline
- 2- Carbamazepine
- 3- Diclofenac
- 4- Paracetamol
- 5- Tramadol

Answer & Comments

Answer: 2- Carbamazepine

Amitriptyline is not the correct answer because the evidence for its use in trigeminal neuralgia is weak.

Equally, non-steroidals, opiates and paracetamol are not as effective as anti-convulsants such as carbamazepine or gabapentin.

Topical agents have proved disappointing in the management of the condition.

[Q: 2526] OnExamination 2012 - Endocrinology

A 57-year-old woman presents with a temperature of 39.6°C, tachycardia and jaundice.

Her husband tells you that she has been increasingly confused and agitated over the past few days. Her only past history of note is an inguinal hernia repair in the previous week.

On examination her BP is 105/70 mmHg, her pulse is 130, atrial fibrillation, she has jaundiced sclerae. She is agitated and poorly compliant with the examination.

Investigations show:

Haemoglobin 10.9 g/dl(11.5-16.0)

White cell count $10.8 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 120 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 78 U/l (5-40)

Bilirubin 72 $\mu\text{mol/l}$ (<17)

TSH <0.05 IU/l (0.5-4.5)

Which of the following treatments is likely most rapidly to impact on her symptoms?

- 1- Carbimazole
- 2- Diclofenac
- 3- Potassium iodide
- 4- Prednisolone

5- Propylthiouracil

Answer & Comments

Answer: 3- Potassium iodide

Whilst both carbimazole and propylthiouracil are reasonable options for the control of thyrotoxicosis they take longer to exert their effect than potassium iodide.

Non-steroidals are used in the treatment of subacute thyroiditis with prednisolone an option in patients who fail to respond.

[Q: 2527] OnExamination 2012 - Endocrinology

An 18-year-old woman comes to the clinic complaining of acne and hirsutism. She has no medical history of note and her only medication is the oral contraceptive pill.

On examination her BP is 140/82 mmHg, pulse is 80 and regular and her BMI is 28. There are obvious features of virilisation.

Investigations show:

Haemoglobin 12.0 g/dl(11.5-16.0)

White cell count $5.4 \times 10^9/L$ (4-11)

Platelets $200 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 5.2 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (79-118)

LH/FSH ratio normal

Which of the following is most likely to be elevated?

- 1- 17-OH progesterone
- 2- 21-OH progesterone
- 3- Aldosterone
- 4- Cortisol
- 5- Urinary 21-ketosteroids

Answer & Comments

Answer: 1- 17-OH progesterone

21-hydroxylase deficiency leads to a reduction rather than an elevation in aldosterone and cortisol levels. Due to the enzyme block, cortisol cannot be made effectively and androgens are made instead.

Urinary 17-ketosteroid levels (androgen metabolites) are elevated in the condition.

21-OH progesterone levels are not elevated in congenital adrenal hyperplasia (CAH).

[Q: 2528] OnExamination 2012 - Endocrinology

A 45-year-old man is admitted with drowsiness and confusion. According to a neighbour he has been complaining of increasing problems with thirst and passing large volumes of urine over the past few days.

On examination his BP is 100/60 mmHg, his pulse is 95 and regular, and he has signs of a right lower respiratory tract infection.

Whilst you are examining him a nurse checks his finger prick glucose which is measured at 36.2 mmol/l.

Which of the following investigations would be most suggestive of a diagnosis of diabetic ketoacidosis?

- 1- Amylase 400 U/l
- 2- Bicarbonate 24 mmol/l
- 3- Lactate 1.6 mmol/l
- 4- Right lower lobe consolidation on chest x ray
- 5- Urinary tract infection on urine screen

Answer & Comments

Answer: 1- Amylase 400 U/l

A raised amylase in the absence of frank pancreatitis is common in patients with diabetic ketoacidosis (DKA), indeed many patients complain of a degree of abdominal pain at the time of presentation. No specific

management is required and amylase falls with rehydration and control of blood glucose.

Bicarbonate of 24 and lactate of 1.6 would both count against a diagnosis of ketoacidosis and favour an alternative such as hyperosmolar non-ketotic (HONK) hyperglycaemia.

Infection can precipitate presentation with HONK or DKA, therefore again possible urine infection or pneumonia would not be useful differentiators here.

[Q: 2529] OnExamination 2012 - Endocrinology

A 16-year-old girl comes to the clinic for review with primary amenorrhoea. Apart from surgery for hernias as an infant, she has no significant past medical history.

On examination she is 1.65 m in height and has a BP of 110/70 mmHg, her pulse is 64 and regular. She has relatively normal breast development but sparse body hair and no secondary sexual hair. Her external genitalia look normal.

Investigation shows:

Haemoglobin 12.8 g/dl (11.5-16.0)

White cell count $6.0 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.6 mmol/l (3.5-5)

Creatinine 80 $\mu\text{mol/l}$ (79-118)

Urea 5.2 mmol/l (2.5-6.7)

Testosterone 15 nmol/l (11-40)

Which of the following is the most likely diagnosis?

- 1- Androgen insensitivity syndrome (AIS)
- 2- Kallman's syndrome
- 3- Klinefelter's syndrome
- 4- Noonan's syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 1- Androgen insensitivity syndrome (AIS)

Kallman's syndrome is associated with failure of the olfactory bulb to develop, leading to loss of gonadotropin releasing hormones.

Klinefelter's is associated with male phenotype, and an XXY karyotype.

Noonan's is associated with short stature and a similar phenotype to Turner's in women, although patients with Noonan's do have normal female organs. In males Noonan's may be associated with delayed puberty.

Turner's is associated with XO karyotype, absent uterus and streak ovaries.

[Q: 2530] OnExamination 2012 - Endocrinology

A 52-year-old woman with a history of type 2 diabetes comes to the clinic for review.

She is currently managed with metformin 1 g BD with respect to glucose control, and her only other medication at the moment is lisinopril 20 mg daily and simvastatin 40 mg.

On examination her BP is 138/82 mmHg, her pulse is 82 and regular. Her BMI is 27 kg/m².

Investigations show:

Haemoglobin 11.4 g/dl(11.5-16.5)

White cells 7.3 x 10⁹/L (4-11)

Platelet 184 x 10⁹/L (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 119 µmol/l (79-118)

HDL cholesterol 0.9 mmol/l (1.0-2.3)

LDL cholesterol 3.9 mmol/l (<4.0)

Triglycerides 3.1 mmol/l (0.5-1.7)

HbA1c 9.3% (<5.5)(89 mmol/mol)(<36)

Which of the following is the most appropriate initial step to impact on her triglycerides?

- 1- Additional blood glucose lowering therapy
- 2- Exercise programme
- 3- Fibrate therapy
- 4- High dose statin therapy
- 5- Omega 3 fatty acid supplementation

Answer & Comments

Answer: 1- Additional blood glucose lowering therapy

The answer is A, additional blood glucose lowering therapy.

Under-treatment with respect to blood glucose lowering therapy leads to hypertriglyceridaemia and raised HbA1c. As such the first priority in this patient is to improve her glucose control with a second oral agent.

JBS2 guidelines suggest that all patients with type 2 diabetes should be prescribed a statin, even if their cholesterol is within the target range, although statin therapy impacts most on low-density lipoprotein (LDL) cholesterol.

In patients with type 2 diabetes who have hypertriglyceridaemia despite optimal glucose control and statin therapy, treatments targeted for triglyceride reduction, such as niacin, fibrates or omega-3 fatty supplementation should be considered.

[Q: 2531] OnExamination 2012 - Endocrinology

A 32-year-old woman treated with hydrocortisone 10 mg in the morning and 10 mg in the evening for Addison's disease, presents to the clinic with poor compliance.

She feels that the hydrocortisone upsets her stomach and wants to switch to enteric coated prednisolone.

What would be the appropriate corresponding daily dose of prednisolone?

- 1- 4 mg daily

- 2- 5 mg daily
- 3- 7 mg daily
- 4- 10 mg daily
- 5- 15 mg daily

Answer & Comments

Answer: 2- 5 mg daily

The approximate equivalent glucocorticoid action of prednisolone to hydrocortisone is 4:1.

Hence the equivalent dose for 20 mg of hydrocortisone is roughly 5 mg per day of prednisolone.

For other glucocorticoid dose conversions try this online glucocorticoid dose calculator

[Q: 2532] OnExamination 2012 - Endocrinology

A 55-year-old male with type 2 diabetes is seen at annual review.

His glycaemic control is sub-optimal on diet alone and his most recent HbA1c is 7.9% (3.8-6.4). You elect to treat him with metformin 500 mg BD.

Which of the following would be the most appropriate interval to re-check his HbA1c?

- 1- Two weeks
- 2- One month
- 3- Two - three months
- 4- Four - six months
- 5- Six - twelve months

Answer & Comments

Answer: 3- Two - three months

The HbA1c is a reflection of the glycosylation of the haemoglobin moiety by glucose.

There is a strong correlation between the glycosylation of this molecule and average plasma glucose concentrations, hence its

widespread use in clinical practice as a tool to assess glycaemic control.

Furthermore, studies reveal its prognostic significance in both microvascular and macrovascular risk.

The life span of the red cell is 120 days. HbA1c reflects average blood glucose levels during the half-life of the red cell (about 60 days) and so the recommended appropriate interval for re-measuring HbA1c following change in therapy is two months.

[Q: 2533] OnExamination 2012 - Endocrinology

Side effects of recombinant human growth hormone (rhGH) therapy include which of the following?

- 1- Aplastic anaemia
- 2- Benign intracranial hypertension (BIH)
- 3- Creutzfeldt-Jakob disease (CJD)
- 4- Leukaemia
- 5- Proliferative retinopathy

Answer & Comments

Answer: 2- Benign intracranial hypertension (BIH)

Unlike the old pituitary-derived growth hormone (GH), rhGH is not associated with CJD as it is manufactured by recombinant techniques.

rhGH therapy has been associated with BIH probably due to the fluid retention associated with GH therapy.

[Q: 2534] OnExamination 2012 -
Haematology

What is the most effective bisphosphonate for use in reducing bone pain and preventing pathological fractures in patients with metastatic breast cancer?

- 1- Alendronic acid
- 2- Ibandronic acid
- 3- Olpadronate
- 4- Pamidronate
- 5- Zoledronic acid

Answer & Comments

Answer: 5- Zoledronic acid

Multiple randomised control studies have proven the efficacy of Zometa in treatment of bone metastasis from breast cancer.

It is commonly given for six months and if the patient responds then they can be switched to daily ibandronic acid to prevent repeat visits to hospital.

Zometa has a risk of osteonecrosis of the jaw which must be explained to patients before they are treated.

[Q: 2535] OnExamination 2012 -
Haematology

A 70-year-old female presents with a three month history of exertional dyspnoea and chest pain. She admitted to a poor diet, some vague abdominal pains and having lost 7 kg in weight.

Examination revealed pallor, patches of vitiligo on her arms and trunk, ankle oedema and a palpable spleen.

Investigations revealed:

Haemoglobin 5 g/dL(11.5-16.5)

MCV 105 fL(80-96)

White cell count $2 \times 10^9/L$ (4-11)

Platelet count $50 \times 10^9/L$ (150-400)

Bilirubin 40 $\mu\text{mol/L}$ (1-22)

ALT 60 U/L(1-31)

AST 40 U/L(5-35)

LDH 1000 U/L(10-250)

Which one of the following is the most likely diagnosis?

- 1- Aplastic anaemia
- 2- Autoimmune haemolytic anaemia
- 3- Dietary folate deficiency
- 4- Pernicious anaemia
- 5- Sideroblastic anaemia

Answer & Comments

Answer: 4- Pernicious anaemia

There is pancytopenia with anaemia being more significant. The anaemia is macrocytic.

Lactate dehydrogenase (LDH) is very high with some derangement of liver function tests (LFTs). Aplastic anaemia would cause pancytopenia but not a raised LDH.

Autoimmune haemolysis and sideroblastic anaemia would not cause pancytopenia.

Folate deficiency and pernicious anaemia would both cause the above results - the LDH is elevated due to ineffective erythropoiesis and likewise the deranged LFTs.

Pernicious anaemia is more likely given the history of other autoimmune disease.

Of note, with such a low haemoglobin one would expect a much higher mean corpuscular volume

(MCV); but sometimes when the deficiency is severe, the red cell anisopoikilocytosis causes a lower MCV.

[Q: 2536] OnExamination 2012 -
Haematology

A 72-year-old man presents with a five day history of cough, dyspnoea and fever.

His chest x ray shows a left basal consolidation.

His full blood count shows:

Haemoglobin 11 g/dL (13.0-18.0)

White cell count $30 \times 10^9/L$ (4-11 $\times 10^9$)

Neutrophils $10 \times 10^9/L$ (1.5-7 $\times 10^9$)

Lymphocytes $20 \times 10^9/L$ (1.5-4 $\times 10^9$)

Monocytes $1 \times 10^9/L$ (0-0.8 $\times 10^9$)

Eosinophils $0.4 \times 10^9/L$ (0.04-0.4 $\times 10^9$)

Basophils $0.1 \times 10^9/L$ (0-0.1 $\times 10^9$)

Which one of the following is the most appropriate test to establish the diagnosis?

- 1- Bone marrow aspirate
- 2- Bone marrow cytogenetics
- 3- CT abdomen
- 4- Immunophenotyping of white cells
- 5- Sputum cytology and AFB

Answer & Comments

Answer: 4- Immunophenotyping of white cells

Apart from the mild neutrophilia which could be explained by the infection the significant abnormality on the FBC is the lymphocyte count. Such a high lymphocyte count could be suggestive of a lymphoproliferative disorder such as chronic lymphocytic leukaemia. The best way to diagnose these is immunophenotyping of the blood - non-invasive and will give a diagnosis.

The patient may have lymphadenopathy or splenomegaly which would show on CT but no diagnosis can be made from this.

A bone marrow is invasive and the BM is sometimes not involved in low grade lymphoproliferative disorders and similarly there may be no cytogenetic abnormality.

The FBC is not suggestive of TB or malignancy, therefore sputum examination would not be useful.

[Q: 2537] OnExamination 2012 - Haematology

A 67-year-old man presents with a five week history of pain and swelling affecting left knee, both ankles and his right wrist.

He has had three episodes of right basal pneumonia in the last year and has lost 6 kg in weight.

His investigations are as follows:

WCC $12.1 \times 10^9/L$ (4-11)

Hb 9.8 g/dL (13.0-18.0)

MCV 79fL (80-96)

Platelets $543 \times 10^9/L$ (150-400)

ESR 43 mm in the first hour (0-20mm/1st hour)

CRP 21 mg/L (<10)

CPK 110U

RF 1/80

ANA Negative

ENA Negative

Radiographs of hands and feet Normal

What is the most likely diagnosis?

- 1- Mixed connective tissue disease
- 2- Paraneoplastic syndrome
- 3- Polyarteritis nodosa
- 4- Polymyalgia rheumatica
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 2- Paraneoplastic syndrome

The suggestion here is lung malignancy with an associated paraneoplastic syndrome.

Paraneoplastic syndrome can present with an asymmetrical arthralgia which more commonly affects the lower limbs.

False positive rheumatoid factors can occur but should be of low titre.

The age of onset is usually lower than that for rheumatoid arthritis or polymyalgia rheumatica.

[Q: 2538] OnExamination 2012 - Haematology

A 22-year-old male student is admitted with weakness and tiredness. He has otherwise been well.

Examination reveals a petechial rash on the lower legs and conjunctival pallor. He takes no medication and denies any illicit drug use.

Investigations reveal:

Haemoglobin 4 g/dL (13.0-18.0)

White cell count $1 \times 10^9/L$ (4-11)

Platelets $20 \times 10^9/L$ (150-400)

Clotting profile Normal

U+Es & liver function tests Normal

Which of the following is the likely diagnosis?

- 1- Acute lymphocytic leukaemia
- 2- Acute myeloid leukaemia
- 3- Aplastic anaemia
- 4- Henoch-Schönlein purpura
- 5- Hodgkin's lymphoma

Answer & Comments

Answer: 3- Aplastic anaemia

This patient appears to have complete suppression of all his marrow components suggesting aplastic anaemia.

The acquired condition may be associated with:

Drug therapy such as cytotoxics

Chloramphenicol

Infections such as viral hepatitis

Ionising radiation and

Chemicals.

[Q: 2539] OnExamination 2012 - Haematology

A 55-year-old male presents with anorexia and weight loss of 12 months duration. Over this year he has had two deep vein thromboses (DVTs) and had the last whilst his INR was 2 (less than 1.4).

He remains on long term warfarin therapy with an INR above 2.6. Examination reveals that he is pigmented and has a postural drop in his blood pressure of 15 mmHg.

Investigations are as follows:

Sodium 131 mmol/l (137-144)

Potassium 5.0 mmol/l (3.5-4.9)

INR 3.0 (<1.4)

A short Synacthen test reveals a baseline cortisol concentration at time 0 of 120 nmol/l which rises to 155 nmol/l after 30 minutes (normal response greater than 550 nmol/l).

Which single diagnosis would explain this patient's illness?

- 1- Addison's disease
- 2- Antiphospholipid syndrome
- 3- Autoimmune polyendocrine syndrome (Schmidt's disease)
- 4- Pituitary infarction
- 5- Protein S deficiency

Answer & Comments

Answer: 2- Antiphospholipid syndrome

With a history of recurrent DVT and confirmed hypoadrenalism, this patient is likely to have the antiphospholipid syndrome. Antiphospholipid syndrome is a primary diagnosis or may co-exist with systemic lupus erythematosus.

Anticardiolipin antibodies or lupus anticoagulant may be present.

It is associated with arterial and venous thrombosis and has a predilection for the

adrenal veins causing adrenal infarction with consequent hypoadrenalism.

Addison's disease is an autoimmune phenomenon and is not associated with DVT.

The pigmentation (due to increased adrenocorticotrophic hormone [ACTH] in hypoadrenalism) would exclude pituitary infarction as the cause of the hypoadrenalism.

Hypoadrenalism is not associated with protein S deficiency.

Autoimmune polyendocrine syndrome is associated with

Hypothyroidism

Type 1 diabetes

Addison's disease.

[Q: 2540] OnExamination 2012 - Haematology

Which of the following statements relates to acquired sideroblastic anaemia?

- 1- Haemosiderinuria is a feature
- 2- Has increased methaemoglobinaemia
- 3- It is characterised by the presence of ringed sideroblasts in the peripheral blood
- 4- It shows increased haptoglobin
- 5- There may be some response to pyridoxine therapy

Answer & Comments

Answer: 5- There may be some response to pyridoxine therapy

Sideroblasts are found in marrow.

Haptoglobin falls during haemolysis and may climb with 'acute phase' response.

There is an occasional response to pyridoxine.

Methaemoglobinaemia and haemosiderinuria are features of intravascular haemolysis.

[Q: 2541] OnExamination 2012 - Haematology

Which of the following is a proto-oncogene?

- 1- The BCRab1 translocation (Philadelphia chromosome)
- 2- The N-Myc gene
- 3- The retinoblastoma gene
- 4- The WT1 (first Wilm's tumour) gene
- 5- The WT2 (second Wilm's tumour) gene

Answer & Comments

Answer: 2- The N-Myc gene

Oncogenes are endogenous human deoxyribonucleic acid (DNA) sequences that arise from normal genes called proto-oncogenes.

Proto-oncogenes are normally expressed in many cells, particularly during fetal development, and are thought to play an important regulatory role in cell growth and development.

Alterations in the proto-oncogene can activate an oncogene, which produces unregulated gene activity, contributing directly to tumourogenesis.

Oncogene alterations are important causes of: Rhabdomyosarcomas (ras oncogene)

Burkitt's lymphoma (C-myc is translocated intact from its normal position on chromosome 8 to chromosome 14)

Neuroblastoma (N-myc proto-oncogene is seen in a proportion of patients with poor prognosis).

They should be contrasted with tumour suppressor genes. In this situation, the genes normally down regulate cell growth, and require inactivation to allow malignant growth. Examples include retinoblastoma.

[Q: 2542] OnExamination 2012 -
Haematology

Which of the following regarding salivary gland pleomorphic adenomas is correct?

- 1- They are the most common salivary gland tumour
- 2- Are commoner in the sub-mandibular than the parotid gland
- 3- In the parotid gland most commonly arise medial to the facial nerve
- 4- Are more common in males than in females
- 5- Typically enhance following intravenous contrast injection in CT

Answer & Comments

Answer: 1- They are the most common salivary gland tumour

A. They are the most common salivary gland tumour representing 70% to 80% of all benign salivary gland tumours.

B. Eighty four per cent occur in the parotid gland.

C. Ninety per cent of parotid gland pleomorphic adenomas arise lateral to the facial nerve.

D. They occur most often in women over 40.

E. Usually they do not enhance.

[Q: 2543] OnExamination 2012 -
Haematology

Which of the following concerning diamorphine elixir for the relief of pain in terminal patients is correct?

- 1- Analgesia is enhanced if cocaine is added
- 2- Constipation is a characteristic sequel to treatment
- 3- Dependence occurs rapidly
- 4- Initial sedation typically continues whilst the drug is administered

- 5- The same amount of pain relief is produced as when the same dose is given via intramuscular injection

Answer & Comments

Answer: 2- Constipation is a characteristic sequel to treatment

Sedation occurring in the first few days typically wears off, leaving the patient alert.

Hallucinations also tend to occur.

An aperient should always be added to the treatment regime.

Addiction is not a problem.

An intramuscular injection is three times more effective than the same oral dose.

(Cornwall Trainers)

[Q: 2544] OnExamination 2012 -
Haematology

Which of the following is associated with a GH secreting pituitary tumour?

- 1- Gs alpha subunit mutation
- 2- H-ras mutation
- 3- p53 mutation
- 4- Pit-1 mutation
- 5- Rb 1 mutation

Answer & Comments

Answer: 1- Gs alpha subunit mutation

A stimulatory mutation of the Gs protein alpha subunit has been noted in approximately 30% of growth hormone (GH) secreting pituitary tumours.

[Q: 2545] OnExamination 2012 -
Haematology

An 82-year old man presents to his general practitioner with a six month history of fatigue and increasing exertional dyspnoea.

Investigations show:

Haemoglobin 7.5 g/dL (13.0-18.0)

MCV 112 fL (80-96)

White blood cells $3.12 \times 10^9/L$ (4-11 $\times 10^9$)

Neutrophils 34%

Blasts 1%

Platelets $12 \times 10^9/L$ (150-400 $\times 10^9$)

A bone marrow aspirate stained with Perls' stain showed ring sideroblasts.

What is the most likely diagnosis?

- 1- Aplastic anaemia
- 2- Chronic myeloid leukaemia
- 3- Metastatic bone marrow infiltration
- 4- Myelodysplastic syndrome
- 5- Myelofibrosis

Answer & Comments

Answer: 4- Myelodysplastic syndrome

The patient has a macrocytic anaemia, thrombocytopenia and neutropenia with a small number of circulating blasts. This suggests a diagnosis of myelodysplastic syndrome, and this is supported by the finding of ring sideroblasts in the marrow.

Ring sideroblasts contain an abnormally high concentration of iron - usually stored in perinuclear mitochondria.

Perls' stain (which stains for iron) shows this iron deposition as a dark ring around the margin of the nucleus.

[Q: 2546] OnExamination 2012 - Haematology

At which point in the cell cycle is the cell most sensitive to radiation-induced apoptosis?

- 1- G0
- 2- G1
- 3- G2-M

4- S

5- S-G2

Answer & Comments

Answer: 3- G2-M

Normal and cancerous cells exhibit different radiosensitivities during different phases of the cell cycle.

They are most sensitive in G2-M phase when the cell is preparing to and actively dividing due to the fragile nature of the intracellular structure during this event.

[Q: 2547] OnExamination 2012 - Haematology

A 61-year-old man presents with haematuria. He is on warfarin for chronic atrial fibrillation.

His FBC shows a Hb of 112 g/L and his INR is 9 - the patient is haemodynamically stable.

The consultant on take advises that this patient needs reversal of the warfarin.

Of the following, which would be the blood product/s of choice?

- 1- Cryoprecipitate
- 2- Fresh frozen plasma/prothrombin concentrate
- 3- Packed cells
- 4- Platelets
- 5- Recombinant factor VII.

Answer & Comments

Answer: 2- Fresh frozen plasma/prothrombin concentrate

Fresh frozen plasma/prothrombin concentrates are products of choice for warfarin reversal (option B).

While packed cells are important to treat significant bleeding it would not be indicated at this stage (option D).

Cryoprecipitate, recombinant factor VII and platelets are not indicated for warfarin reversal (options A, D and E).

[Q: 2548] OnExamination 2012 - Haematology

A 46-year-old woman presents with a rapidly increasing mass on the left side of her neck over her thyroid gland. She has noticed some problems with dysphagia over the past few months, but no other symptoms of note apart from perhaps a slow increase in her weight and some tiredness.

On examination her BP is 122/72 mmHg. Her pulse is 72 and regular. Her BMI is 31. Respiratory and abdominal examination is unremarkable. Palpation of the left side of her neck reveals thyroid enlargement with associated lymphadenopathy.

Investigations show:

Haemoglobin 11.5 g/dl(11.5-16.5)

White cells $8.3 \times 10^9/L$ (4-11)

Platelets $185 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 96 $\mu\text{mol/l}$ (79-118)

Thyroid stimulating hormone 7.6 mu/l (0.5-5.0)

Lactate dehydrogenase 640 U/l (240-280)

Erythrocyte sedimentation rate 82 mm/hr(<20)

Which of the following is the most likely diagnosis?

- 1- Follicular thyroid carcinoma
- 2- Graves' disease
- 3- Hashimoto's disease
- 4- Hodgkin's lymphoma
- 5- Thyroid lymphoma

Answer & Comments

Answer: 5- Thyroid lymphoma

This rare lymphoma is frequently associated with Hashimoto's thyroiditis. Hypothyroidism is observed in 30-40% and that suspicion is raised by the gradual weight gain and raised TSH seen here.

Her raised ESR, haemoglobin at the lower end of the normal range, and her raised LDH all raise the possibility of lymphoma. Hoarseness, respiratory difficulty and cough can also occur as presenting symptoms.

Biopsy is the investigation of choice, but the sample obtained from fine needle aspiration (FNA) alone may not be sufficient to come to a conclusion on architecture.

The commonest types of thyroid lymphoma are

Large cell

Follicular

MALT.

[Q: 2549] OnExamination 2012 - Haematology

A 72-year-old man presents to the haematology clinic. He has suffered increasing headaches over the past few weeks, and unfortunately suffered a myocardial infarction some four weeks ago. He has been buying anti-histamines over the counter because of increasing itching.

During his admission it was noted that he had a marked elevation in haemoglobin, white cells and platelets. He is a non-smoker with no history of chest disease.

On examination in the clinic today he is hypertensive with a BP of 155/90 mmHg. Heart sounds are normal and his chest is clear. He looks plethoric with a ruddy complexion, and you notice that he has splenomegaly on abdominal examination.

Investigations show

Haemoglobin 19.8 g/dl(13.5-18)

White cell count $18.7 \times 10^9/L$ (4-10)

Platelets $672 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 140 $\mu\text{mol/l}$ (60-120)

Which of the following is the most likely mutation that he carries?

- 1- Bcr-abl
- 2- HER-1
- 3- HER-2
- 4- JAK 1
- 5- JAK 2

Answer & Comments

Answer: 5- JAK 2

JAK2 V617F is detectable in 95% of patients with primary polycythaemia. It is a cytoplasmic tyrosine kinase which is responsible for signal transduction of haemopoietic growth factors, including erythropoietin.

JAK2 mutation is a primary event in the development of primary polycythaemia, with homozygosity for the mutation conferring a proliferative advantage for the cells concerned.

Currently a new range of agents targeted against JAK2 are under development for the treatment of myeloproliferative disorders.

[Q: 2550] OnExamination 2012 - Haematology

A firm 2-3 cm mass is palpable in the upper outer quadrant of the right breast of a 52-year-old woman. There are no palpable axillary lymph nodes.

A lumpectomy with axillary node dissection is performed and the breast lesion is found to have positive immunohistochemical staining for HER2/neu (c-erb B2).

Staining for oestrogen and progesterone receptors is negative.

Which of the following additional treatment options is most appropriate, based upon these findings?

- 1- Radical mastectomy
- 2- St John's wort
- 3- Tamoxifen
- 4- Trastuzumab
- 5- Vancomycin

Answer & Comments

Answer: 4- Trastuzumab

This is an infiltrating ductal carcinoma.

The lack of oestrogen receptor staining suggests a poor response to hormonal therapy with tamoxifen.

The positive C-erb B2 (HER2/neu) staining suggests that trastuzumab (Herceptin) may be effective.

[Q: 2551] OnExamination 2012 - Haematology

A 30-year-old woman has a right mastectomy and axillary lymph node dissection for a carcinoma diagnosed by fine needle aspiration cytology.

The histological pattern is that of a poorly differentiated carcinoma that is negative for oestrogen and progesterone receptors, but is positive for HER2/neu. One axillary lymph node demonstrates micro-metastases. Her 32-year-old sister is found to have a similar lesion.

Which of the following statements regarding risk factors for this lesion is the most appropriate?

- 1- A history of late menarche is likely to be present in females in this family
- 2- Fibrocystic changes were present for many years

- 3- She had a history of exposure to hydrocarbon compounds
- 4- She has a positive antinuclear antibody test
- 5- These findings suggest a BRCA-1 mutation

Answer & Comments

Answer: 5- These findings suggest a BRCA-1 mutation

A small number of breast cancers are the result of an inherited BRCA-1 mutation (or BRCA-2), but the family history of breast cancer at a young age makes this more likely.

Early menarche and late menopause and nulliparity are risks for breast cancer.

Autoimmune diseases do not appreciably increase the risk for breast cancer.

[Q: 2552] OnExamination 2012 - Haematology

A 60-year-old lady with bruising is investigated and found to have the following full blood count:

Haemoglobin 13 x10 g/dL(11.5-16.5)

White cell count 6.3 x 10⁹/L (4-11 x10⁹)

Platelet count 15 x 10⁹/L (150-400 x10⁹)

She refuses to give consent to a bone marrow biopsy.

What is the most appropriate management plan?

- 1- Intravenous immunoglobulin
- 2- No treatment
- 3- Oral prednisolone
- 4- Platelet transfusion
- 5- Splenectomy

Answer & Comments

Answer: 3- Oral prednisolone

This lady most likely has idiopathic thrombocytopenic purpura.

The history should highlight any drug causes (not mentioned here) and a blood film would help exclude leukaemia.

A bone marrow examination is useful especially in the older person.

Platelet transfusion would not be helpful without treating the underlying cause.

No treatment is often an option but this lady is older and has bruising.

Given the circumstances the best management plan is to treat with steroid.

[Q: 2553] OnExamination 2012 - Haematology

A 61-year-old who has smoked for 40 years presents with thoracic back pain.

His investigations reveal:

Haemoglobin 11.1 g/dL (13.0-18.0)

Urea 9.3 mmol/L (2.5-7.5)

Creatinine 298 µmol/L (60-110)

Calcium 3.67 mmol/L (2.2-2.6)

Albumin 30 g/L (37-49)

Total protein 97 g/L (61-76)

Thoracic spine x ray Collapse of T8

Which investigation would confirm the diagnosis?

- 1- Bone marrow aspirate
- 2- Creatinine clearance
- 3- CXR
- 4- ESR
- 5- PTH

Answer & Comments

Answer: 1- Bone marrow aspirate

This man has myeloma. The smoking is a red herring.

Myeloma typically presents with back pain often associated with pathological fractures.

He is mildly anaemic, there is renal impairment and hypercalcaemia, with a raised total protein secondary to a paraproteinaemia.

Bone marrow examination would reveal increased plasma cells (greater than 4% and usually greater than 30%). The erythrocyte sedimentation rate will be raised, but the bone marrow aspirate would confirm the diagnosis irrefutably.

[Q: 2554] OnExamination 2012 - Haematology

A 69-year-old male presents with tiredness and dyspnoea and is diagnosed with acute myeloid leukaemia.

Which of the following is the most important prognostic factor?

- 1- Elevated lactate dehydrogenase activity
- 2- Karyotype of bone marrow
- 3- Monocytic morphology
- 4- Number of blasts in bone marrow
- 5- White cell count at diagnosis

Answer & Comments

Answer: 2- Karyotype of bone marrow

A, C, and D have no prognostic value.

White cell count at diagnosis is however important, but most important is the karyotype of bone marrow, as this result stratifies patients into lower risk, standard risk and poor risk, which has prognostic significance.

[Q: 2555] OnExamination 2012 - Haematology

A 16-year-old girl with sickle cell disease presented with malaise and rapidly increasing dyspnoea.

A full blood count showed:

Hb 5.1 g/dL (11.5-16.5)

Reticulocyte count $5.5 \times 10^9/L$ (25-85 $\times 10^9$)

What is the most likely cause?

- 1- Epstein-Barr virus
- 2- Hepatitis E virus
- 3- Human immunodeficiency virus
- 4- Human papillomavirus-16 (HPV 16)
- 5- Parvovirus B19

Answer & Comments

Answer: 5- Parvovirus B19

Aplastic crisis in sickle-cell anaemia (SSA) is caused by infection with the parvovirus B19.

The virus infects red cell progenitors in bone marrow, resulting in cessation of erythropoiesis and a very rapid drop in haemoglobin.

The condition is self-limited, with bone marrow recovery occurring in 7-10 days, followed by brisk reticulocytosis.

[Q: 2556] OnExamination 2012 - Haematology

A 28-year-old pregnant woman is being treated for a deep vein thrombosis with unfractionated heparin.

A recent blood test shows:

Haemoglobin 9.8 g/dL (11.5-16.5)

White cell count $9.5 \times 10^9/L$ (4-11)

Platelets $35 \times 10^9/L$ (150-400)

What would be the best course of action for this woman?

- 1- Change to hirudin
- 2- Change to low molecular weight heparin
- 3- Change to warfarin
- 4- Danaparoid
- 5- No change in treatment and observe

Answer & Comments

Answer: 4- Danaparoid

This patient appears to have heparin-induced thrombocytopenia (HIT). When HIT is suspected, heparin treatment should be discontinued and alternative anticoagulation should be started.

The heparinoid danaparoid appears to be the drug of choice for acute treatment and prophylaxis because of its low placental permeability.

Hirudin should only be used when either cross-reactivity with heparin-induced antibodies or cutaneous allergy against heparinoids are observed.

[Q: 2557] OnExamination 2012 - Haematology

In the consideration of disseminated intravascular coagulation (DIC), which of the following statements is most correct?

- 1- In DIC associated with sepsis secondary to retained products of conception, treatment of antibiotics will alleviate the process
- 2- Organ failure is a common finding in DIC
- 3- The intrinsic pathway is not involved in the pathophysiology of DIC
- 4- The presence of DIC does not increase mortality from the underlying disease
- 5- There are no randomised control trials to guide treatment in DIC

Answer & Comments

Answer: 2- Organ failure is a common finding in DIC

DIC is caused by the enhanced and abnormally sustained generation of thrombin.

Organ failure is a common finding, being as common as bleeding in DIC, and is likely to be due to fibrin deposition within the organ.

The presence of DIC significantly increases mortality rates in affected patients, and treatment of the underlying cause of the DIC, for example, sepsis, does not always lead to resolution of the condition.

Recombinant human activated protein C has been shown to be effective in reducing mortality from DIC in patients with sepsis. Several clinical trials have been published to guide treatment in DIC, one of which confirms the improved mortality with recombinant human activated protein C.

Secondary bursts of thrombin formation seen in DIC are instigated by the intrinsic pathway.

For a well informed review see BMJ 2003;327:974-7.

[Q: 2558] OnExamination 2012 - Haematology

A 68-year-old female with terminal bowel cancer is receiving optimal doses of morphine sulphate therapy.

Which of the following effects may be expected with the addition of a partial opioid agonist?

- 1- Increased analgesia
- 2- Increased respiratory depression
- 3- Increased sedation
- 4- No change
- 5- Reduced analgesia

Answer & Comments

Answer: 5- Reduced analgesia

Partial opioid agonists (for example, buprenorphine), when used in association with morphine, may produce a reduction in the analgesic effect due to partial antagonism.

This is an aspect of pain management that needs to be considered when using combination therapies.

[Q: 2559] OnExamination 2012 -
Haematology

A study of a new chemotherapy drug for lung cancer is reported in a medical journal. The authors state that with the new agent the five year mortality rate was 60%. Without treatment the five year mortality rate was 80%.

Which of the following represents the absolute risk reduction using this treatment?

- 1- 10%
- 2- 20%
- 3- 25%
- 4- 33%
- 5- 40%

Answer & Comments

Answer: 2- 20%

The absolute risk reduction is an important figure and should always be quoted instead of the the relative risk reduction.

Examples: If a drug reduces the incidence of heart attacks from 10% to 5% then:

The control event rate (CER) is 10%

The experimental event rate (EER) is 5%

The relative risk reduction (RRR) is 50%

The absolute risk reduction (ARR) is 5%

The number needed to treat (NNT) is $100\% / 5\% = 20$.

[Q: 2560] OnExamination 2012 -
Haematology

A 45-year-old woman noticed tinnitus in her left ear which progressed over some weeks to hearing loss in that ear.

On physical examination she is found to have a marked decrease in hearing on the left, with Rinne test indicating air conduction better

than bone conduction. The other cranial nerves I - VII and IX - XII are intact.

A brain MRI scan revealed a solitary, fairly discrete 3 cm mass located in the region of the left cerebellopontine angle.

Which of the following statements is most appropriate to tell the patient regarding these findings?

- 1- A test for HIV-1 is likely to be positive
- 2- Other family members should undergo MR imaging of the brain
- 3- Remissions and exacerbations are likely to occur in coming years
- 4- The lesion can be resected with a good prognosis
- 5- You are unlikely to survive for more than a year

Answer & Comments

Answer: 4- The lesion can be resected with a good prognosis

These acoustic neuromas are benign neoplasms.

A solitary mass is unlikely to be part of neurofibromatosis (which could be familial).

[Q: 2561] OnExamination 2012 -
Haematology

Which of the following conditions is most likely to be associated with thrombocytopenia?

- 1- Haemophilia A
- 2- Hereditary haemorrhagic telangiectasia
- 3- Pernicious anaemia
- 4- Porphyria
- 5- Uraemia

Answer & Comments

Answer: 3- Pernicious anaemia

Pernicious anaemia is usually a megaloblastic anaemia but may also be associated with a pancytopenia.

The platelet count is usually normal in chronic renal failure but there is a platelet function abnormality.

[Q: 2562] OnExamination 2012 - Haematology

A 68-year-old man complained of tiredness and lethargy.

On examination there was 2 cm hepatomegaly and 7 cm splenomegaly.

Investigations show:

Haemoglobin 17.4 g/dL (13.0-18.0)

White cell count $39.4 \times 10^9/L$ (4-11 $\times 10^9$)

White cell differential:

Neutrophils $22.2 \times 10^9/L$ (1.5-7 $\times 10^9$)

Lymphocytes $1.1 \times 10^9/L$ (1.5-4 $\times 10^9$)

Monocytes $1.0 \times 10^9/L$ (0-0.8 $\times 10^9$)

Eosinophils $0.4 \times 10^9/L$ (0.04-0.4 $\times 10^9$)

Basophils $2.1 \times 10^9/L$ (0-0.1 $\times 10^9$)

Metamyelocytes $1.2 \times 10^9/L$

Myelocytes $10.9 \times 10^9/L$

Myeloblasts $1.3 \times 10^9/L$

Nucleated RBC3 per 100 rbc

Platelet count $585 \times 10^9/L$ (150-400 $\times 10^9$)

What is the most likely diagnosis?

- 1- Acute myeloid leukaemia
- 2- Chronic myeloid leukaemia (CML)
- 3- Essential thrombocythaemia
- 4- Myelofibrosis
- 5- Primary proliferative polycythaemia (rubra vera)

Answer & Comments

Answer: 2- Chronic myeloid leukaemia (CML)

The presentation is typical with vague symptoms of malaise and splenomegaly.

The blood film also shows the typical high white cell count and there are all stages of myeloid cell maturation present in the peripheral blood with the metamyelocytes suggesting CML.

Thrombocythaemia is also seen in CML.

[Q: 2563] OnExamination 2012 - Haematology

Which of the following does not have a role in the management of chronic cancer pain?

- 1- Carbamazepine
- 2- Clodronate
- 3- Dexamethasone
- 4- Nifedipine
- 5- Pinavarium

Answer & Comments

Answer: 5- Pinavarium

Pinavarium is used to reduce the pain duration in irritable bowel syndrome (IBS).

Carbamazepine is in use for the treatment of neuropathic pain of malignancy, diabetes and other disorders.

Clodronate inhibits osteoclastic bone resorption and is used to treat malignant bone pain and the associated hypercalcaemia.

The corticosteroids are used to treat pain from central nervous system tumours.

Reducing the inflammation and oedema relieves the pain caused by neural compression.

Nifedipine helps relieve painful oesophageal spasm and tenesmus associated with gastrointestinal tumours.

Painful bladder spasm may be relieved by oxybutinin.

[Q: 2564] OnExamination 2012 -
Haematology

In sickle cell disease, which of the following is correct?

- 1- Exchange transfusions prior to major surgery on HbSS patients aims to lower the HbS concentration to 60%
- 2- It is caused by the substitution of glutamic acid by valine at position 4 on the beta chain of haemoglobin
- 3- The erythrocytes of haemoglobin AS patients can sickle at a pO_2 of 5 - 6 kPa (40 - 50 mmHg)
- 4- The erythrocytes of haemoglobin SC patients may sickle at a pO_2 of 4 kPa (30 mmHg)
- 5- The Sickledex test involves adding a reagent to blood which allows the nature of the haemoglobinopathy to be determined

Answer & Comments

Answer: 4- The erythrocytes of haemoglobin SC patients may sickle at a pO_2 of 4 kPa (30 mmHg)

Sickle cell disease in a haemoglobinopathy is caused by the substitution of glutamic acid by valine at position 6 (from the N-terminal) of the beta chain.

It is inherited as an autosomal gene, heterozygous (HbAS) and homozygous (HbSS) forms exist.

A low partial pressure of oxygen (PO_2) causes HbS to polymerise and precipitate resulting in sickling of the erythrocyte. HbSS patients sickle at PO_2 of 5 - 6 kPa and HbAS patients sickle at PO_2 of 2.5 - 4 kPa.

A mild disease is produced when heterozygotes for HbS combine with other haemoglobins, for example, haemoglobin C, thus creating HbSC. Sickling occurs at around 4 kPa.

Diagnosis of sickle cell disease requires the detection of HbS.

The Sickledex test involves the addition of reagent to blood; turbidity confirming the presence of HbS, but it gives no information on other haemoglobins.

Haemoglobin electrophoresis is the only investigation that determines the nature of the haemoglobinopathy.

[Q: 2565] OnExamination 2012 -
Haematology

A previously fit 30-year-old male presents with a two month history of weight loss, tiredness and nausea.

Investigations show:

Haemoglobin 10.5 g/dL (13.0-18.0)

MCV 88 fL (80-96)

White cell count $6.0 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $450 \times 10^9/L$ (150-400 $\times 10^9$)

Serum Sodium 130 mmol/L (137-144)

Serum Potassium 5.7 mmol/L (3.5-4.9)

Serum Urea 3.0 mmol/L (2.5-7.5)

Serum creatinine 78 $\mu\text{mol/L}$ (60-110)

Serum total T_4 55 nmol/L (50-150)

Serum TSH 8 mU/L (0.4-5)

Which of the following is the most useful diagnostic investigation?

- 1- Anti-thyroid peroxidase antibody titre
- 2- Free thyroxine concentration
- 3- Insulin tolerance test
- 4- Short Synacthen test
- 5- TRH test

Answer & Comments

Answer: 4- Short Synacthen test

This patient presents with weight loss, tiredness and nausea. He has hyponatraemia,

hyperkalaemia and what appears to be a mild primary hypothyroidism.

The diagnosis is likely to be Addison's (primary hypoadrenalism) disease and the most appropriate test would be a short Synacthen test.

The link between Addison's and primary hypothyroidism is that they are both conditions in the complex of autoimmune polyendocrine syndrome. Other possible associations of this cluster would be

Type 1 diabetes

Vitiligo

Pernicious anaemia and

Chronic active hepatitis.

An insulin tolerance test is contraindicated in patients in whom cortisol is less than 100 nmol/L.

A thyrotropin-releasing hormone (TRH) test is rarely performed these days and really is an irrelevance.

[Q: 2566] OnExamination 2012 - Haematology

In which of the following do mutations of the p53 gene frequently occur?

- 1- Bronchial carcinoma
- 2- Colonic polyps
- 3- Cystic fibrosis
- 4- Huntington's disease
- 5- Type 2 diabetes mellitus

Answer & Comments

Answer: 1- Bronchial carcinoma

p53 is a tumour suppressor gene and inactivating mutations of this gene occur in a large proportion of human cancers.

[Q: 2567] OnExamination 2012 - Haematology

Which RBC antigen is involved in the entry of P. vivax into red blood cells?

- 1- Anti-D
- 2- Anti-S
- 3- Duffy
- 4- Kell
- 5- Kidd

Answer & Comments

Answer: 3- Duffy

The Duffy antigen receptor facilitates the entry of P. vivax into the red blood cells and Duffy negative individuals are therefore resistant to this strain.

A similar situation exists with P. ovale but Duffy negative offers slightly less protection.

[Q: 2568] OnExamination 2012 - Haematology

You are evaluating a new agent which is thought to improve the recognition of foreign antigen by antigen presenting cells (APCs).

Which of the following correctly represents one aspect of the physiology of APCs?

- 1- Antigen is presented via MHC class I complexes
- 2- Antigen presented on APCs is recognised by CD4 positive cells
- 3- APCs are required before a response to viruses can be generated
- 4- Direct antigenic stimulation still requires APCs
- 5- Follicular dendritic cells express MHC class 2

Answer & Comments

Answer: 2- Antigen presented on APCs is recognised by CD4 positive cells

Extracellular antigen which is not directly recognised as foreign requires processing by APCs to generate an immune response. This process involves these cells expressing antigenic peptides in conjunction with MHC class II.

Antigen is presented via MHC class II complexes, MHC class I aids in the recognition of virally infected cells.

Direct stimulation of an immune response may occur in the absence of APCs.

Follicular dendritic cells are a distinct lineage which do not express MHC class II, but can still bind the Fc portion of antibodies.

APCs are not required before an immune response to viral infection can be successfully mounted.

[Q: 2569] OnExamination 2012 - Haematology

By what mechanism do the platinum based chemotherapies cause DNA damage and cell death?

- 1- Alkylating agent
- 2- Antimetabolite
- 3- DNA cross linkage
- 4- Inhibition of topoisomerase
- 5- Unknown

Answer & Comments

Answer: 3- DNA cross linkage

Cisplatin cross-links DNA in several different ways, interfering with cell division by mitosis.

The damaged DNA elicits DNA repair mechanisms, which in turn activate apoptosis when repair proves impossible.

Examples of platinum based chemotherapies are cisplatin, carboplatin and oxaliplatin.

[Q: 2570] OnExamination 2012 - Haematology

Upregulation of which of the following proteins is associated with multi-drug chemotherapy resistance?

- 1- BCL-2
- 2- CYP2D6
- 3- Cytochrome P450
- 4- p53
- 5- P-glycoprotein

Answer & Comments

Answer: 5- P-glycoprotein

P-glycoprotein is a member of the adenosine triphosphate (ATP)-binding cassette transporters which actively remove harmful substances from the cytoplasm.

If upregulated these proteins can pump chemotherapeutic agents out of tumour cells leading to drug resistance.

[Q: 2571] OnExamination 2012 - Haematology

Which virus is commonly associated with nasopharyngeal carcinoma?

- 1- Epstein-Barr virus
- 2- Hepatitis B
- 3- Human papilloma virus 16
- 4- Human papilloma virus 18
- 5- Human T-lymphotrophic virus

Answer & Comments

Answer: 1- Epstein-Barr virus

Epstein-Barr virus is detectable in over 90% of nasopharyngeal cancers of which the most common type is the undifferentiated form.

[Q: 2572] OnExamination 2012 -
Haematology

Which malignancy is most associated with the Lambert-Eaton myasthenic para-neoplastic syndrome (LEMS)?

- 1- Adenocarcinoma lung cancer
- 2- Metastatic bowel cancer
- 3- Metastatic melanoma
- 4- Small cell lung cancer
- 5- Squamous cell lung cancer

Answer & Comments

Answer: 4- Small cell lung cancer

Lambert-Eaton myasthenic syndrome is a rare paraneoplastic disorder associated with antibodies directed against voltage-gated calcium channels.

Approximately 60% of patients with LEMS will have an underlying malignancy.

[Q: 2573] OnExamination 2012 -
Haematology

A 35-year-old woman is diagnosed with a below knee deep vein thrombosis (DVT).

She is currently undergoing endocrine treatment for breast cancer.

Which agent is she likely to have been prescribed?

- 1- Anastrozole
- 2- Exemestane
- 3- Fulvestrant
- 4- Megace
- 5- Tamoxifen

Answer & Comments

Answer: 5- Tamoxifen

Of all the options, only tamoxifen is strongly associated with an increased risk of thrombosis.

Patients must be told this at the time of prescription and steps taken to minimise any other risk factors such as a sedentary lifestyle and smoking.

[Q: 2574] OnExamination 2012 -
Haematology

A 35-year-old woman develops an erythematous rash over her left nipple after breast feeding her child.

It is not painful but has not resolved with multiple courses of antibiotics. She has noted some recent nipple inversion.

What is the best investigation?

- 1- CT chest, abdomen and pelvis
- 2- Mammogram
- 3- MRI of breast
- 4- Skin biopsy
- 5- Ultrasound of breast

Answer & Comments

Answer: 4- Skin biopsy

This is Paget's disease of the breast. It presents insidiously and is similar in appearance to eczema; as such it often goes undiagnosed for several months.

Most cases are associated with invasive breast cancer, or ductal carcinoma in situ. Malignant cells infiltrate into the epidermis via the mammary duct epithelium, leading to thickening of the affected skin.

Skin biopsy with immunohistochemistry is the first line investigation. Investigations should also be done for underlying malignancy - biopsy if a lump is palpable, imaging if no lump is palpable.

Management is usually surgical with post-operative radiotherapy being offered to young patients with a high chance of recurrence.

[Q: 2575] OnExamination 2012 -
Haematology

A 75-year-old man presents with irritative and obstructive urinary symptoms of six months duration. He has noticed occasional haematuria and associated nocturia five times a night.

PR examination and subsequent prostate biopsy confirms prostate cancer.

What histological grading system is used to grade prostate cancer?

- 1- Ann Arbor
- 2- Breslow's depth
- 3- Duke's
- 4- Gleason
- 5- TNM staging

Answer & Comments

Answer: 4- Gleason

TNM staging is used for the majority of cancers but it is a staging system, not a grading system.

Ann Arbor is used to stage lymphoma.

Duke's staging is historically used for colon cancer but is less used in modern practice.

Breslow's depth is used in melanoma.

Gleason grading takes account of the most prevalent tumour pattern in the pathological system (1-5) and the second most prevalent tumour pattern (1-5).

It is presented as, for example, Gleason 3+4 = 7. This is important as a Gleason 4+3 = 7 obviously has a worse prognosis than a Gleason 3+4 = 7 even though they both have the same total score.

[Q: 2576] OnExamination 2012 -
Haematology

A 35-year-old woman presents to the

emergency medical unit with an acutely swollen, tense left calf. A subsequent ultrasound scan reveals a deep vein thrombosis (DVT).

She has been treated for the past two years with an endocrine agent to prevent recurrence of a breast cancer.

With which endocrine agent is she likely to have been treated?

- 1- Anastrozole
- 2- Exemestane
- 3- Fulvestrant
- 4- Letrozole
- 5- Tamoxifen

Answer & Comments

Answer: 5- Tamoxifen

Patients must be consented for the increased risk of DVT when taking tamoxifen.

Although this is only a small increase in risk per person, due to the large numbers of patients treated with this agent it will be linked to a significant number of DVT cases seen.

For more information including trials data please see the NICE guidance.

[Q: 2577] OnExamination 2012 -
Haematology

Which of the following investigations is not done routinely for a patient with an acute sickle cell crisis?

- 1- Full blood count
- 2- Reticulocyte count
- 3- Cultures
- 4- Cross match
- 5- Bone x ray

Answer & Comments

Answer: 5- Bone x ray

Although bone x rays can show bone infection and avascular necrosis they are not done routinely as they will not aid management in the majority of patients presenting with a sickle cell crisis.

Full blood count is vital to establish any acute worsening of the patient's anaemia. White cell count may be raised in infection.

Reticulocyte count is raised in haemolysis and splenic sequestration and decreased in aplastic crises.

Cultures are essential in patients in whom infection is suspected. Cultures will confirm the pathogens present and give sensitivities.

Cross matching the patient is important as they may require a blood transfusion.

Option A is incorrect as this investigation is done routinely for a patient presenting with an acute sickle cell crisis.

Option B is incorrect as this investigation is done routinely for a patient presenting with an acute sickle cell crisis.

Option C is incorrect as this investigation is done routinely for a patient presenting with an acute sickle cell crisis.

Option D is incorrect as this investigation is done routinely for a patient presenting with an acute sickle cell crisis.

Option E is correct as this investigation is not done routinely for a patient presenting with an acute sickle cell crisis.

[Q: 2578] OnExamination 2012 - Haematology

A patient presents with acute promyelocytic leukaemia (APL).

What is the likely mechanism underlying leukaemogenesis?

- 1- Aberrant fusion of 2 genes
- 2- Impaired protein degradation
- 3- Over expression of cellular oncogene
- 4- Post-translational modification
- 5- Telomere shortening

Answer & Comments

Answer: 1- Aberrant fusion of 2 genes

In APL one of the retinoic acid receptor genes, RARA, is fused to PML in the great majority of patients as a result of the chromosomal translocation t(15; 17).

[Q: 2579] OnExamination 2012 - Haematology

A 40-year-old gentleman presents to the Emergency department with a two week history of lethargy, low grade fever and gum bleeding. He is obtunded.

His full blood count shows a white cell count of $350 \times 10^9/L$, haemoglobin of 5.4 g/dL and a platelet count of $23 \times 10^9/L$.

Which of the following would be the most appropriate treatment option in this case?

- 1- Cytotoxic chemotherapy
- 2- Intravenous broad-spectrum antimicrobials.
- 3- Leukapheresis followed by cytotoxic chemotherapy.
- 4- Transfusion of 3 units of red cell concentrate
- 5- Transfusion of one adult therapeutic dose of single donor platelets

Answer & Comments

Answer: 3- Leukapheresis followed by cytotoxic chemotherapy.

This question covers the presentation of acute leukaemia with hyperleukocytosis.

Acute leukaemia can present with evidence of hyperleukocytosis. There is a predominance of

CNS and chest symptomatology, and management should include reduction of the white cell mass by leukapheresis until the appropriate diagnosis is reached, whence the effect of leukapheresis should be consolidated with the appropriate cytotoxic therapy.

Transfusion of red cell concentrate can worsen the hyperviscosity; thus option D is incorrect.

Whereas transfusion of platelet support and antimicrobials is also indicated, the most appropriate treatment would be leukapheresis followed by cytotoxics in the acute setting, thus eliminating answers A, B and E.

[Q: 2580] OnExamination 2012 - Haematology

Which one of the following vaccinations should not be given to patients undergoing chemotherapy?

- 1- Hepatitis A
- 2- Influenza
- 3- Pneumococcus
- 4- Rubella
- 5- Tetanus

Answer & Comments

Answer: 4- Rubella

Live vaccines should not be given whilst having chemotherapy and for six months afterwards. These include

Rubella

Mumps

Measles

MMR (the triple vaccine for measles, mumps and rubella)

BCG (for tuberculosis)

Yellow fever.

Vaccinations with non-live vaccines are safe extra space, but until the immune system is back to normal, they may not give as much protection against infection as they usually would.

[Q: 2581] OnExamination 2012 - Haematology

Which of the following infusion times would be appropriate during the transfusion of a blood product in a stable patient?

- 1- A platelet transfusion should be given over 90 minutes
- 2- A packed cell transfusion should be given over 20 minutes
- 3- A platelet transfusion should be given over 60 minutes
- 4- A packed cell transfusion should be given over 90 minutes
- 5- A platelet transfusion over 120 minutes

Answer & Comments

Answer: 4- A packed cell transfusion should be given over 90 minutes

In a stable patient red cell packs may be transfused over 90-120 minutes while a platelet transfusion should not take more than 20-30 minutes (hence option D is correct).

Rapid infusion of red cells or fresh frozen plasma may be required in an acutely bleeding patient but not in this patient who is stable (hence not A, B, C and E).

[Q: 2582] OnExamination 2012 - Haematology

A 62-year-old man presents with extreme fatigue, weight loss and night sweats. He has been feeling very unwell for the past few months and has taken early retirement from his job. He has problems eating because he feels constantly full.

On examination his BP is 142/82 mmHg, his pulse is 85 and regular, he looks pale. He has gross hepatosplenomegaly.

Investigations show:

Hb 8.9 g/dl(13.5-18)

WCC $25.0 \times 10^9/L$

Increased neutrophils, basophils and eosinophils (4-11)

PLT $171 \times 10^9/L$ (150-400)

Na 139 mmol/l (135-146)

K 4.8 mmol/l (3.5-5)

Cr $137 \mu\text{mol/l}$ (79-118)

Bone marrow Hypercellular with increased myeloid cell line precursors

He starts imatinib therapy but is unable to tolerate it due to diarrhoea, which fails to resolve with a series of interventions.

Which of the following is the most appropriate next treatment for him?

- 1- Busulphan
- 2- Dasatinib
- 3- Interferon alpha and cytarabine
- 4- Methotrexate
- 5- Nilotinib

Answer & Comments

Answer: 3- Interferon alpha and cytarabine

There has been some debate as to whether patients who are intolerant of imatinib should be trialled on another kinase inhibitor such as dasatinib or nilotinib; however the most recent available NICE guidance suggests that conventional therapy with interferon alpha and cytarabine may be more appropriate.

Cytogenetic improvement is seen in around 70% of patients treated with dual therapy for three months or longer.

[Q: 2583] OnExamination 2012 - Haematology

A 74-year-old man is being managed at the haematology/oncology clinic for suspected myeloma. He complains of symptoms of increasing shortness of breath over the past few weeks, with increased lethargy, decreased exercise tolerance, and increasing lower limb oedema.

On examination he looks pale, his BP is 139/81 mmHg, pulse 89. His heart sounds are normal, but there are bilateral crackles on auscultation of the chest and he has pitting lower limb oedema.

Investigations show

Haemoglobin 10.2 g/dl(13.5-18)

White cell count $8.7 \times 10^9/L$ (4-10)

Platelets $185 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine $135 \mu\text{mol/l}$ (60-120)

Albumin 22 g/l (35-50)

Urine Protein +++

What is the most likely cause of his underlying proteinuria?

- 1- AA amyloidosis
- 2- AL amyloidosis
- 3- BPP amyloidosis
- 4- Cystatin C amyloidosis
- 5- Glomerulonephritis

Answer & Comments

Answer: 2- AL amyloidosis

AL amyloidosis is associated with deposition of immunoglobulin light chains, and is caused by multiple myeloma.

He has a mixed picture of heart failure and proteinuria which is likely to be due to both cardiac and renal amyloid deposition. Given

his degree of hypoalbuminaemia it is likely that light chains would be easily detectable in the urine.

AA amyloidosis occurs in conjunction with systemic inflammatory conditions, cystatin C amyloidosis in conjunction with Icelandic hereditary cerebral haemorrhage and amyloidosis, and beta protein precursor amyloidosis with Alzheimer's disease and Down's syndrome.

Treatment is driven by chemotherapy for the underlying myeloma.

[Q: 2584] OnExamination 2012 - Haematology

A 48-year-old woman with a history of epilepsy and ischaemic heart disease presented with the following full blood count.

Haemoglobin 7.4 g/dL (11.5 - 16.5)

Mean cell volume 125 fL (80 - 96)

White cell count $2.5 \times 10^9/L$ (4 - 11)

Platelet count $130 \times 10^9/L$ (150 - 400)

Which of the following medications is the most likely cause?

- 1- Carbamazepine
- 2- Clopidogrel
- 3- Furosemide
- 4- Phenytoin
- 5- Spironolactone

Answer & Comments

Answer: 4- Phenytoin

There is a macrocytic anaemia with low platelets and WCC typical of a nutritional deficiency.

Phenytoin can lead to folate deficiency and is therefore the most likely cause.

[Q: 2585] OnExamination 2012 - Haematology

A 45-year-old man is diagnosed with acute promyelocytic leukaemia.

Which of the following chromosomal translocations is associated with this type of leukaemia?

- 1- t(8;9)
- 2- t(8;21)
- 3- t(9;22)
- 4- t(15;17)
- 5- t(17;22)

Answer & Comments

Answer: 4- t(15;17)

Acute promyelocytic leukaemia is characterised by a chromosomal translocation involving the retinoic acid receptor-alpha gene on chromosome 17 (RARA).

In 95% of cases, retinoic acid receptor-alpha (RARA) gene on chromosome 17 is involved in a reciprocal translocation with the promyelocytic leukaemia gene (PML) on chromosome 15.

[Q: 2586] OnExamination 2012 - Haematology

Interferon alpha immunotherapy is used as treatment of which for the following conditions?

- 1- Acute lymphoblastic leukaemia
- 2- Acute myeloid leukaemia
- 3- Burkitt's lymphoma
- 4- Hairy cell leukaemia
- 5- Myelodysplastic syndrome

Answer & Comments

Answer: 4- Hairy cell leukaemia

"Interferon-alpha is an immune system hormone which is very helpful to a relatively small number of patients, and somewhat helpful to most patients. Most commonly, the drug helps stabilize the disease or produce a slow, minor improvement. The typical dosing schedule injects 3 million units of Interferon-alpha (not pegylated versions) three times a week, although the original protocol began with six months of daily injections." Wikipedia: Hairy Cell Leukaemia

[Q: 2587] OnExamination 2012 - Haematology

A 34-year-old Asian lady presented with tiredness and lethargy.

Her full blood count shows:

Haemoglobin 10.3 g/dL(11.5-16.5)

Platelet count $320 \times 10^9/L$ (150-400 $\times 10^9$)

White cell count $10.6 \times 10^9/L$ (4-11 $\times 10^9$)

MCV 68 fL(80-96)

HbA₂ 5.2%(2-3)

Which of the following is the most likely diagnosis?

- 1- Acute myeloid leukaemia
- 2- Beta-thalassaemia major
- 3- Beta-thalassaemia trait
- 4- Hereditary spherocytosis
- 5- Sickle cell disease

Answer & Comments

Answer: 3- Beta-thalassaemia trait

Microcytic anaemia would immediately raise the suspicion of iron deficiency perhaps from gastrointestinal or menstrual blood loss. However, the MCV here is disproportionately low. This combined with a raised HbA₂ makes the diagnosis of beta-thalassaemia trait the most likely diagnosis.

"The diagnosis of beta thalassemia minor usually is suggested by the presence of an isolated, mild microcytic anemia, target cells on the peripheral blood smear, and a normal red blood cell count. An elevation of Hb A₂ (2 alpha-globin chains complexed with 2 delta-globin chains) demonstrated by electrophoresis or column chromatography confirms the diagnosis of beta thalassemia trait. The Hb A₂ level in these patients usually is approximately 4-6%. In rare cases of concurrent severe iron deficiency, the increased Hb A₂ level may not be observed, although it becomes evident with iron repletion. The increased Hb A₂ level also is not observed in patients with the rare delta-beta thalassemia trait." eMedicine

[Q: 2588] OnExamination 2012 - Haematology

A 39-year-old male is receiving cisplatin based chemotherapy as adjuvant therapy for lymphoma.

Which of the following is a typical side effect of cisplatin?

- 1- Cerebellar ataxia
- 2- Haemorrhagic cystitis
- 3- Optic neuritis
- 4- Ototoxicity
- 5- Rhabdomyolysis

Answer & Comments

Answer: 4- Ototoxicity

Typical side effects of cisplatin include

Marrow toxicity

Ototoxicity

Peripheral neuropathy

Nephrotoxicity

Alopecia

Changes in taste.

Although optic neuritis is described it is not a typical side effect.

[Q: 2589] OnExamination 2012 - Haematology

A 28-year-old primigravid woman developed a swollen painful left leg at 12 weeks gestation.

Doppler ultrasound of her leg venous system showed a left popliteal vein thrombosis.

Which one of the following treatments is associated with the greatest risk to the fetus?

- 1- Aspirin
- 2- Intravenous unfractionated heparin
- 3- Subcutaneous low molecular weight heparin
- 4- Subcutaneous unfractionated heparin
- 5- Warfarin

Answer & Comments

Answer: 5- Warfarin

Oral anticoagulants are teratogenic and should not be given in the first trimester of pregnancy. Oral anticoagulants cross the placenta, and increase the risk of fetal and placental haemorrhage.

Aspirin appears to be relatively safe, as are heparins.

[Q: 2590] OnExamination 2012 - Haematology

A 23-year-old footballer was prescribed ibuprofen by his GP for a sprained ankle. Several hours later he felt very unwell and was passing dark urine.

The peripheral blood film shows many schistocytes.

The laboratory results show:

Haemoglobin <9 g/dL(13.0-18.0)

WBC $7 \times 10^9/L$ (4-11) with normal differentials

Platelets $450 \times 10^9/L$ (150-400)

Reticulocyte count 5%(0.5-2.4)

Bilirubin 40 mol/L(1-22)

What is the most likely cause for his presentation?

- 1- Allergic reaction
- 2- Autoimmune haemolytic anaemia
- 3- Glucose-6-phosphate dehydrogenase deficiency
- 4- Paroxysmal nocturnal haemoglobinuria
- 5- Pyruvate kinase deficiency

Answer & Comments

Answer: 3- Glucose-6-phosphate dehydrogenase deficiency

This is a case of intravascular haemolysis with haemoglobinuria.

The patient has a history of taking ibuprofen which is an oxidant and causes haemolysis in patients with G-6-PD deficiency.

Oxidative stressors can be infectious agents, drugs, chemicals and certain legumes. In G-6-PD deficient patients, oxidative stress exposes interior sulfhydryl groups that are oxidised and cannot be reduced, leading to irreversible denaturation of the haemoglobin with Heinz body formation.

Schistocytes are red blood cell fragments that result from membrane damage. They are sometimes referred to as 'bite cells'.

[Q: 2591] OnExamination 2012 - Haematology

What is the mechanism of action of low molecular weight heparin?

- 1- Activation of plasminogen
- 2- Chelation of calcium
- 3- Inhibition of activated factor X
- 4- Inhibition of antithrombin

5- Inhibition of vitamin K-dependent carboxylase

Answer & Comments

Answer: 3- Inhibition of activated factor X

The shorter chain low molecular weight (LMW) fractions of heparin inhibit activated factor X but have less effect on thrombin (and on coagulation in general) than the high molecular weight (HMW) species.

[Q: 2592] OnExamination 2012 - Haematology

A 45-year-old woman presents with a one year history of weight gain and intermittent sweating.

What is the most likely diagnosis?

- 1- Carcinoid syndrome
- 2- Hypothyroidism
- 3- Insulinoma
- 4- Lymphoma
- 5- Pheochromocytoma

Answer & Comments

Answer: 3- Insulinoma

The clinical scenario is classic of insulinoma.

Weight gain is the key differentiating feature here - sweating being more commonly shared with the other conditions except hypothyroidism. There is nothing else offered, other than insulinoma, that explains both symptoms in this middle aged woman.

As primary ovarian failure is not offered which would seem the most probable answer then the features would otherwise suggest an insulinoma which is commoner in females and unlike carcinoid and lymphoma is associated with weight gain rather than weight loss.

Pheochromocytoma is associated with bouts of sweating but not weight gain - there is also

no mention of other typical features such as palpitations and hypertension.

[Q: 2593] OnExamination 2012 - Haematology

A patient who received total body irradiation for the treatment of Hodgkin's lymphoma develops graft versus host disease (GVHD).

Which of the following blood products is likely to have caused this?

- 1- Cryoprecipitate
- 2- FFP
- 3- Frozen deglycerolised red blood cells
- 4- Immunoglobulin
- 5- Packed red blood cells

Answer & Comments

Answer: 5- Packed red blood cells

Graft versus host disease (GVHD) occurs when donor lymphocytes engraft in a susceptible recipient.

Products implicated in cases of transfusion associated (TA)-GVHD include:

Non-irradiated whole blood

Packed red blood cells

Platelets

Granulocytes and

Fresh non-frozen plasma.

The following have not been implicated:

Frozen deglycerolised red blood cells

Fresh frozen plasma and

Cryoprecipitate.

[Q: 2594] OnExamination 2012 - Haematology

A patient attends for breast screening and asks you the following questions.

Which statement is correct?

- 1- Early diagnosis does not change the rate of death from breast cancer
- 2- In young patients with a BRCA mutation, mammographic screening has a low sensitivity for detecting tumours
- 3- Mammographic screening is more sensitive in patient groups with denser breast tissue
- 4- Mammographic screening is offered to all women aged 20-75 years
- 5- p53 mutation is a commonly identified in subjects with breast cancer

Answer & Comments

Answer: 2- In young patients with a BRCA mutation, mammographic screening has a low sensitivity for detecting tumours

In young patients mammograms are not particularly sensitive in detecting tumours. This is because their breast tissue is denser than in older patients. MRI and ultrasound may help to delineate breast cancer in such patients. Mammography is more sensitive in older patient groups partly because in general the breast tissue is less dense.

Mammographic screening of all women between the ages of 50 and 70 years can reduce mortality from breast cancer by 25%. There is no consensus regarding the value of breast cancer screening among women who are 40- to 49-years-old. There is no evidence for routine screening below this age.

The presence of a germ-line mutation of the BRCA1 or BRCA2 gene increases the risk of breast cancer considerably, and patients with these mutations should be offered the opportunity to receive screening at much younger than 50 years.

p53 mutations are the most common genetic change identified in human neoplasia. In breast carcinoma it is associated with more aggressive disease, and worse overall survival. The frequency is, however, lower in breast

carcinoma than in other solid tumours, with an overall frequency of approximately 20%. There are certain forms of breast carcinoma, for example medullary, which have a much higher frequency.

[Q: 2595] OnExamination 2012 - Haematology

A 73-year-old man presented with a two week history of breathlessness and easy bruising.

Investigations show:

Haemoglobin 6.9 g/dL (13.0-18.0)

White cell count $0.4 \times 10^9/L$ (4-11)

Platelet count $9 \times 10^9/L$ (150-400)

Bone marrow aspirate all cellular elements reduced.

Which drug is the most likely cause of these abnormalities?

- 1- Aciclovir
- 2- Amiloride
- 3- Amoxicillin
- 4- Paracetamol
- 5- Trimethoprim

Answer & Comments

Answer: 5- Trimethoprim

There is a pancytopenia and marrow aspirate shows reduction in production of all cellular elements.

Trimethoprim is the drug most likely of these five to cause depression of haematopoiesis as this picture would be particularly unusual with paracetamol, amiloride, aciclovir and amoxicillin.

[Q: 2596] OnExamination 2012 - Haematology

A 56-year-old male was admitted for a total hip replacement due to osteoarthritis. There

was no other medical history and physical examination was normal.

A routine pre-operative full blood count (FBC) showed:

Haemoglobin 11 g/dL (13.0-18.0)

Platelet count $170 \times 10^9/L$ ($150-400 \times 10^9$)

White cell count $25 \times 10^9/L$ ($4-11 \times 10^9$)

Neutrophil count $5 \times 10^9/L$ ($1.5-7 \times 10^9$)

Lymphocyte count $19 \times 10^9/L$ ($1.5-4 \times 10^9$)

Monocyte count $0.9 \times 10^9/L$ ($0-0.8 \times 10^9$)

Eosinophil count $0.1 \times 10^9/L$ ($0.04-4 \times 10^9$)

Basophil count $0.08 \times 10^9/L$ ($0-0.1 \times 10^9$)

His blood film shows mature lymphocytes.

What is the most appropriate initial management for this patient?

- 1- Cancel the patient's operation
- 2- Chlorambucil
- 3- Fludarabine
- 4- Observation
- 5- Prednisolone

Answer & Comments

Answer: 4- Observation

The most significant abnormality on the full blood count is the lymphocytosis, with mature lymphocytes seen on film.

In this age group the most likely diagnosis is a low grade lymphoproliferative disorder, for example, chronic lymphocytic leukaemia. This, as mentioned, is a low grade condition, and does not require immediate treatment; patients undergo a period of observation, often quite long, before any treatment is indicated.

The indication for treatment would include:

Disabling B symptoms

Lymphocyte doubling time of less than six months

Bone marrow compromise

Autoimmune haemolysis or immune thrombocytopenia.

He is never going to be cured from this condition, and therefore it would not be necessary to delay/ cancel surgery. He may be slightly more at risk of infection, due to immune dysfunction that accompanies these conditions, and the surgeons should be aware of this.

[Q: 2597] OnExamination 2012 - Haematology

A 17-year-old male with glucose-6-phosphate dehydrogenase (G6PD) deficiency presents with tiredness and is noticed to be jaundiced. These features have developed since he developed a mild chest infection one week ago.

Which one of the following is the most likely haematological finding?

- 1- Haemoglobinuria
- 2- Low mean cell volume
- 3- Positive direct antiglobulin test
- 4- Reduced reticulocyte count
- 5- Spherocytes present on blood film

Answer & Comments

Answer: 1- Haemoglobinuria

G6PD deficiency is a red cell enzymopathy that can lead to acute intravascular haemolysis after exposure to certain drugs, infection, etc.

You would therefore get haemoglobinuria but would not get a positive direct antiglobulin test. The mean corpuscular volume (MCV) and reticulocyte count would be high due to haemolysis.

There is a form of G6PD deficiency where there is a chronic low level haemolysis where there are spherocytes seen - but the clinical information points to intravascular haemolysis after an infection.

[Q: 2598] OnExamination 2012 - Haematology

A 25-year-old female with a history of type 1 von Willebrand's (vWBD) disease is referred for an opinion. She is to have a cervical cone biopsy and the admitting team are concerned about her clotting.

You find that she has a past history of menorrhagia and has had two dental extractions as an adolescent that were uncomplicated.

What is the most useful test to assess her bleeding tendency?

- 1- Activated partial thromboplastin time
- 2- Bleeding time
- 3- Plasma factor VIII activity
- 4- Platelet aggregation
- 5- Prothrombin time

Answer & Comments

Answer: 3- Plasma factor VIII activity

In type I vWBD the prothrombin time (PT) and platelet aggregation will be normal.

Bleeding time, activated partial thromboplastin time (APTT) and FVIIIc are likely to be abnormal.

The bleeding time would be a good screening test, but as we already know she has type I vWBD it will not give a quantitative measurement of her bleeding tendency.

Similarly APTT will not be that useful.

The most useful test in practice is to do the vWB antigen and activity (RICO); But you would also do FVIIIc as this is also low in vWD.

[Q: 2599] OnExamination 2012 - Haematology

By which of the following can folic acid metabolism be affected?

- 1- Brufen
- 2- Penicillin
- 3- Pyrimethamine
- 4- Tetracycline
- 5- Vitamin B₁₂

Answer & Comments

Answer: 3- Pyrimethamine

Drugs which inhibit dihydrofolate reductase are:

Methotrexate

Pyrimethamine and

Trimethoprim.

Drugs which interfere with absorption/storage of folate are:

Phenytoin

Primidone

Oral contraceptives.

[Q: 2600] OnExamination 2012 - Haematology

Concerning immune cell antigen receptors, which of the following statements is false?

- 1- Affinity maturation of the B cell receptor is an important process initiated during the primary immune response
- 2- IgD are surface receptors of B lymphocytes
- 3- In normal individuals T lymphocytes with T cell receptors (TCR) that recognise autoantigens are all deleted to prevent autoimmunity
- 4- TCRs with different antigen specificities can be co-expressed on a single T lymphocytes

- 5- The antigen specificity of the T cell receptor is generated during development

Answer & Comments

Answer: 3- In normal individuals T lymphocytes with T cell receptors (TCR) that recognise autoantigens are all deleted to prevent autoimmunity

T and B lymphocytes express receptors on their surface that recognise antigen in a specific manner. Each individual lymphocyte expresses a single type of receptor with unique specificity (except dual specificity T cells - see below).

The receptor on the B lymphocyte is membrane bound immunoglobulin (IgM and IgD isotype) and recognises particulate antigen, whilst the TCR is a heterodimer that recognises peptide fragments presented by MHC molecules.

The antigen specificity of T and B cells is generated during development by recombination of gene segments encoding the variable domains (antigen recognition domains) of immune receptors. These gene recombinations are random and maturing lymphocytes that express autoreactive receptors which are then deleted or rendered anergic. These processes take place in the thymus (T lymphocytes) and in the bone marrow (B lymphocytes).

However, not all autoreactive lymphocytes are deleted during development. In the case of T lymphocytes, not all proteins are expressed in the thymus, and those that are present only in the periphery or at certain stages of development will encounter mature T cells that can respond to them. Thus, autoreactive T cells exist in the periphery and other mechanisms are responsible for the protection of the body against autoimmunity.

Affinity maturation refers to the process of progressive development of immunoglobulin with higher affinity to the antigen. This occurs

in the germinal centres of lymphoid organs during the evolution of the humoral response and is accomplished by hypermutation of the variable region genes. T cells with dual specificities have been reported although their function is unknown.

[Q: 2601] OnExamination 2012 - Haematology

A 40-year-old woman presents to her GP with a left sided breast lump.

On examination it measures approximately 25 mm and has associated skin tethering. Examination of her axilla reveals a 20 mm mobile lymph node, examination is otherwise unremarkable.

What is the best sequence of investigation of this lump?

- 1- CT breast, mammography, ultrasound guided fine needle aspiration
- 2- Physical examination, breast MRI, CT chest abdomen and pelvis
- 3- Physical examination, mammography, breast MRI
- 4- Physical examination, mammography, CT guided fine needle aspiration
- 5- Physical examination, mammography, ultrasound guided fine needle aspiration

Answer & Comments

Answer: 5- Physical examination, mammography, ultrasound guided fine needle aspiration

The triple assessment of a breast lump is essential to diagnose a breast lump accurately. It involves physical examination, mammography and then ultrasound guided FNA.

A marker may be inserted at this time if the lump is difficult to palpate to aid the surgeons at the time of excision.

Breast MRI is used when the patient presents with inflammatory breast cancer and the margins of the cancer are unclear. This aids the clinician by allowing accurate assessment of response to neo-adjuvant chemotherapy prior to surgical excision.

Staging CT is not used routinely in primary breast cancer, only if there is suspicion of metastatic spread.

[Q: 2602] OnExamination 2012 - Haematology

Which of the following observations best describes the relationship between malaria and HbS?

- 1- Patients with sickle cell disease do not get malaria
- 2- HbS protects against all complications of falciparum malaria
- 3- Only HbSS protects against malaria, HbAS is not protective
- 4- Sickle cell disease is most common in regions where P. falciparum malaria is endemic and in ethnic groups that have migrated from these areas
- 5- Malaria causes damage to red cell DNA, which is why sickle cell disease is more common in malarial regions

Answer & Comments

Answer: 4- Sickle cell disease is most common in regions where P. falciparum malaria is endemic and in ethnic groups that have migrated from these areas

The sickle cell gene is most prevalent in areas where malaria is also prevalent.

Patients with sickle cell trait have just as much risk of contracting P. falciparum malaria compared with patients with HbAA.

However, the reduced red cell life cycle in HbAS reduces parasitaemia, which reduces the risk of severe disease and neurological

complications (for example, seizures and coma).

Option A is incorrect because patients with sickle cell disease have the same risk of developing malaria as patients with HbAS or HbAA.

Option B is incorrect because HbS protects only against severe disease.

Option C is incorrect because HbAS is also protective against the complications of malaria. (In fact, patients with HbSS are at higher risk of severe malaria with complications and have a higher mortality rate.)

Option D is correct. Sickle cell disease is most prevalent in areas where malaria is endemic.

Option E is incorrect. The genetic abnormality is not caused by malaria, but the selective advantage of the carrier state in malarial regions has allowed it to persist in the gene pool (positive selective evolutionary pressure).

[Q: 2603] OnExamination 2012 - Haematology

A 56-year-old man is being reviewed for an elective cholecystectomy in the pre-operative clinic.

He has no co-morbidities apart from two attacks of cholecystitis in the last 12 months. He has never received a blood transfusion in the past.

The request for the blood bank should include which of the following?

- 1- Group and save, direct Combs' test (DAT) and across match for 2 units
- 2- Group and save only
- 3- Group and save as well as cross match
- 4- Cross match for 3 units only
- 5- Group and Save, DAT and a cross match for 3 units.

Answer & Comments

Answer: 2- Group and save only

A 'group and save' is adequate for elective surgeries and is standard practise in most modern blood banks. This will involve blood grouping and its confirmation as well as an antibody screen (option B).

Other options include crossmatch and a direct Coombs' test (options A, C, D and E) which are often done only if the antibody screen test is positive - these are not routinely done for elective surgery unless the patient has had a recent blood transfusion or a history of previous known red cell antibodies.

[Q: 2604] OnExamination 2012 - Haematology

Which of the following is true about manufacture of pooled plasma derivatives?

- 1- Pooled plasma is often sourced from within the UK
- 2- These are usually manufactured from 10 donors at a time
- 3- The process does not involve any viral inactivation steps
- 4- The end product is a freeze dried product
- 5- These products have a short half life typically days.

Answer & Comments

Answer: 4- The end product is a freeze dried product

The plasma derivatives (such as factor VIII) are prepared from several thousand plasma donations typically 20 000 or 5000 kg of plasma at a time (hence not option B).

Pooled plasma has been sourced from outside UK since 1999 to avoid vCJD risks (hence not option A).

The process involves several chemical steps including ethanol extraction, chromatography

and viral inactivation steps (hence not option C) which results in a freeze dried product (option D).

These products have a long shelf life of several months to years (hence not option E).

[Q: 2605] OnExamination 2012 - Haematology

A 72-year-old woman is admitted by the orthopaedic surgeons for a routine left total hip replacement (THR). She has no past medical history of note apart from well controlled hypertension which is currently managed with a combination of ramipril and amlodipine.

On examination her BP is 142/82 mmHg, her pulse is 75 and regular, her BMI is 23 kg/m². She looks pale, cardiovascular and respiratory examination is unremarkable, but she has splenomegaly on examination of the abdomen.

Investigations show

Haemoglobin 10.4 g/dl(11.5-16.5)

White cell count 35.1 x 10⁹/L

Lymphocytes 31.2(4-11)

Platelets 180 x 10⁹/L (150-400)

Serum sodium 138 mmol/l (135-146)

Serum potassium 4.4 mmol/l (3.5-5)

Creatinine 115 mmol/l (79-118)

Bone marrow aspirate Lymphocytic infiltration

Which of the following is the most appropriate course of action?

- 1- Chlorambucil
- 2- Cyclophosphamide
- 3- Lenalidomide
- 4- Proceed with the hip replacement
- 5- Rituximab

Answer & Comments

Answer: 4- Proceed with the hip replacement

This patient has chronic lymphocytic leukaemia (CLL).

Indications for intervention are very clear, and the implication in this case is that the patient has no symptoms from her CLL.

Guidelines suggest that chemotherapy should be considered when one of the following conditions is satisfied.

Weight loss more than 10%

Extreme fatigue

Progressive marrow failure

Autoimmune anaemia or thrombocytopenia not responding to prednisolone

Progressive splenomegaly

Massive lymphadenopathy or progressive lymphocytosis

Progressive lymphocytosis (an increase of more than 50% in two months or a doubling time of less than six months).

From the history we are given she currently satisfies none of these conditions and can proceed to THR.

[Q: 2606] OnExamination 2012 - Haematology

A 53-year-old woman with inoperable cancer has pain due to posterior abdominal wall infiltration. This has been controlled well with Kapake (codeine 30 mg and paracetamol 500 mg), two tablets four times per day.

The patient has been admitted with nausea and vomiting the cause of which is, as yet, unknown. Because she cannot retain her analgesics, she has severe pain in her loin.

What is the best option for controlling her pain until the vomiting settles?

1- Fentanyl skin patch

2- Intramuscular pethidine

3- Morphine four hourly orally and as needed intramuscularly

4- Rectal non-steroidal anti-inflammatory drug

5- Subcutaneous diamorphine by continuous infusion

Answer & Comments

Answer: 5- Subcutaneous diamorphine by continuous infusion

This patient has inoperable carcinoma and already needs opiate analgesia orally; as she is vomiting she will need parenteral analgesia.

The most effective way of achieving this, and being able effectively to titrate the dose to achieve adequate analgesia, is subcutaneous diamorphine by continuous infusion.

Fentanyl patches are difficult to titrate because they are used for 72 hours. You usually therefore only use them once a patient has a stable opiate usage. Intramuscular pethidine has a delayed onset and its effect is prolonged, which again is not ideal when you do not know what the patient's opiate requirements are. Oral morphine is unlikely to be tolerated whilst she is vomiting. Non-steroidals are unlikely to be sufficient in this case.

[Q: 2607] OnExamination 2012 - Haematology

Which of the following statements concerning abnormalities of the haemoglobin molecule is true?

1- Alpha thalassaemia is due to a deficiency of beta-chain production

2- HbS is caused by a single base mutation on the beta-chain

3- Genes for the alpha and beta chains are located on the same chromosome

4- In thalassaemia, persistence of HbF is an adverse prognostic sign

- 5- Oligonucleotide probes may assist in the diagnosis of haemoglobinopathies in adolescents

Answer & Comments

Answer: 2- HbS is caused by a single base mutation on the beta-chain

A. Alpha thalassaemia is due to abnormalities of the alpha chain. Persistence of HbF has survival advantages in severely affected subjects.

C. Alpha is located on 16, beta on 11.

E. Hb electrophoresis are used in the adult, rather than oligonucleotide probes as used in the fetus.

[Q: 2608] OnExamination 2012 - Haematology

A 65-year-old lady with a history of recurrent DVT has been weaned off her warfarin and started on intravenous heparin prior to cardiac bypass for ischaemic heart disease.

She seems to require very high doses of heparin to achieve adequate anticoagulation especially during surgery.

Which of the following conditions would explain her thrombophilia and her heparin resistance?

- 1- Activated protein C resistance
- 2- Antithrombin III deficiency
- 3- Lupus anticoagulant
- 4- Protein C deficiency
- 5- Protein S deficiency

Answer & Comments

Answer: 2- Antithrombin III deficiency

"Cardiac surgery produces a unique activation of coagulation due to the presence of the cardiopulmonary bypass (CPB) circuit. Whilst not yet fully elucidated, the mechanisms of

activation of coagulation during CPB may involve activation of fX by the tissue factor-mediated pathway within the pericardial cavity, in addition to direct generation of fXa on the surface of monocytes by Cathepsin G, a substance released from activated monocytes. The inhibition of fXa in these situations involves the AT-dependent mechanism of action of heparin." British Journal of Anaesthesia, 2002, Vol. 88, No. 4 467-469

[Q: 2609] OnExamination 2012 - Haematology

A 60-year-old patient with metastatic breast carcinoma attends clinic complaining of pain in the jaw and ulceration within the oral cavity which has persisted for four weeks following a dental extraction. She has had a course of antibiotic therapy for suspected secondary infection of the ulceration.

On examination there is ulceration within the oral cavity which extends as far as the underlying mandible.

Which of the following drugs is likely to be responsible for her presentation?

- 1- Anastrozole
- 2- Diclofenac
- 3- Prednisolone
- 4- Tamoxifen
- 5- Zoledronic acid

Answer & Comments

Answer: 5- Zoledronic acid

The likely causative agent is the nitrogen containing bisphosphonate zoledronic acid.

The clinical scenario suggests a diagnosis of bisphosphonate associated osteonecrosis of the jaw. This is a recently recognised adverse effect of bisphosphonate therapy. This is a consequence of potent anti-resorptive action of the nitrogen containing bisphosphonates.

Most cases have been associated with zoledronic acid and pamidronate given intravenously for metastatic bone disease. The reported incidence in patients with malignancy treated with these drugs is between 1.3-4.0%.

Dental disease is a recognised predisposing factor.

The lesions usually heal with minimal surgical debridement, chlorhexidine mouthwashes, antibiotics and analgesia.

[Q: 2610] OnExamination 2012 -
Haematology

An 80-year-old man presents with tiredness and weakness.

A diagnosis of myelodysplastic syndrome is suspected.

Which of the following statements regarding myelodysplastic syndrome is correct?

- 1- Absence of ring sideroblasts on the blood film excludes myelodysplasia as a diagnosis
- 2- Cytotoxic chemotherapy is likely to be part of his treatment
- 3- He is more likely to die from an infection than from leukaemic transformation
- 4- If blast cells constitute 1% of the total white cells, this signifies leukaemic transformation.
- 5- On a blood film, neutrophils typically show toxic granulation

Answer & Comments

Answer: 3- He is more likely to die from an infection than from leukaemic transformation

The patient has myelodysplastic syndrome (MDS).

Myelodysplastic syndrome is a disease of old age. Men are affected more frequently than women. 80% of patients present because of symptoms of anaemia. The blood film typically

shows pancytopenia with hypogranular neutrophils. The number of blasts seen varies.

The disease can be classified into the following subtypes(WHO classification 2008):

1. Refractory anaemia with unilineage dysplasia- ie anaemia , neutropaenia or thrombocytopaenia (<5% blasts)
2. Refractory anaemia with ring sideroblasts (<5% blasts; >15% sideroblasts)
3. Refractory anemia with multilineage dysplasia (based on bone marrow dysplasia in 2 or more myeloid lineages)
3. Refractory anaemia with excess blasts-1(5-9% blasts) and refractory anemia with excess blasts -2 (10-19%)
5. Myelodysplasia unclassified
6. Myelodysplasia with isolated 5qdel(cytogenetic abnormality with prognostic significance)

Blasts > 20% is now classified as acute myeloid leukemia.

Few patients require aggressive therapy and most need only supportive care. As the vast majority are elderly patients with other medical conditions, excessive intervention is unwarranted.

Transfusions of packed red cells or platelets may be required and antibiotics for intercurrent infections.

Granulocyte-colony stimulating factor (G-CSF) and recombinant erythropoietin (r-Epo) can improve blood counts. Aggressive cytotoxic chemotherapy is generally reserved for treatment of transformation to acute myelogenous leukemia (AML) in younger patients.

Median survival is two years. Patients are more likely to have serious infections or life-threatening bleeds than blastic transformation.

[Q: 2611] OnExamination 2012 -
Haematology

A 30-year-old female presents to the antenatal clinic with her first pregnancy.

During the interview she reports that she has been entirely well but her sister had suffered a deep vein thrombosis in her second pregnancy. A thrombophilia screen shows that she is heterozygous for factor V Leiden (FVL).

Which is the most appropriate action for this patient?

- 1- She should be informed to seek medical attention if she becomes aware of calf swelling or pain
- 2- She should be treated with aspirin 75 mg daily
- 3- She should be treated with prophylactic low molecular weight heparin
- 4- She should be treated with prophylactic unfractionated heparin
- 5- She should receive warfarin

Answer & Comments

Answer: 1- She should be informed to seek medical attention if she becomes aware of calf swelling or pain

Although she is heterozygous for factor V Leiden, she has not had a previous thrombotic event.

There is no need to anticoagulate her throughout pregnancy. However she is at increased risk - pregnant and FVL - and should be very alert to the symptoms and signs of a thrombotic event.

There is no evidence of benefit from aspirin to reduce her thrombotic risk.

For more information on this topic please see the following link to the RCOG guideline:

<http://www.rcog.org.uk/files/rcog-corp/GTG37aReducingRiskThrombosis.pdf>

[Q: 2612] OnExamination 2012 -
Haematology

A 65-year-old lady presents with weight loss, lethargy and lower limb weakness. She is now unable to mobilise without assistance and complains of some urinary incontinence.

On examination she is cachectic and there is a fungating mass in her left breast. She is able to move her hips but has quadriceps wasting and fasciculation bilaterally. She is unable to flex or extend her knees with absent knee jerks. She has power 1/5 for dorsiflexion and extension with evidence of clonus and positive Babinski sign. She has reduced anal tone and saddle paraesthesia.

What is the diagnosis?

- 1- Amyotrophic lateral sclerosis
- 2- Brown-Sequard syndrome
- 3- Cauda equina syndrome
- 4- Conus medullaris syndrome
- 5- Subacute combined degeneration of the cord

Answer & Comments

Answer: 4- Conus medullaris syndrome

This lady has breast cancer which is disseminated and gone to her spine to cause compression.

There is compression of the conus medullaris to give her a mixture of upper and lower motor signs (LMN). Because of the anatomy of the spinal cord if there is compression at the level of the conus medullaris some of the cord is compressed to cause upper motor (UMN) signs and some of the nerves are compressed to give lower motor signs. Hence she has UMN signs in L5-S2 but LMN signs in L3-4.

Cauda equina would give just LMN signs, and so she would not have positive Babinski sign and clonus.

Amyotrophic lateral sclerosis is the commonest form of motor neurone disease. There would be a mixture of UMN and LMN signs; however they do not have any sensory signs or incontinence.

Brown-Sequard syndrome is due to hemisection of the cord and so the patient will have UMN signs in one leg and loss of pain and temperature sensation in the contralateral leg.

Subacute combined degeneration of the cord is due to degeneration of the posterior and lateral spinal columns. It can cause bilateral spastic paresis with loss of vibration sensation, tingling and positive Babinski's sign. It is due to B vitamin deficiency or Friedreich's ataxia.

[Q: 2613] OnExamination 2012 - Haematology

A 45-year-old man is to undergo knee surgery. He has a history of factor IX deficiency. You are concerned about the prospect of significant bleeding during surgery.

Which of the following is most likely to reduce his risk of bleeding?

- 1- Mefenamic acid
- 2- Tranexamic acid
- 3- Vasopressin
- 4- Vitamin K
- 5- von Willebrand factor

Answer & Comments

Answer: 2- Tranexamic acid

Tranexamic acid inhibits thrombolysis without increasing the risk of thrombosis. As such it may be of value in patients undergoing surgery who have inherited factor IX deficiency in order to reduce the perioperative risk of bleeding.

Recombinant factor IX is of course also an option where it is available, although patients

have a high tendency to form neutralising antibodies to factor IX.

Vasopressin is associated with a significant increase in levels of both factor VIII and von Willebrand factor in haemophilia A.

Any increase seen in factor IX levels after vasopressin is however much more minor. As such tranexamic acid is a much more useful therapeutic choice.

None of the other options given has any role in the management of factor IX deficiency.

[Q: 2614] OnExamination 2012 - Haematology

By what mechanism does topoisomerase catalyse DNA replication?

- 1- Acts as a promoter
- 2- DNA synthesis
- 3- Helix torsion release
- 4- Homologous repair
- 5- Non-homologous end joining

Answer & Comments

Answer: 3- Helix torsion release

Topoisomerase releases torsion in the DNA helix during replication.

It accomplishes this by cutting the DNA helix at specific points to allow it to unravel and then ligates the ends together again. This allows large proteins such as DNA polymerase to replicate DNA along the sequence.

Topoisomerase is therefore an important target for chemotherapeutic agents such as topotecan which can arrest cells in S-phase and induce apoptosis.

[Q: 2615] OnExamination 2012 - Haematology

A patient with Hodgkin's lymphoma undergoes mantle field radiotherapy.

Several months later the patient complains that when they flex or extend their neck they feel an electric shock phenomenon down their back and into their limbs.

What is the patient describing?

- 1- Cervical arthritis
- 2- Cervical spine stenosis
- 3- Lhermitte's sign
- 4- Malignant spinal cord compression
- 5- Uhthoff's phenomenon

Answer & Comments

Answer: 3- Lhermitte's sign

Lhermitte's sign is classically associated with multiple sclerosis and suggests a lesion of the dorsal columns of the cervical cord or of the caudal medulla.

Radiation myelopathy is a potential cause of this but it can also be present in many other conditions, for example vitamin B₁₂ deficiency.

If following radiotherapy it usually resolves in two to three months.

[Q: 2616] OnExamination 2012 - Haematology

A 35-year-old woman presents to the oncology clinic with post-coital bleeding. A cervical biopsy confirmed a squamous cell carcinoma of the cervix.

With which of the following strain variations of human papilloma virus (HPV) is she likely to be infected?

- 1- 1 and 2
- 2- 2 and 8
- 3- 8 and 16
- 4- 16 and 18
- 5- 18 and 22

Answer & Comments

Answer: 4- 16 and 18

Cervical cancer is the most common cancer worldwide and is associated with HPV 16 and 18 in approximately 70% of cases.

New vaccines are currently available in the United Kingdom to help immunise against this virus and hopefully prevent future cases of cervical cancer.

[Q: 2617] OnExamination 2012 - Haematology

What is the best initial investigation for a patient with suspected malignant spinal cord compression?

- 1- CT chest, abdomen and pelvis
- 2- MRI brain
- 3- MRI spine
- 4- Nerve conduction studies
- 5- Spinal x ray

Answer & Comments

Answer: 3- MRI spine

Due to the spine being compressed by a soft tissue lesion MRI gives the best image quality to identify the site of disease accurately and to allow prompt treatment with either radiotherapy or surgical decompression.

[Q: 2618] OnExamination 2012 - Haematology

Which of the following histopathological subtypes is essential for successful treatment with cetuximab?

- 1- Her-2/neu negative
- 2- Her-2/neu positive
- 3- K-ras mutated
- 4- K-ras wild-type
- 5- VEGF overexpression

Answer & Comments

Answer: 4- K-ras wild-type

Cetuximab is licensed by NICE in metastatic colorectal cancer for k-ras wild-type proven patients who require downstaging prior to surgical resection of liver metastatic disease. This is always given in combination with chemotherapy and causes an acne type rash as its major side effect.

Her-2 status is currently only required in breast cancer patients for consideration of treatment with Herceptin; there are trials currently underway researching its role in treatment of other cancers such as gastric cancer.

[Q: 2619] OnExamination 2012 - Haematology

A 30-year-old woman with a strong family history of breast cancer is referred to the genetics service for counselling.

What is the DNA repair mechanism by which the BRCA1 and BRCA2 proteins act?

- 1- Base excision repair
- 2- Double strand DNA break repair
- 3- Non-homologous end joining
- 4- Nucleotide excision repair
- 5- Single strand DNA break repair

Answer & Comments

Answer: 2- Double strand DNA break repair

The BRCA proteins are involved in homologous recombination to repair DNA double strand breaks.

Mutations in either of the genes encoding these proteins puts the patient at significantly higher risk of developing breast and ovarian cancers, so that some women opt for prophylactic surgery to prevent this.

Future treatment options with PARP inhibitors take advantage of this deficiency in DNA repair to kill cancer cells via synthetic lethality.

[Q: 2620] OnExamination 2012 - Haematology

A 65-year-old woman presents to the oncology clinic with a two month history of cough and haemoptysis.

A suspicious lesion on a recent chest x ray was biopsied and confirms a bronchogenic adenocarcinoma.

Currently the patient is short of breath causing her to be in bed for about three hours every day. She can manage the stairs but is markedly breathless when she reaches the top. She is currently unable to work. Her husband helps around the house but she does not need help with her activities of daily living.

What is the patient's performance status, as measured on the World Health Organization scale?

- 1- 0
- 2- 1
- 3- 2
- 4- 3
- 5- 4

Answer & Comments

Answer: 3- 2

0. Asymptomatic. (Fully active, able to carry on all pre-disease activities without restriction).

1. Symptomatic but completely ambulatory. (Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature. For example, light housework, office work).

2. Symptomatic, less than 50% in bed during the day. (Ambulatory and capable of all self-care but unable to carry out any work

activities. Up and about more than 50% of waking hours).

3. Symptomatic, more than 50% in bed, but not bedbound. (Capable of only limited self-care, confined to bed or chair 50% or more of waking hours).

4. Bedbound. (Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair).

5. Death.

[Q: 2621] OnExamination 2012 - Haematology

A 16-year-old girl of African origin presents to the emergency department with a one week history fever and lethargy.

Shortly before developing her symptoms she received a course of antibiotics from her GP for an upper respiratory infection. She also complains of two to three days of pain and swelling in her hands. The patient tells you that she has had similar attacks before.

On examination she is pyrexial, with a heart rate of 109 and oxygen saturations of 91% on air. There is painful dactylitis of both her hands. The remainder of her examination was normal.

Initial investigations reveal haemoglobin of 9.3 g/dL; reticulocytes of 8 % and a white cell count of $13 \times 10^9/L$. ECG, urinalysis and electrolytes are normal. C reactive protein is 76.

You decide to treat the patient as a sickle cell crisis.

What treatment would you start in the Emergency department?

- 1- Analgesia
- 2- Analgesia and oxygen
- 3- Analgesia, oxygen and hydration
- 4- Analgesia, oxygen, hydration and antibiotics

- 5- Analgesia, oxygen, hydration, antibiotics and hydroxycarbamide

Answer & Comments

Answer: 4- Analgesia, oxygen, hydration and antibiotics

Analgesia: start with paracetamol and then add in a non-steroidal anti-inflammatory, for example, ibuprofen. If this does not control the pain then opioid analgesics should be used, for example, morphine sulphate. Often patients can give you information regarding which analgesics work for them.

Oxygen: the patient is hypoxic and will benefit from oxygen therapy. A rate of 2 L/min given via a nasal cannula should be started.

Hydration: This is important to correct any intravascular depletion. Oral fluid therapy may be sufficient but if the patient is severely dehydrated or unable to take oral fluids then intravenous therapy is required.

Antibiotics: Antibiotics should be started if there is evidence of infection, for example, green sputum, positive urinalysis, pyrexia or raised inflammatory markers. Start with broad-spectrum antibiotics and rationalise once sensitivities become available.

Hydroxycarbamide (and bone marrow transplantation) have roles to play in the management of sickle cell disease but they are not used in the acute setting.

Blood transfusion in this patient should be considered as she is anaemic with a raised reticulocyte count but you must also take into account the clinical condition of the patient.

Option A is wrong because although analgesia is indicated in this situation it is not the only treatment that you should give.

Option B is wrong because although analgesia and oxygen are indicated in this situation they are not the only treatments that you should give.

Option C is wrong because although analgesia, oxygen and hydration are indicated in this situation they are not the only treatments that you should give.

Option D is correct as it contains all the treatments that should be given in the acute setting.

Option E is wrong because although analgesia, oxygen, hydration and antibiotics are indicated in this situation hydroxycarbamide is not indicated in the acute setting.

The correct management of a sickle cell crisis would entail oxygenation, hydration with careful management of fluid balance, analgesia, predominantly based on opioids, and blood product support, including if required exchange transfusion to get the HbS fraction to less than 30%.

HbF switching therapies such as hydroxycarbamide are not instituted acutely.

[Q: 2622] OnExamination 2012 - Haematology

A 67-year-old woman presents with acute severe back pain. She is normally fit and well, but there is a strong family history of osteoporosis.

Hb 10.6 g/dl (12-16)

MCV 85 (80-90)

Calcium 2.9 mmol/l (2.2-2.6)

Phosphate 2.2 mmol/l (0.8-1.2)

Alkaline phosphatase 126 iu/l (50-150)

Total protein 76g/l (60-83)

Albumin 30g/l (35-45)

What is the most likely underlying diagnosis?

- 1- Metastatic disease
- 2- Multiple myeloma
- 3- Osteoporosis
- 4- Paget's disease

5- Sarcoidosis

Answer & Comments

Answer: 2- Multiple myeloma

This patient has hypercalcaemia/hyperphosphataemia and hyperglobulinaemia. (The globulin level is raised at 46 g/l total protein - albumin = 46. A normal level should be below 36g/l.)

This together with normocytic anaemia and probable vertebral collapse would be highly suggestive of multiple myeloma.

She needs serum immunoelectrophoresis, urinary Bence-Jones protein and bone marrow biopsy.

The hyperphosphataemia in multiple myeloma is due to reduced renal excretion which may be directly due to renal impairment or interference with excessive protein load.

[Q: 2623] OnExamination 2012 - Haematology

A 75-year-old lady is brought to the Emergency department by her next of kin after a three week history of having "gone off her feet".

A history of back pain radiating anteriorly around her chest and bilateral weakness of her legs is elicited. Physical examination shows a paraparesis.

Blood investigations are notable for haemoglobin of 9.5 g/dL, serum calcium of 3.6 mmol/L and a creatinine of 250 µmol/L.

Which of the following would be the most appropriate initial investigation?

- 1- Bone marrow biopsy
- 2- Serum protein electrophoresis, quantitative immunoglobulins and serum free light chains
- 3- CT chest, abdomen, pelvis

- 4- Urgent magnetic resonance imaging of her spine
- 5- Urine for creatinine clearance and Bence Jones protein

Answer & Comments

Answer: 4- Urgent magnetic resonance imaging of her spine

The combination of hypercalcaemia, anaemia and renal failure in a patient presenting with spinal cord compression should lead you to consider a diagnosis of multiple myeloma.

Multiple myeloma is a plasma cell disorder with a malignant clone producing a monoclonal paraprotein. Clinical manifestations relate both to substances secreted by the plasma cells and effects of marrow infiltration. Complications include pathological fractures, hyperviscosity syndrome, hypercalcaemia, renal impairment, bone pain and recurrent infections. Spinal cord compression can develop due to vertebral compression fractures or vertebral plasmacytomas.

An urgent MRI of the spine is indicated to determine whether spinal cord compression is present in view of this lady's neurology. Options A, B and E should all be done following this to determine if myeloma is the underlying diagnosis, and help guide further treatment. CT can be used to delineate the extent of disease, but is not a first line investigation for myeloma or spinal cord compression.

It is also important to realise that this level of hypercalcaemia is potentially life-threatening, with risk of arrhythmia or coma. Immediate treatment is with intravenous hydration (rapidly) followed by intravenous bicarbonate.

[Q: 2624] OnExamination 2012 - Haematology

A 76-year-old woman has had Paget's disease

of bone for at least 15 years. She develops a destructive mass in the bony pelvis and a diagnosis of primary tumour is considered.

What is the most likely primary tumour?

- 1- Chondrosarcoma
- 2- Exostosis
- 3- Multiple myeloma
- 4- Osteoma
- 5- Osteosarcoma

Answer & Comments

Answer: 5- Osteosarcoma

Paget's disease of bone usually occurs in later life.

In Paget's disease the continual repair process of bone is disturbed and ends at the stage of vascular osteoid bone. Bones are very weak.

Osteogenic sarcoma complicates 5% of cases.

[Q: 2625] OnExamination 2012 - Haematology

Which of the following best describes the function of the bcr-abl fusion protein?

- 1- Epidermal growth factor
- 2- Fibroblast growth factor
- 3- p53 inhibitor
- 4- Tyrosine kinase
- 5- Vascular endothelial growth factor

Answer & Comments

Answer: 4- Tyrosine kinase

The bcr-abl fusion protein is the proto-oncogene from the Philadelphia chromosome found in CML.

It is a potent tyrosine kinase which stimulates signal transduction and hence mitosis.

[Q: 2626] OnExamination 2012 -
Haematology

A 65-year-old man has locally advanced pancreatic cancer and has been paying privately for treatment with erlotinib (Tarceva) for the past nine months. It has worked effectively for that period but a recent CT scan showed further growth in the tumour.

Which of the following mechanisms best explains this resistance to treatment with erlotinib?

- 1- Development of antibodies to erlotinib
- 2- Lack of autophosphorylation at binding site
- 3- Malabsorption
- 4- Mutation in the ATP binding pocket of the EGFR kinase domain
- 5- Reduced expression of EGFR

Answer & Comments

Answer: 4- Mutation in the ATP binding pocket of the EGFR kinase domain

Erlotinib specifically targets the epidermal growth factor receptor (EGFR) tyrosine kinase (which is required for the conformational change) and binds in a reversible fashion to the adenosine triphosphate binding site.

For the signal to be transmitted, two members of the EGFR family need to come together to form a homodimer. These then use the molecule of adenosine triphosphate (ATP) to autophosphorylate each other, which causes a conformational change in their intracellular structure, exposing a further binding site for binding proteins that cause a signal cascade to the nucleus. By inhibiting the ATP, autophosphorylation is not possible and the signal is stopped.

A key issue with EGFR-directed treatments is that after a period of 8-12 months, the cancer cells become resistant to the treatment. This most commonly occurs due to a mutation in the ATP binding pocket of the EGFR kinase

domain. This prevents the binding of erlotinib (Tarceva).

Some IGR-1R inhibitors are in various stages of development (based either around tyrophostins such as AG1024 or AG538 or pyrrolo[2,3-d]-pyrimidine derivatives such as NVP-AEW541).

[Q: 2627] OnExamination 2012 -
Haematology

Burkitt lymphoma is associated with a mutation of which of the following genes?

- 1- BCL-6 gene
- 2- BCR-ABL gene
- 3- Cyclin D1 gene
- 4- MYC gene
- 5- RAR-alpha gene

Answer & Comments

Answer: 4- MYC gene

Burkitt lymphoma is a monoclonal proliferation of B lymphocytes which results (in approximately 90% of the cases) from chromosome translocations that involve the Myc gene.

A chromosome translocation means that a chromosome is broken which allows it to associate with parts of other chromosomes.

The classic chromosome translocation in Burkitt lymphoma involves chromosome 8, the site of the MYC gene.

[Q: 2628] OnExamination 2012 -
Haematology

Which of the following cytotoxic agents acts by inhibiting purine synthesis?

- 1- Bleomycin
- 2- Cisplatin
- 3- Doxorubicin
- 4- Methotrexate

5- Vincristine

Answer & Comments

Answer: 4- Methotrexate

Methotrexate inhibits purine synthesis. J. Biol. Chem., Vol. 262, Issue 28, 13520-13526, Oct, 1987.

The other drugs have different mechanisms of action.

[Q: 2629] OnExamination 2012 - Haematology

A 53-year-old male is receiving treatment with imatinib for chronic myeloid leukaemia.

Which of the following is imatinib?

- 1- Inhibits guanylate cyclase
- 2- Inhibits HER
- 3- Inhibits MAP kinase
- 4- Inhibits p53
- 5- Inhibits tyrosine kinase

Answer & Comments

Answer: 5- Inhibits tyrosine kinase

Imatinib is an inhibitor of tyrosine kinase and is used in the treatment of conditions such as chronic myelocytic leukaemia (CML) and gastrointestinal stromal tumours (GIST).

It inhibits TK on abl proto-oncogene, c-kit and the PDGF-R.

In CML, the Philadelphia chromosome leads to a fusion protein of abl with bcr (breakpoint cluster region), termed bcr-abl. As this is now a continuously active tyrosine kinase, imatinib is used to decrease bcr-abl activity.

[Q: 2630] OnExamination 2012 - Haematology

A 62-year-old male is diagnosed with chronic myeloid leukaemia and his investigations

show that both Philadelphia chromosome and bcr/abl gene is present.

What is the significance of the presence of the bcr/abl gene?

- 1- Acts on stem cell line DNA
- 2- Blocks apoptosis
- 3- Codes for the production of a tyrosine kinase in the leukaemic cells
- 4- Increases expression of granulocyte colony stimulating factor receptors on the cell membrane.
- 5- Increases production of granulocyte colony stimulating factor

Answer & Comments

Answer: 3- Codes for the production of a tyrosine kinase in the leukaemic cells

The product of the bcr/abl gene that is seen in 97% cases of chronic myeloid leukaemia is a constitutively active tyrosine kinase; this is responsible for the leukaemic process.

[Q: 2631] OnExamination 2012 - Haematology

A 29-year-old woman presents with acute right sided weakness.

She has one child aged 4 years and had two spontaneous abortions in the past. After the birth of her child she developed a DVT and required three months' anticoagulation with warfarin.

Examination revealed a right hemiparesis. A CT head scan showed a left middle cerebral artery territory infarct.

What is the most likely finding on echocardiography?

- 1- Atrial septal defect
- 2- Bicuspid aortic valve
- 3- Left atrial myxoma
- 4- Normal appearances

5- Ventricular septal defect

Answer & Comments

Answer: 4- Normal appearances

This patient has a prothrombotic tendency suggestive of the lupus anticoagulant with recurrent abortions, previous deep vein thrombosis (DVT) and now she has developed a right hemiparesis.

This has occurred off warfarin and it is highly unlikely to be due to any right to left transference of clot.

It is more likely to be due to spontaneous infarct related to the thrombophilia and her heart is likely to be normal.

[Q: 2632] OnExamination 2012 - Haematology

Which of the following statements is true of sickle cell disease?

- 1- A painful shoulder joint will respond to intra-articular corticosteroid injection
- 2- Oral iron supplements are required
- 3- Symptoms of anaemia are usually limiting when Hb equals 8 g/dl
- 4- There is often an inability to concentrate urine
- 5- The spleen is frequently enlarged

Answer & Comments

Answer: 4- There is often an inability to concentrate urine

A urine concentrating defect is quite common in sickle cell anemia, has its onset in early childhood, and may be reversible with prevention of sickle crises. The inner medulla is hypoxic, hypertonic and acidotic and therefore predisposes to sickling of red blood cells, which results in vasoocclusion and reduction in renal medullary blood flow. Associated haematuria increases venous

pressure, which can worsen renal medulla ischaemia. Clinical manifestations depend of the predominant site of tubule involvement: proximal tubule dysfunction impairs urinary concentration, whilst more distal dysfunction impairs potassium excretion.

There is a tendency to iron overload in sickle cell disease and therefore iron therapy is not usually indicated. The spleen is decreased in size after six months of age, due to repeated episodes of venoocclusion and infarction, and patients often have functional hyposplenism and are recommended to take daily penicillin. The anaemia associated with sickle cell disease is usually only symptomatic below 7g/dl, as oxygen is released more readily from erythrocytes. Intra-articular steroids have been associated with a sickle cell crisis, the mechanism of which is not fully understood, but they should be avoided.

[Q: 2633] OnExamination 2012 - Haematology

A 45-year-old Chinese man is found incidentally to have a severely hypochromic and microcytic blood picture, with Hb 11.2g/dl. He is asymptomatic.

Which of the following is the most discriminatory investigation?

- 1- Barium enema
- 2- Bone marrow biopsy
- 3- Gastroscopy
- 4- Haemoglobin electrophoresis
- 5- Ham test

Answer & Comments

Answer: 4- Haemoglobin electrophoresis

Thalassaemia trait is a common, usually asymptomatic abnormality.

Red cells are hypochromic and microcytic, but iron and ferritin stores are normal.

Haemoglobin electrophoresis shows raised HbA2 (greater than 3.5%) and raised HbF (normally consisting predominantly of HbA with trace of HbF and HbA2).

[Q: 2634] OnExamination 2012 - Haematology

What is the mode of inheritance of hereditary non-polyposis colorectal cancer (Lynch syndrome)?

- 1- Autosomal dominant
- 2- Autosomal recessive
- 3- Co-dominance
- 4- Incomplete penetrance
- 5- X linked

Answer & Comments

Answer: 1- Autosomal dominant

Lynch syndrome (HNPCC or hereditary non-polyposis colorectal cancer) is an autosomal dominant genetic condition which has a high risk of colon cancer as well as other cancers including:

Endometrial

Ovary

Stomach

Small intestine

Hepatobiliary tract

Upper urinary tract

Brain and

Skin.

The increased risk for these cancers is due to inherited mutations that impair DNA mismatch repair.

[Q: 2635] OnExamination 2012 - Haematology

Which non-gastrointestinal tumour is

frequently associated with Lynch syndrome?

- 1- Endometrial
- 2- Lung
- 3- Prostate
- 4- Renal
- 5- Sarcoma

Answer & Comments

Answer: 1- Endometrial

Lynch syndrome (HNPCC or hereditary nonpolyposis colorectal cancer) is an autosomal dominant genetic condition which has a high risk of colon cancer as well as other cancers including

Endometrial

Ovary

Stomach

Small intestine

Hepatobiliary tract

Upper urinary tract

Brain and

Skin.

The increased risk for these cancers is due to inherited mutations that impair DNA mismatch repair.

[Q: 2636] OnExamination 2012 - Haematology

A 25-year-old woman presents with oligomenorrhoea. On examination she has a large pelvic mass and is referred for further investigation.

Prior to a planned biopsy of her pelvic mass, she complains of a dry cough. A subsequent chest x ray reveals multiple rounded opacities throughout both lung fields.

What is the best test for monitoring her condition after optimal treatment?

- 1- Alpha-fetoprotein (AFP)
- 2- CA-125
- 3- None
- 4- Regular abdominal ultrasound
- 5- Regular pelvic examination

Answer & Comments

Answer: 1- Alpha-fetoprotein (AFP)

Patients with germ cell tumours are usually young and present in a variety of ways. The diagnosis is usually made on biopsy in the case of ovarian tumours and treatment usually consists of surgery followed by chemotherapy (BEP).

Markers such as AFP, β -human chorionic gonadotropin (HCG) and lactate dehydrogenase (LDH) may be raised but the most sensitive marker used for monitoring treatment efficacy and risk of relapse is AFP.

[Q: 2637] OnExamination 2012 - Haematology

What is the best predictive factor for local recurrence of breast cancer after surgery, chemotherapy and radiotherapy?

- 1- Age
- 2- HER-2/neu status
- 3- Lymph node status
- 4- Oestrogen receptor status
- 5- Tumour grade

Answer & Comments

Answer: 1- Age

Patients below the age of 40 are significantly more likely to develop local recurrence of a breast cancer than those aged 41+.

The exact mechanism for this remains unknown, however it was the most predictive of all factors in the trial.

Patients aged 41-50 are also at a high risk of recurrence (although not as high as under 40) and usually receive a boost of radiotherapy to the tumour bed if they have a grade 3 tumour, positive vascular invasion or lymph node disease.

[Q: 2638] OnExamination 2012 - Haematology

What is the mechanism by which patients with testicular cancer develop gynaecomastia?

- 1- Altered fat metabolism
- 2- Metastatic disease to breast tissue
- 3- Paraneoplastic phenomenon
- 4- Raised oestrogen levels
- 5- Raised testosterone levels

Answer & Comments

Answer: 4- Raised oestrogen levels

High levels of β -HCG in patients with testicular cancers cause increased production of oestrogen which in turn stimulates hypertrophy of breast tissue. This usually resolves with treatment of the underlying cancer.

Rarely gynaecomastia can be the trigger by which a young man will seek medical attention; testicular examination should therefore be done in every case.

[Q: 2639] OnExamination 2012 - Haematology

What is the approximate five year survival for a Dukes' C adenocarcinoma of the colon?

- 1- 10%
- 2- 25%
- 3- 50%
- 4- 80%
- 5- 95%

Answer & Comments

Answer: 3- 50%

The Dukes' staging system has now largely been replaced with the TNM system, however it is still used and referred to in follow up of patients diagnosed and treated recently.

The Dukes' staging system has been proven to correlate well with a patient's chance of survival, a Dukes' C colon cancer has a 40-50% chance of cure at five years.

It is classified as following

Dukes' A: Invasion into but not through the bowel wall

Dukes' B: Invasion through the bowel wall but not involving lymph nodes

Dukes' C: Involvement of lymph nodes

Dukes' D: Widespread metastases.

[Q: 2640] OnExamination 2012 - Haematology

Which of the following tumour markers are used to assess disease activity in metastatic breast cancer?

- 1- AFP
- 2- CA125
- 3- CA19-9
- 4- CA15-3
- 5- PSA

Answer & Comments

Answer: 4- CA15-3

While all the markers given above are used to monitor disease activity, only CA15-3 is used routinely to monitor metastatic breast cancer.

CA125 is monitored in ovarian cancer

CA19-9 in pancreatic cancer

AFP in teratoma and liver cancer with

PSA measured in prostate cancer.

[Q: 2641] OnExamination 2012 - Haematology

In an asymptomatic woman, which of the following conveys the greatest risk of developing breast cancer?

- 1- Early menarche
- 2- Late menopause
- 3- Oral contraceptive use
- 4- Previous fibroadenoma excised aged 25
- 5- Two first degree relatives with breast cancer

Answer & Comments

Answer: 5- Two first degree relatives with breast cancer

Early menarche and late menopause both confer an additional risk of developing breast cancer thought to be due to increased hormone exposure throughout life.

Oral contraceptive use is also associated with a slight increase in risk of developing breast and also endometrial cancer.

A previous fibroadenoma does not increase the patient's risk at all.

[Q: 2642] OnExamination 2012 - Haematology

A 45-year-old woman presents to the oncology clinic with a screen detected left sided breast lump.

The final histology following excision is a grade 3, 14 mm invasive carcinoma with clear vascular invasion.

Oestrogen and progesterone receptor status is positive, HER-2/neu overexpression is also strongly positive.

The patient is considered for adjuvant treatment with Herceptin (trastuzumab).

What is the best test for monitoring the patient while she is receiving Herceptin (trastuzumab)?

- 1- Monthly CA-15.3 measurement
- 2- Regular clinical examination
- 3- Three monthly ECG
- 4- Three monthly echocardiogram
- 5- Three monthly mammogram

Answer & Comments

Answer: 4- Three monthly echocardiogram

Herceptin has revolutionised the treatment of Her-2/neu positive patients, however it has been linked with the development of moderate to severe heart failure in a very small minority of patients.

Herceptin appears to be directly toxic to the cardiac muscle itself with relative sparing of the electrical conductivity of the heart.

As such regular echocardiograms are the best test to assess treatment safety, a reduction of greater than 10% in ejection fraction indicating the need to stop treatment.

BSE Statement on Trastuzumab (Herceptin) Therapy

[Q: 2643] OnExamination 2012 - Haematology

A 65-year-old woman is seen in the oncology clinic following a diagnosis of a grade 3, 14 mm invasive breast cancer with no vascular invasion.

0 of 4 axillary lymph nodes were involved and excision margins were complete.

Staining for oestrogen receptors and progesterone receptors is strongly positive, HER-2 staining is negative.

She is considered for adjuvant chemotherapy and hormone treatments.

Which of the following endocrine agents would be prescribed for this patient?

- 1- Anastrozole
- 2- Exemestane
- 3- Fulvestrant
- 4- Letrozole
- 5- Tamoxifen

Answer & Comments

Answer: 1- Anastrozole

NICE has approved the use of anastrozole for first line adjuvant endocrine treatment of primary breast cancer. It works as an aromatase inhibitor preventing the peripheral conversion of oestrogen (which is the primary source in post-menopausal women).

Fulvestrant is a new pure anti-oestrogen agent which appears to be as effective as anastrozole; it is given by sub-cutaneous injection once every three weeks.

Fulvestrant is not currently given first line in post-menopausal women but this may change in the near future.

See NICE guidance for further details and trials data

[Q: 2644] OnExamination 2012 - Haematology

Which of the following is most commonly associated with prolonged QT interval?

- 1- Hypercalcaemia
- 2- Hyperthyroidism
- 3- Hypocalcaemia
- 4- Hypomagnesaemia
- 5- Hyponatraemia

Answer & Comments

Answer: 3- Hypocalcaemia

Hypocalcaemia causes prolonged QT interval due to an increase in ST segment duration.

Other causes of prolonged QT interval are

Hypothermia

Hypothyroidism

Drugs (amiodarone)

Acute myocarditis

Cerebral injury

Mitral valve prolapse and

Hypertrophic obstructive cardiomyopathy (HOCM).

Hypokalemia

[Q: 2645] OnExamination 2012 - Haematology

A 45-year-old Afro-Caribbean obese woman presented with unexplained confusion, shortness of breath, cold and pain in her fingers and toes.

She is usually fit and well and had only a transient gastrointestinal upset few weeks ago, after which she has felt increasingly tired with worsening confusion. She had no regular medications, did not smoke or use excessive amounts of alcohol. She has returned from a two day trip to Malaysia yesterday.

On examination she was mildly confused, looked generally pale with cold peripheries and very pale nail folds. She was afebrile, mildly tachycardic and tachypnoeic with normal heart sounds and bibasal crepitations on chest auscultation. She had no focal neurological deficit or cranial nerve palsy but during examination she developed a one minute seizure involving the right side of her body.

Her chest x ray showed bilateral peripheral patchy parenchymal opacities and routine bloods showed:

Sodium 137 mmol/l (137-144)

Potassium 5.8 mmol/l (3.5-4.9)

Creatinine 110 µmol/l (60-110)

Urea 7.1mmol/l (2.5-7.5)

Albumin 36 g/l (37-49)

Total bilirubin 28 µmol/l (1-22)

Alk.phosphatase 77 IU/L(30-110)

ALT 14 IU/L(5-40)

LDH 450 IU/L(672)

CRP 8 mg/l (<5)

Hb 7.9 g/dl(13.0-18.0)

Haematocrit 25%

WBC $11.6 \times 10^9/L$ (4-11)

Platelets $20 \times 10^9/L$ (150-400)

MCV 93 fl(80-96)

Prothrombin time 14.2 seconds(11.5-15.5)

INR 1.1<1.4

APTT 21.2 seconds(30-40)

Peripheral smear shows fragmented schistocytes and an elevated reticulocyte count.

What is the most likely cause of this patient's neurological presentation?

- 1- Cerebral malaria
- 2- Cerebral venous sinuses thrombosis
- 3- Haemolytic uraemic syndrome
- 4- Intracranial haemorrhage due to essential thrombocytopenia
- 5- Thrombotic thrombocytopenic purpura (TTP)

Answer & Comments

Answer: 5- Thrombotic thrombocytopenic purpura (TTP)

TTP is a clinical diagnosis and potential diagnosis in any patient with anaemia and thrombocytopenia - 95% of cases are fatal if left untreated.

Symptoms are usually non-specific. Renal and neurological dysfunctions are the main complications.

Examination of the peripheral smear is critical and shows evidence of microangiopathic haemolytic anaemia with fragmented RBCs (schistocytes) and thrombocytopenia. An urgent haematological consultation is recommended for suspected cases. Plasma exchange therapy is the mainstay of treatment.

A pentad of clinical features which characterise the disease are:

Microangiopathic haemolytic anaemia. The peripheral smear shows microangiopathic haemolysis as evidenced by the presence of schistocytes

Thrombocytopenia with purpura

Acute renal insufficiency (usually less marked in TTP than in haemolytic uraemic syndrome)

Neurological abnormalities (usually more marked in TTP than in haemolytic uraemic syndrome) Neurological manifestations are present in most patients, and range from confusion and severe headache, to focal neurological abnormalities, seizures and coma

Fever.

Not all of the above may be present.

Other features are:

Purpura, ecchymosis, and menorrhagia due to thrombocytopenia may also be seen in 20% of cases

Peripheral digit ischaemic syndrome

Nonocclusive mesenteric ischaemia

Adult respiratory distress syndrome (ARDS).

Additional laboratory findings:

The reticulocyte count is generally elevated

Lactate dehydrogenase and bilirubin are often elevated as markers of haemolysis

Direct Coombs' test should be negative to rule out autoimmune haemolytic anaemia

Assays have been developed to measure von Willebrand factor cleaving enzyme (ADAMTS-13) activity. ADAMTS-13 activity can be low, and inhibitors to its activity can often be demonstrated in patients with TTP.

Cerebral malaria is an important differential diagnosis in travellers to the endemic areas and who present with decreased Glasgow coma score (GCS) and history of fevers, but the incubation period is usually seven to 14 days. In this case, the patient developed symptoms gradually and prior to her travel.

A history of fevers would strongly suggest the possibility of malaria although fever may also be present in TTP, sepsis, disseminated intravascular coagulation (DIC) and all can give a similar laboratory picture. TTP in this clinical scenario would be the first on the differential list.

Cerebral venous sinuses thrombosis clinically may present as headache, focal neurological deficit, seizures and decreased level of GCS but pathogenesis is usually associated with prothrombotic conditions (with thrombocytosis being more likely rather than thrombocytopenia).

The pathogenesis of neurological disturbances in TTP is formation of microthrombi in microcirculation.

Haemolytic uraemic syndrome is the main differential in thrombocytopenia and haemolytic anaemia but this presents with more marked renal failure and neurological complications occur less frequently.

This is clearly not essential thrombocytopenia, which, as the definition says, affects only megakaryocytic lineage. In this clinical scenario, there is laboratory evidence of haemolytic anaemia.

Reference:

BMJ Best Practice. Thrombotic thrombocytopenic purpura.

Chang JC, Kathula SK. Various clinical manifestations in patients with thrombotic microangiopathy. *J Investig Med.* 2002 May;50(3):201-6.

[Q: 2646] OnExamination 2012 - Haematology

The mother of a 16-year-old boy with HbSC comes to your practice and asks for advice with regard to the vaccination requirements of her son.

He has had all of his childhood immunisations on schedule.

- 1- Usual childhood immunisation schedule is all that is required
- 2- Usual childhood immunisations and meningococcal C vaccine
- 3- Usual childhood immunisations and yearly influenza vaccine
- 4- Usual childhood immunisations, yearly influenza vaccine, five yearly Pneumovax vaccine
- 5- Usual childhood immunisations, five yearly Pneumovax vaccine and meningococcal C vaccine

Answer & Comments

Answer: 4- Usual childhood immunisations, yearly influenza vaccine, five yearly Pneumovax vaccine

Vaccinations should usually be done at general practice.

All adults who are hyposplenic, including patients with sickle cell disease need:

Yearly influenza vaccine

Pneumococcal C vaccine, (adults and children over 2 years) repeated every five years

Haemophilus influenzae type b; if not already given as part of childhood immunisation

Conjugated meningococcal C vaccine; if not already given as part of childhood immunisation

Meningococcal ACWY vaccine; if travelling to areas with high risk of meningitis.

Option A is incorrect. Patients with sickle cell disease are hyposplenic, and have additional lifelong requirements.

Option B is incorrect. Meningococcal C vaccine is a part of primary immunisation schedule which this young boy should have had already. Had this young boy not been up to date with his childhood immunisation schedule, then he should have a single dose.

Option C is incorrect. Although patients with sickle cell disease do need the yearly influenza vaccination, they also need five yearly Pneumovax.

Option D is correct. This young boy is up to date with all his childhood immunisations; therefore he should need yearly influenza and five yearly Pneumovax vaccinations. It is worth mentioning that all hyposplenic patients should be offered meningococcal ACWY vaccine if travelling to areas at high risk of meningitis.

Option E is incorrect. This young boy is up to date with his immunisation and therefore should not need additional meningococcal C vaccination. He does however need yearly influenza vaccination and five yearly Pneumovax.

[Q: 2647] OnExamination 2012 - Haematology

A 62-year-old gentleman is being investigated for normochromic, normocytic anaemia. He is diagnosed with diabetes mellitus type II and essential hypertension.

His haemoglobin is stable at 9.5 g/dL, his creatinine clearance is calculated at 45 ml/min, ferritin at 50ug/L and his serum

erythropoietin level comes back at 8 (normal range: 4-24 mU/ml).

Which of the following is the most appropriate management?

- 1- Commencement of subcutaneous darbopoietin
- 2- Intravenous iron supplementation
- 3- Check haemoglobin at 6 monthly intervals
- 4- Transfusion aiming for Hb of 10-12 g/dL
- 5- Transfusion aiming for Hb of 12-14 g/dL

Answer & Comments

Answer: 2- Intravenous iron supplementation

This patient has CKD stage 3A (borderline 3B). Renal-related anaemia can start to develop at this stage as alteration in erythropoietin production occurs. It is worsened by reduced dietary intake of iron due to anorexia, impaired intestinal absorption of iron, toxic effect of uraemia on erythroid precursors and reduced red blood cell survival.

It is imperative that renal patients avoid repeated blood transfusion, unless in extremis, so that future renal transplantation will not be precluded by allo-sensitisation.

Before initiation of recombinant erythropoiesis-stimulating agents the patient should be iron replete. The serum ferritin and transferrin saturation should be checked, as most patients will be iron deficient. Targets for treatment are:

- Haemoglobin 10.5-12.5g/dL
- Ferritin: >100ug/L in pre-dialysis and peritoneal dialysis patients, >200ug/L in haemodialysis patients
- Transferrin saturation >20%

This patient should also be referred to a nephrologist, as early assessment of the causes of his renal impairment is beneficial. Patients with CKD stage 3A, who are non-proteinuric, have a low risk of progression and

can usually be managed in the community following initial assessment by a nephrologist. Those with proteinuria are usually managed in secondary care, as the protein is directly toxic to the tubules and this typically results in progression of renal impairment.

[Q: 2648] OnExamination 2012 - Haematology

Which one of the following is a common feature in the presentation of myeloma?

- 1- Hypercalcaemia
- 2- Hyperglycaemia
- 3- Hypocalcaemia
- 4- Hyponatraemia
- 5- Polycythaemia

Answer & Comments

Answer: 1- Hypercalcaemia

The following are presenting clinical features of multiple myeloma:

Older adults - median age 60 years; male more than female

Anaemia

Bone pain - most common in the back or ribs; may present as a pathologic fracture following minimal trauma, especially of the femoral neck

Infection - commonly with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*; due to suppression of antibody production and neutropenia

Hypercalcaemia - nausea, fatigue, confusion, polyuria, constipation

Weight loss is common

Hyperviscosity.

Hypercalcaemia is caused by osteoclast activating factors.

British Committee for Standards in Haematology.

<http://www.bcsghguidelines.com>

www.gpnotebook.com

[Q: 2649] OnExamination 2012 - Haematology

The most common error in transfusion according to the SHOT (serious hazards of transfusion) analysis is which of the following?

- 1- Cross match error in the blood bank laboratory
- 2- Inability to detect antibodies in the blood bank laboratory
- 3- Incorrect indication for transfusion
- 4- Incorrect storage temperature for blood products.
- 5- Wrong identification/ mislabelling of patient or sample

Answer & Comments

Answer: 5- Wrong identification/ mislabelling of patient or sample

Mislabelling of samples, requests or wrongly identifying recipients are the commonest transfusion errors.

This was borne out in the SHOT study which analysed transfusion errors and 'near misses' in a UK wide audit.

Other errors such as cross match error, incorrect storage and transfusion reaction due to an antibody not detected do occur but are rare.

Reference:

L M Williamson, S Lowe, E M Love, H Cohen, K Soldan, D B L McClelland, P Skacel, A J Barbara; Serious hazards of transfusion (SHOT) initiative: analysis of the first two annual reports *BMJ* 1999;319:16

[Q: 2650] OnExamination 2012 - Haematology

Which blood used for an exchange transfusion in a neonate should fulfil these criteria?

- 1- Any blood less than five days old
- 2- Any plasma reduced whole blood in CPD
- 3- Plasma reduced whole blood in CPD which is irradiated
- 4- Plasma reduced whole blood in CPD less than five days old and irradiated
- 5- Plasma reduced whole blood in CPD less than five days old, irradiated and Rh group should be same as the neonate

Answer & Comments

Answer: 4- Plasma reduced whole blood in CPD less than five days old and irradiated

An exchange transfusion requires blood which is plasma reduced whole blood, irradiated and less than five days old (hence option D and not A, B or C).

The Rh group should be compatible with the mother, not the neonate, to avoid haemolytic transfusion reaction in the neonate due to maternal Rh antibodies (hence not option E).

[Q: 2651] OnExamination 2012 - Haematology

A 73-year-old man with extensive bony metastases from carcinoma of the prostate is brought to the Emergency department by his family.

They are concerned as his pain has worsened over the past few days, but increasing his morphine has only resulted in worsening drowsiness and confusion. Currently he is managed with maximal paracetamol and 120 mg of MST BD.

Investigations show:

Haemoglobin 14.1 g/dl(13.5-17.7)

White cell count $7.2 \times 10^9/L$ (4-11)

Platelets $193 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 152 $\mu\text{mol/l}$ (79-118)

Which of the following is the most appropriate way to manage his pain relief?

- 1- Change him to a three day fentanyl patch
- 2- Reduce his MST to 80 mg BD
- 3- Reduce his MST to 100 mg BD and add naproxen
- 4- Start a subcutaneous morphine syringe driver
- 5- Stop his MST and titrate oramorph to his pain

Answer & Comments

Answer: 3- Reduce his MST to 100 mg BD and add naproxen

The key to management of bony metastases is a multimodal approach to managing pain, which involves opiates, paracetamol and an appropriate non-steroidal anti-inflammatory agent. This patient is on both morphine (MST - a slow release preparation of morphine sulphate) and paracetamol.

In this case he is too drowsy because of his morphine, but it is not appropriate to stop it and titrate oramorph when he complains of pain. It is much more appropriate to engineer a small dose reduction and add naproxen. Whilst his creatinine is abnormal, at this stage of his disease, relieving his pain is more important than concerns about worsening his renal function.

We are given no indication that he is unable to eat and drink, so a subcutaneous morphine syringe driver is not appropriate at this stage.

[Q: 2652] OnExamination 2012 - Haematology

A 45-year-old male is being treated with

imatinib for chronic myeloid leukaemia (CML).

Which of the following the class of agent is imatinib?

- 1- Angiogenesis inhibitor
- 2- Epidermal growth factor inhibitor
- 3- Interferon
- 4- Proteasome inhibitor
- 5- Signal transductase inhibitor

Answer & Comments

Answer: 5- Signal transductase inhibitor

Imatinib is a tyrosine kinase inhibitor which blocks the bcr/abl protein from inducing cell growth.

NICE recommend that imatinib should be used to treat people in the accelerated or blast crisis phase of CML.

[Q: 2653] OnExamination 2012 - Haematology

A young woman presents with pallor, tiredness and fatigue.

Her full blood count is reported as typical of acute lymphoblastic leukaemia.

Which of the following is associated with the worst prognosis in ALL?

- 1- Female sex
- 2- Philadelphia chromosome present
- 3- Pre-B phenotype
- 4- Presentation in childhood
- 5- WCC of $21 \times 10^9/L$ at diagnosis

Answer & Comments

Answer: 2- Philadelphia chromosome present

In acute lymphoblastic leukaemia:

Good prognostic factors

FAB L1 type

Common ALL
 Pre-B phenotype
 Low initial WBC
 Poor prognostic factors
 FAB L3 type
 B, T cell type
 Philadelphia translocation, t(9;22)
 Increasing age at diagnosis
 Male sex
 CNS involvement
 High initial WBC (e.g. > 100).

[Q: 2654] OnExamination 2012 - Haematology

A 28-year-old man presented with recurrent nose bleeds and iron deficiency anaemia.

A chest x ray found a shadow over the right lung base and auscultation in this area revealed a bruit.

Which of the following is the most likely diagnosis?

- 1- Ehlers-Danlos syndrome
- 2- Hereditary haemorrhagic telangiectasia
- 3- Idiopathic thrombocytopenic purpura
- 4- von Willebrand's disease
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Hereditary haemorrhagic telangiectasia

This is hereditary haemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) characterised by bleeding from telangiectasia on mucous membranes such as the nose, mouth and gastrointestinal tract.

Clinical examination reveals telangiectasia on the skin.

Arteriovenous malformation may be seen in the lung (as in this case) or brain.

Hereditary Hemorrhagic Telangiectasia Foundation International

[Q: 2655] OnExamination 2012 - Haematology

A 28-year-old man presented with recurrent nose bleeds and iron deficiency anaemia.

A chest x ray found a shadow over the right lung base and auscultation in this area revealed a bruit.

Which of the following is the most likely diagnosis?

- 1- Ehlers-Danlos syndrome
- 2- Hereditary haemorrhagic telangiectasia
- 3- Idiopathic thrombocytopenic purpura
- 4- von Willebrand's disease
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Hereditary haemorrhagic telangiectasia

This is hereditary haemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) characterised by bleeding from telangiectasia on mucous membranes such as the nose, mouth and gastrointestinal tract.

Clinical examination reveals telangiectasia on the skin.

Arteriovenous malformation may be seen in the lung (as in this case) or brain.

Hereditary Hemorrhagic Telangiectasia Foundation International

[Q: 2656] OnExamination 2012 - Haematology

A 26-year-old woman presented at 35 weeks of pregnancy with profuse vaginal bleeding. She had suffered two previous miscarriages.

She had a pulse of 95 beats per minute, blood pressure of 110/84 mmHg and no fetal heart sounds were audible.

Investigations revealed:

Haemoglobin 9.8 g/dl 11.5 - 16.5 g/dL

Platelets $66 \times 10^9/L$ 150 - $400 \times 10^9/L$

Prothrombin time 21 sec (11.5-15.5)

APTT 52 sec (30-40)

Fibrinogen 0.5 g/l (2-4)

What is the most appropriate next step in management?

- 1- Antithrombin III infusion
- 2- Fibrinogen replacement infusion (cryoprecipitate)
- 3- Intravenous heparin
- 4- Platelet transfusion
- 5- Transfusion of two units group O rhesus D negative blood

Answer & Comments

Answer: 2- Fibrinogen replacement infusion (cryoprecipitate)

The clinical picture is disseminated intravascular coagulation.

When bleeding is the major problem, the aim is to maintain the prothrombin and activated thromboplastin time at a ratio of 1.5 times of the control and the fibrinogen level above 1 g/l.

Platelet transfusion is recommended if the count is less than $50 \times 10^9/L$.

Anaemia is not very severe so in this case fibrinogen replacement would be the appropriate first choice with blood transfusion an addition if bleeding continues and patient develops hypovolaemic shock.

[Q: 2657] OnExamination 2012 - Haematology

A 65-year-old female is receiving treatment for colon cancer with a combination chemotherapy regime that includes irinotecan.

Which of the following best describes the action of irinotecan?

- 1- Alkylating agent
- 2- DNA antimetabolites
- 3- Inhibition of protein synthesis
- 4- RNA/DNA antimetabolites
- 5- Topoisomerase inhibitor

Answer & Comments

Answer: 5- Topoisomerase inhibitor

Irinotecan is a chemotherapy agent that is a topoisomerase 1 inhibitor. Chemically, it is a semisynthetic analogue of the natural alkaloid Camptothecin.

Its main use is in colon cancer, particularly in combination with other chemotherapy agents. This includes the regimen FOLFIRI which consists of infusional 5-fluorouracil, leucovorin, and irinotecan.

[Q: 2658] OnExamination 2012 - Haematology

A 26-year-old man presents with dark urine, especially in the early morning. Further investigations show that he has haemoglobinuria and haemolytic anaemia.

A diagnosis of paroxysmal nocturnal hemoglobinuria (PNH) is made.

What is the likely mechanism underlying this condition?

- 1- Aberrant fusion of two genes
- 2- Impaired protein degradation
- 3- Over-expression of cellular oncogene
- 4- Post-translational modification

5- Telomere shortening

Answer & Comments

Answer: 4- Post-translational modification

Post-translational modification by the GPI glycolipid anchor is essential for the surface expression of many membrane proteins.

Defect of GPI biosynthesis due to somatic mutation in the haematopoietic stem cell is the basis for an acquired genetic disease, paroxysmal nocturnal haemoglobinuria.

The other mechanisms are associated with various other diseases.

[Q: 2659] OnExamination 2012 - Haematology

A 31-year-old male is receiving treatment for testicular carcinoma with cisplatin based chemotherapy.

Which of the following best describes the action of cisplatin?

- 1- Alkylating agent
- 2- DNA antimetabolites
- 3- Inhibition of protein synthesis
- 4- RNA/DNA antimetabolites
- 5- Topoisomerase inhibitor

Answer & Comments

Answer: 1- Alkylating agent

Cisplatin is a platinum based chemotherapy used in the treatment of testicular tumours, ovarian tumours and lymphomas. It functions through crosslinking DNA preventing the division required for rapid mitosis. Although it does not have an alkyl group, it is classed as an alkylating agent.

[Q: 2660] OnExamination 2012 - Haematology

A 29-year-old female student nurse presents

with a discrete thyroid swelling.

An isotope scan reveals it to be a "cold nodule". She has scattered local cervical lymphadenopathy.

What is the likely diagnosis?

- 1- Anaplastic carcinoma
- 2- Graves' disease
- 3- Medullary carcinoma
- 4- Papillary carcinoma
- 5- Subacute thyroiditis

Answer & Comments

Answer: 4- Papillary carcinoma

Papillary carcinoma makes up 75% of thyroid tumours and this patient's age (less than 45) puts her in a low risk group.

Usually these tumours present as "cold nodules" on isotope scanning.

These cancers may extend by intraglandular spread or local lymph node invasion. They are slow growing but may become more aggressive spreading locally or metastasising, especially to the lung.

Anaplastic carcinoma is very aggressive and more common in elderly subjects.

Subacute thyroiditis presents with moderate thyroid enlargement, fever, malaise and neck pain. The gland is tender and there may be signs of thyrotoxicosis.

[Q: 2661] OnExamination 2012 - Haematology

A 35-year-old lady with a history of two previous lower limb deep vein thromboses presents with a further DVT. She has a thrombophilia screen performed, which shows the presence of lupus anticoagulant.

What is the best course of action?

- 1- Aspirin
- 2- Aspirin and warfarin

- 3- Long term low molecular weight heparin
- 4- Warfarin for six months
- 5- Warfarin life long

Answer & Comments

Answer: 5- Warfarin life long

This patient has recurrent DVTs and has been shown to have the presence of the lupus anticoagulant.

In the circumstances, evidence would suggest that lifelong anticoagulation with warfarin is required maintaining an international normalised ratio (INR) above 2.5.

[Q: 2662] OnExamination 2012 - Haematology

A 17-year-old woman with non-Hodgkin's lymphoma underwent splenectomy for haemolytic anaemia. She understood that she had an enhanced risk of developing overwhelming pneumococcal sepsis and wished to know how long this risk would persist.

What is the duration of the risk?

- 1- Up to six months
- 2- Up to one year
- 3- Up to five years
- 4- Five to 10 years
- 5- More than 10 years

Answer & Comments

Answer: 5- More than 10 years

The risk is thought to persist lifelong, and lifelong penicillin prophylaxis is recommended.

[Q: 2663] OnExamination 2012 - Haematology

A 75-year-old male is admitted with tiredness and lethargy and is found to have an enlarged

right supraclavicular mass.

Past medical history reveals that he had developed acrocyanosis six months previously and two months ago had been admitted with a chest infection for which he was treated with co-amoxiclav.

Investigations reveal:

Blood film red cell auto-agglutination

Direct antiglobulin test positive

Cold agglutinin test positive.

What is the most likely diagnosis?

- 1- Bronchial carcinoma
- 2- Drug-induced haemolysis
- 3- Mycoplasma pneumoniae infection
- 4- Non-Hodgkin's lymphoma (NHL)
- 5- Paroxysmal cold haemoglobinuria (PCH)

Answer & Comments

Answer: 4- Non-Hodgkin's lymphoma (NHL)

The results are consistent with an autoimmune haemolytic screen caused by a cold antibody. Drug induced haemolysis does not give these results.

Bronchial Ca can give rise to an autoimmune haemolytic process but the antibody is usually warm - you do not get red cell agglutination or a positive cold agglutinin test.

PCH is a rare syndrome of acute intravascular haemolysis after exposure to cold caused by the Donath-Landsteiner antibody. It typically follows a viral illness or syphilis and is usually self limiting.

The results and clinical description of acrocyanosis are consistent with a cold auto antibody (cold autoimmune haemolytic anaemia).

The antibody attaches to the RBCs in the peripheral circulation where the blood is cold, causing agglutination of the RBCs in the small vessels leading to the acrocyanosis.

It is an IgM Ab that can fix complement and cause both intra- and extravascular haemolysis. It can be a primary phenomenon (idiopathic cold haemagglutinin disease) or secondary to infection, for example, *Mycoplasma pneumoniae* or Epstein-Barr virus (EBV) or secondary to lymphoma.

The acrocyanosis developed before the chest infection, and in view of the lymphadenopathy, then NHL is the likely cause.

[Q: 2664] OnExamination 2012 - Haematology

Which one of the following types of thyroid cancer in a 45-year-old woman has the worst prognosis following optimal treatment?

- 1- Anaplastic cancer in a longstanding goitre
- 2- Follicular cancer with bone metastases
- 3- Medullary cancer as part of the MEN type II syndrome
- 4- Papillary cancer with cervical lymph node metastases
- 5- Thyroid lymphoma

Answer & Comments

Answer: 1- Anaplastic cancer in a longstanding goitre

Anaplastic carcinoma usually occurs in middle-aged and older patients with longstanding goitre.

The gland may suddenly increase in size producing pressure symptoms, dysphagia or vocal cord paralysis.

The tumour is resistant to therapy. Death from massive local extension usually occurs within three to 36 months.

Thyroid medullary carcinoma is the next most aggressive, especially so in multiple endocrine neoplasia (MEN) 2B subjects, but less so in 2A subjects.

Lymphoma may respond dramatically to irradiation.

[Q: 2665] OnExamination 2012 - Haematology

A 35-year-old male with a long history of ulcerative colitis is treated for an acute exacerbation which settles following an alteration of his medication.

Six weeks after discharge he is re-admitted with sepsis and his results show:

Haemoglobin 10.5 g/dl (13.0-18.0)

White cell count $2.0 \times 10^9/L$ (4-11)

Platelets $90 \times 10^9/L$ (150-400)

Which one of the following drugs is most likely to be the cause of his pancytopenia?

- 1- Azathioprine
- 2- Mesalazine
- 3- Metronidazole
- 4- Pamidronate
- 5- Prednisolone

Answer & Comments

Answer: 1- Azathioprine

Although both azathioprine and mesalazine cause pancytopenia, it is more commonly seen in patients undergoing azathioprine therapy.

Therefore this is 'most likely' to be the cause.

[Q: 2666] OnExamination 2012 - Haematology

A 19-year-old male with glucose-6-phosphate dehydrogenase deficiency wishes to travel to Africa.

Which one of the following should he be advised to avoid?

- 1- Ibuprofen
- 2- Loperamide
- 3- Mefloquine

- 4- Primaquine
5- Yellow fever vaccine

Answer & Comments

Answer: 4- Primaquine

G6PD deficiency is inherited in an X linked fashion and predisposes red blood cells to haemolysis.

Drugs recognised to predispose to acute haemolysis in G6PD deficiency include antimalarials such as primaquine, sulphonamides, nitrofurantoin and nalidixic acid.

[Q: 2667] OnExamination 2012 - Haematology

Which of the following genes encoding oncoproteins is associated with follicular lymphoma?

- 1- ATM
2- Bcl-2
3- BRCA-1
4- BRCA-2
5- p53

Answer & Comments

Answer: 2- Bcl-2

BRCA-1 and 2 are associated with early breast cancer and are involved in repair of double strand DNA breaks by homologous recombination.

ATM is inherited in a recessive fashion and is also involved in repair of DNA double strand breaks.

p53 is also referred to as the 'guardian of the genome' and is mutated in at least 50% of all breast cancers.

[Q: 2668] OnExamination 2012 - Haematology

In porphyria, which of the following is least likely to precipitate an acute attack?

- 1- Aspirin
2- Menstruation
3- Phenytoin
4- Starvation
5- Thiopentone

Answer & Comments

Answer: 1- Aspirin

Porphyria is a group of diseases characterised by excess production and excretion of porphyrins and their precursors.

They are caused by enzyme defects within the haem metabolic pathway.

Stress, infection, pregnancy, menstruation, starvation and certain drugs may precipitate acute attacks.

Definite precipitants include sulphonamides, barbiturates and phenytoin.

Drugs unsafe in porphyria

[Q: 2669] OnExamination 2012 - Haematology

In which of the following chemotherapeutic agents is the cumulative dose limited due to cardiotoxicity?

- 1- Cisplatin
2- Epirubicin
3- Etoposide
4- Herceptin (trastuzumab)
5- Methotrexate

Answer & Comments

Answer: 2- Epirubicin

Epirubicin and the other anthracycline chemotherapeutic agents are extremely potent but are limited by dose constraints.

Cumulative doses of over 900 mg/m² can lead to significant cardiac toxicity and heart failure.

Herceptin can cause direct myocardial damage and must be monitored with regular echocardiograms but it is not limited to a maximum lifetime dose.

[Q: 2670] OnExamination 2012 - Haematology

At which point in the cell cycle is the cell most resistant to radiation-induced apoptosis?

- 1- G0
- 2- G1
- 3- G2-M
- 4- Late S
- 5- S

Answer & Comments

Answer: 4- Late S

Cells exhibit different sensitivities to radiation in different phases of the cell cycle.

The cell is most radioresistant during late S-phase as there are double the number of chromosomes.

This forms the basis for dose fractionation in radiotherapy.

[Q: 2671] OnExamination 2012 - Haematology

What is the most effective bisphosphonate for use in reducing bone pain and preventing pathological fractures in patients with metastatic breast cancer?

- 1- Alendronic acid
- 2- Ibandronic acid
- 3- Olpadronate

- 4- Pamidronate
- 5- Zoledronic acid

Answer & Comments

Answer: 5- Zoledronic acid

Multiple randomised control studies have proven the efficacy of Zometa in treatment of bone metastasis from breast cancer.

It is commonly given for six months and if the patient responds then they can be switched to daily ibandronic acid to prevent repeat visits to hospital.

Zometa has a risk of osteonecrosis of the jaw which must be explained to patients before they are treated.

[Q: 2672] OnExamination 2012 - Haematology

A 20-year-old man is referred to the oncology clinic with a three week history of weight loss and a dry cough.

A chest x ray shows a large mediastinal mass which is subsequently biopsied showing a poorly differentiated carcinoma.

Which of the following tumour markers confers the best prognosis?

- 1- CA125
- 2- CA15.3
- 3- CA19.9
- 4- CEA
- 5- β -HCG

Answer & Comments

Answer: 5- β -HCG

A young man with a germ cell tumour (raised β -HCG) can expect a greater than 95% cure rate, especially with seminomas.

The patient should also have his alpha-fetoprotein level checked.

The other tumour markers listed here are raised in a variety of other cancer such as

CA 125 - Ovarian

CA 15.3 - Breast

CEA - Colorectal

CA 19.9 - Pancreatic

although they can be raised in other cancers and therefore are only useful in assessing response to treatment or monitoring for early evidence of relapse.

[Q: 2673] OnExamination 2012 - Haematology

Which of the following bacteria confer a decreased risk of developing an oesophageal adenocarcinoma?

- 1- Escherichia coli
- 2- Helicobacter pylori
- 3- Streptococcus bovis
- 4- Streptococcus pneumoniae
- 5- Streptococcus viridans

Answer & Comments

Answer: 2- Helicobacter pylori

Although the mechanism of action is unclear population studies have shown a lower incidence of oesophageal cancer in patients infected with H. pylori.

Reference:

Ye W, Held M, Lagergren J, et al. (2004). "Helicobacter pylori infection and gastric atrophy: risk of adenocarcinoma and squamous-cell carcinoma of the oesophagus and adenocarcinoma of the gastric cardia". *J. Natl. Cancer Inst.* 96 (5): 388-96. doi:10.1093/jnci/djh057

[Q: 2674] OnExamination 2012 - Haematology

Chemotherapy is often given after the cancer

has been completely removed by surgery rather than prior to surgery.

What is the reason for this?

- 1- Because chemotherapy prior to surgery is unproven clinically
- 2- Because the patient cannot tolerate chemotherapy before surgery
- 3- To ensure all the cancer cells are in the most sensitive cell cycle phase
- 4- To reduce the chance of chemotherapy resistance
- 5- To reduce the chance of micrometastasis

Answer & Comments

Answer: 5- To reduce the chance of micrometastasis

Adjuvant chemotherapy is commonly given in many cancers to reduce the risk of local or distant recurrence or metastasis.

This confers a survival benefit to the patient but is not without risks which should be explained to the patient during consenting. One of the most serious complications is neutropenic sepsis, which if untreated, could result in a patient's death.

Neoadjuvant chemotherapy is commonly given to downstage a cancer to make it either operable or to reduce the need for radical surgery. It is often followed by adjuvant chemotherapy or radiotherapy.

[Q: 2675] OnExamination 2012 - Haematology

Which of the following antiemetics is most useful following treatment with a platinum based chemotherapy?

- 1- Cyclizine
- 2- Dexamethasone
- 3- Metoclopramide
- 4- Ondansetron

5- Prochlorperazine

Answer & Comments

Answer: 4- Ondansetron

Post-chemotherapy nausea and vomiting are very important side effects to try and control because of the significant morbidity associated.

Not all chemotherapeutic agents are equally emetogenic; the platinum based chemotherapies are most likely to cause sickness while the antimetabolites such as 5-FU are usually well tolerated.

Treatment with a 5-HT₃ antagonist is particularly useful in platinum based chemotherapy where it also avoids the dystonic side effects noted with metoclopramide use.

[Q: 2676] OnExamination 2012 - Haematology

What is the best initial treatment for superior vena cava obstruction (SVCO)?

- 1- CT scan of the chest
- 2- High dose dexamethasone prescription
- 3- Referral for urgent radiotherapy to the superior vena cava
- 4- Referral for urgent stenting of the superior vena cava
- 5- Therapeutic enoxaparin administration

Answer & Comments

Answer: 2- High dose dexamethasone prescription

The patient is likely to need either stenting or radiotherapy to his SVC but initial treatment with steroids will reduce the surrounding oedema and improve venous return from the head and neck, improving symptoms and providing extra time to ensure the correct diagnosis and subsequent treatment.

[Q: 2677] OnExamination 2012 - Haematology

A 45-year-old woman presents with a screen detected left sided breast lump. This is confirmed on biopsy to be an invasive carcinoma, grade 2.

She undergoes a wide local excision and axillary node sampling with intra-operative radiotherapy to the tumour bed via MammoSite.

Post-operatively, what radiation precautions need to be taken with this patient?

- 1- Apply a zone of exclusion of 2 metres around the patient for 24 hours
- 2- Isolate in a lead lined side room for 24 hours
- 3- Isolate in a side room for 24 hours
- 4- None
- 5- The patient needs to wear a standard lead-lined apron for 24 hours

Answer & Comments

Answer: 4- None

Much confusion surrounds the use of radiotherapy, especially how patients are cared for on the ward.

It is critical to distinguish between whether the patient has had external beam radiotherapy, brachytherapy or use of an unsealed source.

External beam radiotherapy or use of targeted intraoperative radiotherapy does not render the patient radioactive.

Use of brachytherapy methods can involve insertion of radioactive seeds or beads which may require some radiation protection precautions depending on the site.

Use of an unsealed source, for example radioiodine treatment of thyroid cancer, has substantial need for precautions and patients

need to be isolated in a lead-lined side room, often for several days.

[Q: 2678] OnExamination 2012 - Haematology

A patient is seen in the oncology clinic with chronic myeloid leukaemia (CML).

What reciprocal chromosomal translocation is he likely to have?

- 1- 2 and 9
- 2- 8 and 14
- 3- 9 and 12
- 4- 9 and 22
- 5- 12 and 22

Answer & Comments

Answer: 4- 9 and 22

CML is associated with the Philadelphia chromosome, a reciprocal translocation of chromosomes 9 and 22 designated as t(9;22)(q34;q11).

This translocation fuses the bcr and abl genes creating the bcr-abl fusion protein which is constitutively active within the nucleus leading to increased cell proliferation and reduced DNA repair.

[Q: 2679] OnExamination 2012 - Haematology

A 65-year-old woman is diagnosed with primary breast cancer and is seen in the oncology clinic.

As part of her adjuvant treatment she is recommended to start treatment with anastrozole to prevent recurrence of her cancer.

A DEXA scan organised at the time of prescription reveals a T score of -2.6 although she has suffered no fragility fractures to date.

What is the next correct step in endocrine management of this patient?

- 1- Continue anastrozole
- 2- Continue anastrozole and prescribe a bisphosphonate.
- 3- Stop anastrozole
- 4- Stop anastrozole and convert to exemestane
- 5- Stop anastrozole and start tamoxifen

Answer & Comments

Answer: 2- Continue anastrozole and prescribe a bisphosphonate.

In a post-menopausal woman the endocrine treatment of choice for preventing recurrence of her primary breast cancer is an aromatase inhibitor.

Aromatase inhibitors work by causing severe oestrogen deprivation which increases the risk of osteoporosis. Aromatase inhibitors can be continued in a patient who has suffered no fragility fractures providing adequate measures are taken for bone protection, for example, prescribing a bisphosphonate.

In patients who suffer a fragility fracture tamoxifen must be considered as this does have a partial oestrogen agonist action on bone, reducing the risk of osteoporosis.

[Q: 2680] OnExamination 2012 - Haematology

A 70-year-old woman with known metastatic breast cancer to her lungs and bones presents with a symptomatic pleural effusion whilst taking anastrozole.

Subsequent drainage of this effusion reveals it to be malignant in nature.

The breast MDT suggests switching her endocrine agent to exemestane.

What is the mechanism of action of exemestane?

- 1- Competitive oestrogen receptor antagonist
- 2- Non-steroidal aromatase inhibitor

- 3- Pure oestrogen receptor antagonist
- 4- Steroidal aromatase inhibitor
- 5- Synthetic progesterone derivative

Answer & Comments

Answer: 4- Steroidal aromatase inhibitor

Anastrozole and letrozole are non-steroidal aromatase inhibitors.

Tamoxifen is a competitive oestrogen receptor antagonist with partial oestrogen agonist actions on bone.

Fulvestrant is a pure oestrogen receptor antagonist given via the subcutaneous route.

Megace is a synthetic progesterone derivative with anti-tumour properties.

[Q: 2681] OnExamination 2012 - Haematology

A 35-year-old woman is seen in the oncology clinic following a diagnosis of a grade 3, 14 mm invasive breast cancer with no vascular invasion.

0 of 4 axillary lymph nodes were involved and excision margins were complete.

She is considered for adjuvant chemotherapy and hormone treatments.

Which of the following endocrine agents would be prescribed for this patient?

- 1- Anastrozole
- 2- Exemestane
- 3- Fulvestrant
- 4- Letrozole
- 5- Tamoxifen

Answer & Comments

Answer: 5- Tamoxifen

NICE has approved the use of tamoxifen for first line endocrine treatment of an adjuvant breast cancer patient.

It is not appropriate to use an aromatase inhibitor as the patient's ovaries will be producing oestrogen, which could drive further cancer development.

Fulvestrant is a new pure anti-oestrogen agent which appears to be as effective as anastrozole. It is given by sub-cutaneous injection once every three weeks.

Fulvestrant is not currently given first line in post-menopausal women but this may change in the near future.

See NICE guidance for further details and trials data.

[Q: 2682] OnExamination 2012 - Haematology

A couple who are expecting their first child present to you for advice.

Both parents are known to be carriers of sickle cell trait HbS and want to know if their child will inherit the disease.

What do you tell them?

- 1- There is no chance their child will inherit the disease
- 2- There is a 25% chance their child will inherit the disease
- 3- There is a 50% chance their child will inherit the disease
- 4- There is a 75% chance their child will inherit the disease
- 5- There is a 100% chance their child will inherit the disease

Answer & Comments

Answer: 2- There is a 25% chance their child will inherit the disease

If both parents carry the sickle cell gene there is a 25% chance that their child will inherit the disease since the gene is inherited in an autosomal recessive fashion.

Although there is no primary prevention for sickle cell disease genetic counselling can help advise heterozygous parents.

Prenatal diagnosis is available by chorionic villus sampling at 8-10 weeks gestation or by amniocentesis at 14-16 weeks gestation.

[Q: 2683] OnExamination 2012 - Haematology

A 10-year-old boy is noticed to be jaundiced on return from a holiday in Africa with his parents. He is on antimalarial prophylaxis.

His complete blood count shows haemoglobin of 8 g/dL, with Heinz bodies and blister cells on blood film examination.

Which of the following relates to this disorder?

- 1- It is most commonly precipitated by peas
- 2- This is a common autosomal dominant disorder
- 3- The antimalarial prophylaxis has no relation to the laboratory findings
- 4- Transfusion is strictly merited in each case
- 5- Treatment involves strict avoidance of known precipitants

Answer & Comments

Answer: 5- Treatment involves strict avoidance of known precipitants

This question relates to the management of G-6-PD deficiency.

G-6-PD is the most common inherited enzyme defect in humans; an X linked inheritance pattern (hence answer B is incorrect).

It is mostly commonly precipitated by several classes of drugs, including antimalarials (hence answer C is incorrect) and is also associated with ingestion of broad beans (favism - hence answer A is incorrect).

Treatment revolves around avoidance of all known precipitating factors, and blood product support should only be given in

unstable, symptomatic patients (so answer D is incorrect).

[Q: 2684] OnExamination 2012 - Haematology

Which one of the following is in keeping with a diagnosis of myeloma-induced hypercalcaemia?

- 1- Acute hepatic failure
- 2- Colitis
- 3- Polyuria and polydipsia
- 4- Prolonged Q-T interval on ECG
- 5- Tetany

Answer & Comments

Answer: 3- Polyuria and polydipsia

Hypercalcaemia causes acute renal failure, a shortened Q-T interval on ECG as well as polyuria and polydipsia.

The abdominal symptoms include constipation, nausea and vomiting, peptic ulceration - due to increased gastrin secretion, abdominal pain and pancreatitis.

Tetany is caused by hypocalcaemia.

GP Notebook www.gpnotebook.com

[Q: 2685] OnExamination 2012 - Haematology

For which of the following patients would a gamma irradiated blood product be recommended?

- 1- A 37-year-old patient with Hodgkin's lymphoma receiving chemotherapy
- 2- A 16-year-old thalassaemic receiving regular transfusions
- 3- A 42-year-old lady receiving adjuvant hormonal therapy for breast cancer post radical mastectomy
- 4- A 19-year-old nulliparous female after a road traffic accident

5- Post-operatively for carcinoma of the colon in a 50-year-old male

Answer & Comments

Answer: 1- A 37-year-old patient with Hodgkin's lymphoma receiving chemotherapy

The most common indications for irradiated blood products include

Those at risk of transfusion associated graft versus host disease such as neonates

Those receiving purine analogues based chemotherapy

Hodgkin's lymphoma

Immunodeficiency states and

Post bone marrow transplants (hence option A is correct).

The other scenarios described here do not necessarily represent an immunosuppressed state in the list of conditions eligible for a irradiated blood product (options B, C, D and E are incorrect).

[Q: 2686] OnExamination 2012 - Haematology

You are asked to review urgently a 32-year-old woman who is receiving a blood transfusion following a post partum haemorrhage which occurred after the birth of her second baby.

Apparently she required a three unit blood transfusion after the birth of her first child. A short time after the transfusion began she became acutely short of breath, with saturations of only 91% on air, and severe wheezing.

On examination she is pyrexial 37.8°C, her BP is 110/60 mmHg, her pulse 89 and regular. She has marked bilateral wheeze on auscultation of her chest.

Investigations reveal

Haemoglobin 10.4 g/dl(11.5-16.0)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $179 \times 10^9/L$ (150-400)

Serum sodium 138 mmol/l (135-146)

Serum potassium 3.7 mmol/l (3.5-5)

Serum creatinine 100 $\mu\text{mol/l}$ (79-118)

CXR Bilateral pulmonary infiltrates

paO₂ 8.4 kPa(10-13)

paCO₂ 5.2 kPa(4.8-6.1)

Which of the following is the most likely diagnosis?

1- Acute haemolytic transfusion reaction

2- Acute non-haemolytic transfusion reaction

3- Cardiogenic pulmonary oedema

4- IgE mediated transfusion reaction

5- Transfusion associated lung injury

Answer & Comments

Answer: 5- Transfusion associated lung injury

Transfusion associated lung injury (TRALI) occurs in patients who have received a multi-unit blood transfusion previously and are then re-transfused some time later.

Two hypotheses are proposed for the cause of TRALI, that it is either

Due to HLA antigens in the donor blood reacting with neutrophil antigens in the patient, leading to neutrophil migration to pulmonary capillaries

or that

The neutrophils responsible do not actually require donor HLA antigens to react, and are just primed by infection, surgery or inflammation.

What is common to both hypotheses though, is that the neutrophils lead to a local release of cytokines, increased capillary permeability, and non-cardiogenic pulmonary oedema, accounting for the presentation with wheeze and hypoxia which is seen here.

[Q: 2687] OnExamination 2012 -
Haematology

A 40-year-old lady presents with a swollen right calf. She has a history of mental health problems and is on a number of medications.

Which of the following treatments increases the risk of thromboembolism?

- 1- Antipsychotics
- 2- Benzodiazepines
- 3- Monoamine oxidase inhibitors
- 4- Selective serotonin reuptake inhibitors
- 5- Tricyclic antidepressants

Answer & Comments

Answer: 1- Antipsychotics

The oral contraceptive and antipsychotics are possible causes of thromboembolism.

[Q: 2688] OnExamination 2012 -
Haematology

In idiopathic thrombocytopenic purpura there are antibodies directed at which of the following?

- 1- ADP receptor
- 2- Antithrombin III
- 3- ATP receptor
- 4- Glycoprotein IIb/IIIa complex
- 5- Platelet-activating factor

Answer & Comments

Answer: 4- Glycoprotein IIb/IIIa complex

In many cases of idiopathic thrombocytopenic purpura, the cause is not actually idiopathic but autoimmune, with antibodies against platelets being detected in approximately 80% of patients.

Most often these antibodies are against platelet membrane glycoproteins IIb-IIIa or Ib-IX, and are of the IgG type.

The coating of platelets with IgG renders them susceptible to opsonisation and phagocytosis by splenic macrophages.

[Q: 2689] OnExamination 2012 -
Haematology

Which of the following hereditary cancer syndromes is associated with an increased risk of ovarian cancer?

- 1- Hereditary non-polyposis colorectal cancer
- 2- Multiple endocrine neoplasia
- 3- Peutz-Jeghers syndrome
- 4- von Hippel-Lindau syndrome
- 5- Xeroderma pigmentosa

Answer & Comments

Answer: 1- Hereditary non-polyposis colorectal cancer

While all of the above hereditary cancer syndromes cause a patient to be at an increased risk of developing various cancers, only HNPCC increases the risk of ovarian cancer (along with many other cancers).

This is due to inherited mutations with DNA mismatch repair.

[Q: 2690] OnExamination 2012 -
Haematology

A 16-year-old boy with easy bruising and excessive bleeding from a tooth extraction is found to have von Willebrand's disease.

He is due to have further dental extractions and DDAVP is prescribed.

What is the mechanism of action of DDAVP in von Willebrand's disease?

- 1- Acts as a substitute carrier for factor VIII
- 2- Inhibits breakdown of von Willebrand's factor
- 3- Prevents renal excretion of von Willebrand's factor

- 4- Stimulates release of von Willebrand's factor from endothelial cells
- 5- Turns on the gene associated with von Willebrand's factor production

Answer & Comments

Answer: 4- Stimulates release of von Willebrand's factor from endothelial cells

DDAVP may be given to increase the amount of the von Willebrand factor long enough for surgery or dental procedures to be performed.

DDAVP can provide a twofold to fivefold increase in plasma von Willebrand factor and factor VIII concentrations.

It induces cyclic adenosine monophosphate (cAMP)-mediated vWF secretion by a direct effect on endothelial cells.

[Q: 2691] OnExamination 2012 - Haematology

A 14-year-old boy presents with excessive bleeding from a tooth cavity following an extraction at the dentist.

His investigations show:

Haemoglobin 13.2 g/dL (13.0-18.0)

Platelet count $260 \times 10^9/L$ (150-400 $\times 10^9$)

White cell count $8 \times 10^9/L$ (4-11 $\times 10^9$)

Prothrombin time 14 s (11.5-15.5)

Activated partial thromboplastin time 45 s (30-40)

Factor VIII 45 U/dL (50-150)

Which of the following is the most likely diagnosis?

- 1- Disseminated intravascular coagulation
- 2- Haemophilia A
- 3- Haemophilia B
- 4- Idiopathic thrombocytopenic purpura
- 5- von Willebrand's disease

Answer & Comments

Answer: 5- von Willebrand's disease

This young boy with excessive bleeding has a slightly raised APTT and slightly reduced factor VIII.

Haemophilia is therefore unlikely and von Willebrand's is the most likely.

DIC and ITP would typically be associated with thrombocytopenia.

[Q: 2692] OnExamination 2012 - Haematology

A previously well 75-year-old lady presented with tiredness and a mildly raised lymphocyte count on her full blood count. A blood film reports 'Smudge cells seen. Is this lady known to have Chronic Lymphocytic Leukaemia?'

What is the most appropriate next investigation to confirm this lady's diagnosis?

- 1- Bone marrow aspirate
- 2- Bone marrow trephine
- 3- Immunophenotyping
- 4- Serum immunoglobulins
- 5- Ultrasound scan

Answer & Comments

Answer: 3- Immunophenotyping

"A definitive diagnosis of CLL is based on the combination of a lymphocytosis and characteristic lymphocyte morphology and immunophenotype." British Committee for Standards in Haematology Guideline for CLL diagnosis 2005

The other tests are additional investigations all used in the workup of CLL.

[Q: 2693] OnExamination 2012 - Haematology

A 35-year-old lady presented with left-sided weakness.

She has a young family with a 5-year-old son and a 2-year-old daughter. Previously she had two spontaneous abortions. After the birth of her last child she developed a deep vein thrombosis (DVT) and received three months of anticoagulation with warfarin.

On examination she has left-sided weakness with pyramidal signs. A CT head scan showed a right middle cerebral artery territory infarct.

Which of the following is the most likely diagnosis?

- 1- Hypertension
- 2- Kawasaki syndrome
- 3- Patent foramen ovale
- 4- Systemic lupus erythematosus
- 5- Thrombotic thrombocytopenic purpura

Answer & Comments

Answer: 4- Systemic lupus erythematosus

This patient has a prothrombotic tendency suggestive of the lupus anticoagulant with recurrent abortions, previous DVT and now she has developed a left hemiparesis.

[Q: 2694] OnExamination 2012 - Haematology

A 22-year-old male presents with episodic nausea and abdominal pain although he has maintained a normal weight. The symptoms have been attributed to irritable bowel syndrome. There are no abnormalities on examination.

Blood tests were performed which reveal:

Haemoglobin 12.2 g/dl(13.0-18.0)

MCV 92 fl(80-96)

White cell count $6.5 \times 10^9/L$ (4-11)

Platelets $310 \times 10^9/L$ (150-400)

Reticulocytes 5%(0.5-2.4)

Bilirubin 42 $\mu\text{mol/l}$ (1-22)

AST/ALP Normal

Coombs' test Negative

Haptoglobin Undetectable

Which of the following is the likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Dubin-Johnson syndrome
- 3- Gilbert's syndrome
- 4- Hereditary spherocytosis
- 5- Viral hepatitis

Answer & Comments

Answer: 4- Hereditary spherocytosis

This patient has an elevated bilirubin concentration and elevated reticulocyte count suggesting haemolysis.

The most likely explanation would be hereditary spherocytosis which could be confirmed on blood film. This too explains the symptoms - nausea and abdominal pains suggesting gallstones, which are common even in mild disease.

[Q: 2695] OnExamination 2012 - Haematology

A 48-year-old woman presents with a history of intestinal polyps and multiple lipomas on the arms and back. She now has a small palpable nodule in her neck. Thyroid function tests and thyroid antibodies are normal.

Which of the following tumours is she at increased risk of developing?

- 1- Anaplastic carcinoma of the thyroid
- 2- Follicular carcinoma of the thyroid
- 3- Medullary carcinoma of the thyroid
- 4- Papillary carcinoma of the thyroid
- 5- Thyroid lymphoma

Answer & Comments

Answer: 4- Papillary carcinoma of the thyroid

This lady has Gardner's syndrome, or familial adenomatous polyposis, characterised by multiple small and large intestinal tumours and lipomas. Osteomata and fibromas are also seen.

It is a rare familial condition, when arising from mutations of the APC gene is inherited in an autosomal dominant fashion.

Gardener's syndrome carries an increased risk of papillary carcinoma of the thyroid with a preponderance for female patients.

[Q: 2696] OnExamination 2012 - Haematology

A 30-year-old male patient presents with sudden deterioration and haematuria 15 minutes after starting blood transfusion.

His pulse rate is 120 beats per minute and blood pressure is 70/ 40 mmHg.

Which of the following is the most likely cause?

- 1- ABO incompatibility
- 2- Anaphylaxis to anaesthetic agents
- 3- Disseminated intravascular coagulation
- 4- Graft versus host disease
- 5- Rhesus incompatibility

Answer & Comments

Answer: 1- ABO incompatibility

Immediate life threatening reactions with intravascular haemolysis are caused by complement activating IgG or IgM antibodies.

They are usually ABO antibodies and these reactions can occur after transfusion of a few millilitres of blood.

[Q: 2697] OnExamination 2012 - Haematology

A 62-year-old male undergoes surgery for caecal carcinoma.

Which of the following tumour markers is most appropriate for the continued surveillance of this patient?

- 1- AFP
- 2- CA 19-9
- 3- CA 27-29
- 4- CA 125
- 5- CEA

Answer & Comments

Answer: 5- CEA

CEA is the most appropriate tumour marker for the monitoring of potential recurrence of colonic cancer.

CEA is also elevated in breast, melanoma and pancreatic malignancy to name but a few.

The value of CA 19-9 is higher concentrations often reflect more advanced pancreatic cancer.

[Q: 2698] OnExamination 2012 - Haematology

A 27-year-old woman presented with a history of sudden onset right-sided weakness and dysphasia lasting eight hours. She had returned to the United Kingdom from Australia two days previously.

There was no significant past medical history and physical examination was normal. Chest x ray, ECG and a CT head scan were all normal.

Which one of the following investigations is most likely to reveal the underlying cause of this episode?

- 1- Carotid Doppler ultrasonography
- 2- Cerebral angiography
- 3- MRI of head
- 4- Transoesophageal echocardiography
- 5- Transthoracic echocardiography

Answer & Comments

Answer: 4- Transoesophageal echocardiography

The history here suggests a lower limb deep vein thrombosis with peripheral embolus through a patent foramen ovale, leading to a left sided cerebrovascular event.

This is termed the paradoxical embolus so-called because a thromboembolus arising from the venous circulation can end up in the systemic circulation.

Transoesophageal echocardiography is the investigation of choice to investigate for a patent foramen ovale, although transthoracic echocardiography with contrast may be an alternative.

[Q: 2699] OnExamination 2012 - Haematology

A 52-year-old male presents with a history of lethargy and epistaxis over the last one month.

Examination reveals numerous bruises over arms and legs, splenomegaly and retinal haemorrhages.

A full blood count shows:

Haemoglobin 7 g/dL (13.0-18.0)

White cell count $14 \times 10^9/L$ ($4-11 \times 10^9$)

Platelet count $20 \times 10^9/L$ ($150-400 \times 10^9$)

His blood film reveals white cells predominantly myeloblasts and promyelocytes

Which one of the following investigations would be of most prognostic value?

- 1- Bone marrow aspiration
- 2- Bone marrow trephine biopsy
- 3- Cerebrospinal fluid examination
- 4- Cytogenetic karyotype
- 5- Immunophenotyping

Answer & Comments

Answer: 4- Cytogenetic karyotype

The history, full blood count results and the blood film are suggestive of acute myeloid leukaemia as there are numerous myeloblasts on film.

Of the answers given the cytogenetic karyotype is of most prognostic value.

The cytogenetic karyotype divides people into three categories:

Good risk

Standard risk and

Poor risk.

[Q: 2700] OnExamination 2012 - Haematology

A 65-year-old woman is seen in the oncology clinic following a diagnosis of a strongly oestrogen/progesterone receptor positive breast cancer.

She is considered for adjuvant treatment with anastrozole, an endocrine agent.

What further investigation does this patient require?

- 1- Bone scan
- 2- Chest x ray
- 3- CT chest, abdomen and pelvis
- 4- DEXA scan
- 5- Urine dip

Answer & Comments

Answer: 4- DEXA scan

Aromatase inhibitors work by preventing peripheral conversion of oestrogen and therefore cause profound oestrogen deprivation in a post-menopausal woman.

This increases the risk of osteoporosis and fragility fractures.

A DEXA scan must be done at the start of treatment to identify those patients in whom a bisphosphonate must be considered for bone protection.

[Q: 2701] OnExamination 2012 - Haematology

A 62-year-old male attends the Emergency Department with a severe nose bleed. He is known to have alcoholic cirrhosis.

His investigations reveal:

Haemoglobin 10.9 g/dl(13.0-18.0)

White cell count $5 \times 10^9/L$ (4-11)

Platelet count $60 \times 10^9/L$ (150-400)

Prothrombin time 17.5 s(11.5-15.5)

APPT 42 s(30-40)

Fibrinogen 0.7 g/l (1.8-5.4)

What is the most appropriate blood product for this patient?

- 1- Cryoprecipitate
- 2- Factor VIII
- 3- Platelets
- 4- Prothrombin complex concentrate
- 5- Whole blood

Answer & Comments

Answer: 1- Cryoprecipitate

The most significant abnormality is the low fibrinogen. Therefore the best product to correct the fibrinogen out of those given is cryoprecipitate.

To correct a coagulopathy you need to aim for:

Fibrinogen >1.0 g/l

Platelets $>50 \times 10^9/L$

PT and APTT <1.5 upper range of normal

So from the results you can see the most significant abnormality is the low fibrinogen.

The platelets are low and activated partial thromboplastin time/prothrombin time (APTT/PT) prolonged but not really sufficient to cause bleeding.

[Q: 2702] OnExamination 2012 - Haematology

A 30-year-old man presents with episodic jaundice and anaemia and has been diagnosed with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

On further testing his wife has normal plasma G6PD activity.

What is the risk of their children developing this condition?

Which one of the following statements is correct?

- 1- 50% of their children will be affected, irrespective of gender
- 2- All their children will be affected
- 3- All their daughters will be affected
- 4- All their sons will be affected
- 5- None of their children will be affected

Answer & Comments

Answer: 5- None of their children will be affected

G6PD is X linked - therefore females are carriers, and are not usually affected, unless there is inactivation of their X chromosome. Males are affected.

Males will pass on the 'bad' X chromosome to their daughters so that they become carriers, and as said above they are not usually affected. Males pass on their Y chromosomes to any sons, therefore they will not be affected.

In the question the male is affected, but as the female has normal levels of the enzyme, we are assuming she is not a carrier (although

strictly she could be a carrier and have normal levels).

The male will pass on the X chromosome to any daughters, who will not be affected, as they will have a 'good' X from the mothers, and the father will pass on the Y chromosome to his sons, who will not be affected.

[Q: 2703] OnExamination 2012 - Haematology

A 32-year-old man was prescribed an oral antibiotic for a urinary tract infection.

Two days later he noticed that his urine was increasingly dark in colour.

Investigations revealed:

Haemoglobin 8.5g/dL (13.0-18.0)

Reticulocytes $147 \times 10^9/L$ (25-85 $\times 10^9$)

Blood film: marked anisopoikilocytosis and bite cells.

What is the most likely diagnosis?

- 1- Acute myeloid leukaemia
- 2- Autoimmune haemolytic anaemia
- 3- Haemoglobin H disease
- 4- Hereditary spherocytosis
- 5- Paroxysmal cold haemoglobinuria

Answer & Comments

Answer: 2- Autoimmune haemolytic anaemia

Paroxysmal cold haemoglobinuria (PCH) is a rare type of autoimmune haemolytic anaemia (AIHA) occurring primarily in children.

The classic symptom of PCH is a sudden onset of haemoglobinuria following exposure to cold, even for a few minutes. Symptoms may occur minutes to hours following exposure to cold. Haemoglobinuria is not always present because in some persons with PCH the autoantibody level is not high enough to cause intravascular haemolysis. PCH is usually of

abrupt onset in the setting of an infectious disease.

Given the patient's age and the specific history in this case the diagnosis is unlikely to be PCH.

If the diagnosis were hereditary spherocytosis then the blood film would show spherocytes.

In haemoglobin H disease the typical inclusions can be demonstrated in erythrocytes stained with brilliant cresyl blue and a chronic microcytic, hypochromic anaemia would be present.

Haemolytic anaemia may be precipitated by sulfonamides and also by penicillins.

This gentleman may have been treated with trimethoprim or a penicillin which then caused AIHA with the typical blood film.

The most appropriate answer to this question is B, given the patient's age, the lack of history of exposure to cold, and the history which is given of antibiotic prescription.

[Q: 2704] OnExamination 2012 - Haematology

You have been called to the ward by the senior nurse, to review a repeat calcium result. The repeat result is 3.9 mmol/l (2.2-2.6), the previous result four hours earlier was 3.2.

The patient has a disseminated malignancy with an unknown primary.

Which of the following statements is most correct when considering the hypercalcaemia of malignancy?

- 1- A prolonged QT interval is associated with hypercalcaemia
- 2- Bisphosphonates inhibit osteoblast function thereby lowering calcium
- 3- Calcitonin is of greater benefit than bisphosphonates in the treatment of hypercalcaemia of malignancy

- 4- NSAIDs are indicated for bone pain in this patient
- 5- On neurological examination, hyporeflexia may be exhibited

Answer & Comments

Answer: 5- On neurological examination, hyporeflexia may be exhibited

This is an oncological emergency affecting 20-40% of patients with advanced cancer.

Hyporeflexia is a common clinical sign in patients with significant hypercalcaemia.

Other signs include the classic mnemonic:

Bones - Bone pain, especially if the PTH is elevated

Stones - Renal calculi

Groans - Constipation and likely subsequent abdominal pain

Psychic moans - Depression and confusion

As well as nausea and vomiting, fatigue and pancreatitis.

Electrocardiogram changes in hypercalcaemia include bradycardia, prolonged PR interval, short QT interval, widened T waves and arrhythmias.

Bisphosphonates inhibit bone resorption by osteoclasts, and are the first line pharmacological treatment of hypercalcaemia of malignancy.

Calcitonin use is limited by its association with anaphylaxis.

Non-steroidal anti-inflammatory drugs (NSAIDs) should not be prescribed in patients with hypercalcaemia as they reduce renal blood flow thus inhibiting urinary calcium excretion.

[Q: 2705] OnExamination 2012 - Haematology

Which of the following patients with Hodgkin's disease has the worst prognosis?

- 1- 25-year-old man with inguinal lymphadenopathy
- 2- 25-year-old woman with mediastinal and inguinal lymphadenopathy
- 3- 25-year-old woman with mediastinal and inguinal lymphadenopathy and night sweats
- 4- 25-year-old man with mediastinal and inguinal lymphadenopathy and pruritis
- 5- 25-year-old man with cervical and mediastinal lymphadenopathy

Answer & Comments

Answer: 3- 25-year-old woman with mediastinal and inguinal lymphadenopathy and night sweats

Prognosis in Hodgkin's disease depends on staging and presence of B symptoms.

Patient A has Stage IA disease (one lymph node area).

Patient E has stage IIA disease (two lymph node areas on same side of diaphragm).

Patients B and D have stage IIIA disease (disease in lymph nodes on both sides of diaphragm).

Pruritis is not a B symptom and is not of prognostic significance.

Patient C has stage IIIB disease (as night sweats are a B symptom).

[Q: 2706] OnExamination 2012 - Haematology

A 64-year-old man has terminal cancer with hepatic metastases. He is treated with oral morphine (Oramorph) solution for pain relief.

Which is the most important pharmacodynamic factor in determining the appropriate timing between doses?

- 1- Bioavailability
- 2- First pass metabolism
- 3- Gastric emptying
- 4- Plasma half life
- 5- Renal clearance

Answer & Comments

Answer: 4- Plasma half life

Morphine undergoes extensive first pass metabolism in the liver.

However it is the plasma half life which defines the timing of the doses.

An increased dose may be required if the patient develops tolerance to the morphine dose.

[Q: 2707] OnExamination 2012 - Haematology

Which one of the following statements is true of B cell CLL?

- 1- Autoimmune thrombocytopenia is uncommon
- 2- Diffuse infiltration of bone marrow indicates good prognosis
- 3- Late transformation to ALL occurs in the majority of patients
- 4- Reduced immunoglobulins are a risk of recurrent viral infections
- 5- Stage A disease should be treated with chemotherapy

Answer & Comments

Answer: 1- Autoimmune thrombocytopenia is uncommon

Immune thrombocytopenia occurs in only 2% of cases.

Hypogammaglobulinaemia predisposes to encapsulated bacteria, for example, pneumococcus/H. influenzae causes death in 30% cases.

There are two transformations in chronic lymphocytic leukaemia (CLL):

CLL/PL (10%)

Richter's syndrome (5% = high grade non-Hodgkin's lymphoma).

Treatment only for Stage B, C and A with clear evidence of progression.

[Q: 2708] OnExamination 2012 - Haematology

Regarding retinoblastoma which of the following statements is correct?

- 1- Bilateral involvement is found in 70% of cases.
- 2- The predisposition may be inherited as an autosomal recessive condition.
- 3- There is an increased risk of autoimmune disease.
- 4- They have often metastasised by the time of diagnosis.
- 5- They usually present with leukocoria.

Answer & Comments

Answer: 5- They usually present with leukocoria.

The incidence is 1 in 16,000 live births.

Genetic predisposition occurs in 20% of patients with unilateral disease, and 30% of patients with bilateral disease.

The gene has been localised to 13q and the inherited form is associated with an increased risk of malignancy such as osteosarcoma and pineal tumours. It may be inherited as autosomal dominant.

The commonest presentation is leukocoria (yellowish white pupil reflex), and there may be diminished or absent vision or strabismus.

Late symptoms are pupil irregularity, hyphema, pain, proptosis, and signs of raised intracranial pressure.

The tumours have rarely metastasised before they are detected.

[Q: 2709] OnExamination 2012 - Haematology

A 23-year-old male presents with a deep vein thrombosis (DVT). He has no past medical history but his mother has suffered from deep vein thromboses.

Which of the following is likely to be found on haematological assessment?

- 1- Antithrombin deficiency
- 2- Factor V (FV) Leiden mutation
- 3- Lupus anticoagulant
- 4- Protein C deficiency
- 5- Protein S deficiency

Answer & Comments

Answer: 1- Antithrombin deficiency

Antithrombin deficiency is an autosomal dominant (AD) condition present in 0.02-1.1% of the population and is found in 4% of subjects who present with a thromboembolism.

Factor V Leiden is a possibility, although it seems less likely as the inheritance pattern seems more likely to be AD.

Similarly as the son had a DVT this would be far less likely with FV Leiden than antithrombin (AT) III, as thrombosis is more often precipitated in females on the oral contraceptive pill (OCP).

See Simioni P, Sanson BJ, Prandoni P, et al. Thromb Haemost 1999 Feb;81(2):198-202,

who show that "The annual incidences of total and spontaneous venous thromboembolic events in carriers of AT, PC or PS defects (n=181) were 1.01% and 0.40%, respectively, as compared to 0.10% and 0.04% in non-carriers, respectively (relative risks both 10.6). In carriers of Factor V Leiden (n= 224), the annual incidences of total and spontaneous venous thromboembolism were 0.28% and 0.11%, respectively, as compared to 0.09% and 0.04% in non-carriers, respectively (relative risks 2.8 and 2.5)."

See also "Risk of a first venous thrombotic event in carriers of a familial thrombophilic defect. The European Prospective Cohort on Thrombophilia (EPCOT)." J Thromb Haemost. 2005 Mar;3(3):459-64

[Q: 2710] OnExamination 2012 - Haematology

Which of the following statements is true of sarcoidosis?

- 1- Central caseation occurs in the sarcoid granuloma
- 2- Hypercalcaemia due to increased renal synthesis of 1-hydroxylase
- 3- It can produce Mikulicz's syndrome
- 4- Prognosis is poor when sarcoidosis presents acutely with bilateral hilar lymphadenopathy and erythema nodosum
- 5- Serum angiotensin converting enzyme (ACE) is useful for diagnosis of sarcoidosis

Answer & Comments

Answer: 3- It can produce Mikulicz's syndrome

Lofgren's syndrome is the combination of erythema nodosum and bilateral hilar lymphadenopathy (stage 1 radiograph). The prognosis is good with 80% resolving spontaneously, and have a normal CXR after one year.

Hypercalcaemia (2-10%) and hypercalciuria (up to 50%) are well recognised in sarcoidosis. The pattern resembles hypervitaminosis D, with:

Elevated serum calcium

Normal serum phosphate and

Normal/slightly raised alkaline phosphatase.

There is elevated 1,25-dihydroxycholecalciferol due to increased production by alveolar pulmonary macrophages and macrophages in granulomata.

Treat with rehydration and corticosteroids.

Serum ACE is produced by sarcoid granulomata from activation and differentiation of monocyte-macrophage system. It is a membrane bound glycoprotein, found mainly in the lung capillary endothelium.

ACE has poor diagnostic sensitivity (ability to detect disease) and specificity (ability to exclude disease), but is raised in active sarcoidosis. It is useful in monitoring of disease activity.

Mikulicz's syndrome is the enlargement of lacrimal glands and parotid glands, caused by sarcoidosis. Other causes include lymphoma and leukaemia.

Sarcoidosis is chronic multisystem non-caseating granulomatous disease. Central fibrinoid necrosis may occur, but tends to be focal and limited unlike the purulent necrosis/caseation seen in tuberculosis.

[Q: 2711] OnExamination 2012 - Haematology

Which of the following has been shown to increase the risk of prostate cancer?

- 1- Caucasian ethnicity
- 2- Exposure to cadmium

- 3- Family history of colon cancer
- 4- Low intake of animal fats
- 5- Occupational exposure to dust

Answer & Comments

Answer: 2- Exposure to cadmium

Black African and black Caribbean ethnicity is associated with a higher risk of prostate cancer than white.

A family history of breast cancer increases the risk of prostate cancer, as does a family history of prostate cancer.

An occupation in farming also seems to increase the risk of prostate cancer.

High intake of animal fats, and low selenium intake, as well as exposure to radiation and cadmium all increase the risk of prostate cancer.

[Q: 2712] OnExamination 2012 - Haematology

Concerning neurofibromatosis type 1 (NF1), which one of the following statements is true?

- 1- Bilateral acoustic neuromas are common
- 2- Clinical severity in individuals is similar in a given family
- 3- New mutations occur rarely
- 4- Pigmented spots on the iris are a characteristic feature
- 5- The diagnosis is likely if two café au lait patches are present

Answer & Comments

Answer: 4- Pigmented spots on the iris are a characteristic feature

Lisch nodules of the iris are present in more than 90% of patients.

Bilateral acoustic neuromas are a hallmark feature of neurofibromatosis type 2.

Expressivity of the gene is highly variable and members of the same family usually show wide differences in clinical symptoms.

NF1 is one of the most common autosomal dominant conditions. However almost half of all cases give no family history and are new mutations. The mutation rate is estimated to be 1:10,000 gametes.

The diagnosis is suggested by six or more café au lait macules (spots), each over 5 mm in diameter in prepubescent individuals and over 15 mm in post pubertal individuals.

[Q: 2713] OnExamination 2012 - Haematology

A 64-year-old man presents with haematuria.

Cystoscopy discovers a transitional cell carcinoma of the bladder.

Occupational exposure to which of the following is a recognised risk factor for bladder cancer?

- 1- Aflatoxin
- 2- Aniline dye
- 3- Beryllium
- 4- Mercury
- 5- Strongyloides stercoralis

Answer & Comments

Answer: 2- Aniline dye

Risk factors for bladder cancer include

Smoking

Exposure to aniline dyes in the printing and textile industry

Rubber manufacture

Cyclophosphamide

Schistosomiasis.

[Q: 2714] OnExamination 2012 - Haematology

Which of the following statements is most true regarding polycythaemia rubra vera (PRV)?

- 1- PRV is often associated with hypertension and smoking
- 2- PRV is usually associated with a high haemoglobin, but with neutropenia and thrombocytopenia
- 3- PRV may be characterised by a raised packed cell volume (PCV) and decreased plasma volume
- 4- The diagnosis of PRV is based on a high red cell mass, normal oxygen saturations and splenomegaly
- 5- Venesection treatment will improve long term survival rates

Answer & Comments

Answer: 4- The diagnosis of PRV is based on a high red cell mass, normal oxygen saturations and splenomegaly

The diagnosis of PRV is based on a high red cell mass, normal oxygen saturations and splenomegaly.

A decreased plasma volume causing a raised PCV is known as apparent or spurious polycythaemia. This may be associated with hypertension or smoking.

PRV is usually associated with a raised haemoglobin and often with a high platelet count and white cell count.

Venesection will lessen the rates of thrombotic complications but there is no evidence that venesection improves long term survival rates.

[Q: 2715] OnExamination 2012 -
Haematology

A 21-year-old man with non-Hodgkin's lymphoma and haemolytic anaemia is assessed for splenectomy.

When should Pneumovax vaccine be administered?

- 1- One month after surgery
- 2- One month before surgery
- 3- One week after surgery
- 4- One week before surgery
- 5- Perioperatively

Answer & Comments

Answer: 2- One month before surgery

The vaccine should be given a minimum of two weeks before elective splenectomy in order to ensure an optimal antibody response.

In emergency splenectomy the patient should be immunised as soon as possible after recovery from the operation and before discharge from hospital.

Unvaccinated patients splenectomised some time earlier should be vaccinated at the first opportunity.

Vaccination is delayed for at least six months after immunosuppressive chemotherapy or radiotherapy during which time prophylactic antibiotics should be given.

[Q: 2716] OnExamination 2012 -
Haematology

A 62-year-old Caribbean man with new onset type 2 diabetes presents to the Emergency department.

He has increasing lethargy and tiredness since starting a sulphonylurea a few days earlier.

On examination he has jaundiced sclerae, his BP is 135/72 mmHg, and pulse is 95. His mucous membranes look a little pale.

Investigations show:

Haemoglobin 10.2 g/dl (13.5-17.7) (Heinz bodies seen)

White cell count $10.2 \times 10^9/l$ (4-11)

Platelets $198 \times 10^9/l$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Bilirubin 80 $\mu\text{mol/l}$ (<17)

Which of the following is the most likely diagnosis?

- 1- Autoimmune haemolytic anaemia
- 2- Cold agglutinin disease
- 3- Glucose-6-phosphate dehydrogenase deficiency
- 4- Obstructive jaundice
- 5- Paroxysmal nocturnal haemoglobinuria

Answer & Comments

Answer: 3- Glucose-6-phosphate dehydrogenase deficiency

Autoimmune haemolytic anaemia would be associated with a more chronic course, and the close proximity to use of sulphonylurea is much more suggestive of G-6-PD deficiency.

Cold agglutinins are associated with mycoplasma or haematological malignancy.

Obstructive jaundice would not usually be associated with anaemia

Paroxysmal nocturnal haemoglobinuria (PNH) presents with episodes of haemolysis and

Venous thrombosis usually at a younger age.

[Q: 2717] OnExamination 2012 -
Haematology

An elderly lady with breast cancer is starting diamorphine elixir for painful bony metastases.

Which of the following is the most appropriate comment to make to her caregiver?

- 1- A laxative will need to be used
- 2- Dependence on diamorphine is likely and could cause problems
- 3- If pain relief is not adequate cocaine may need to be introduced
- 4- Sedation is likely to be an ongoing problem with diamorphine
- 5- The same dose could be given IM to achieve the same effect.

Answer & Comments

Answer: 1- A laxative will need to be used

A laxative should always be started in conjunction with narcotics to avoid distressing constipation.

Sedation occurring in the first few days typically wears off.

If pain relief is inadequate the dose should be increased; cocaine may produce hallucinations.

Addiction is not an issue in the terminally ill.

IM is three times more effective than the same oral dose.

[Q: 2718] OnExamination 2012 - Haematology

A 31-year-old woman comes to the clinic for review of chronic diarrhoea. She tells you she is opening her bowels some four to five times per day, and has lost 5 kg in weight over the past six months.

There is no blood and the diarrhoea has a strong smell and is difficult to flush away.

On examination her BP is 110/70 mmHg, pulse is 75 and regular, her BMI is 21.

Investigations show:

Haemoglobin 10.8 g/dl(11.5-16.0)

MCV 75 fL(80-96)

White cell count $9.3 \times 10^9/L$ (4-11)

ESR 41 mm/hr(<10)

Platelets $182 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.6 mmol/l (3.5-5)

Creatinine 115 micromol/l (79-118)

Albumin 24g/L(35-50)

Which of the following investigations is likely to be most useful in confirming the diagnosis?

- 1- Anti-endomysial antibodies
- 2- Colonoscopy
- 3- CT abdomen
- 4- Faecal elastase
- 5- Faecal fat estimation

Answer & Comments

Answer: 1- Anti-endomysial antibodies

The age of the patient and symptoms consistent with malabsorption, coupled with low albumin and iron deficiency anaemia fit best with a diagnosis of coeliac disease. As such anti-endomysial antibodies are the most appropriate of the investigations listed to confirm the diagnosis.

Colonoscopy is useful only if lower GI pathology is suspected, and CT abdomen is not very useful to confirm a diagnosis of coeliac.

Faecal elastase is a test for pancreatic insufficiency, and whilst faecal fat estimation will be useful in confirming malabsorption, it will not differentiate between pancreatic pathology and small bowel disease.

[Q: 2719] OnExamination 2012 - Haematology

What is the mechanism of action of hydroxycarbamide in the setting of its use in sickle cell disease?

- 1- Stimulation of the production of fetal haemoglobin
- 2- Decreasing the tendency of HbS to polymerise
- 3- Reducing the permeability of red blood cell membranes
- 4- Increasing the life span of sickle shaped red blood cells
- 5- Causing vasodilation

Answer & Comments

Answer: 1- Stimulation of the production of fetal haemoglobin

Stimulation of the production of fetal haemoglobin is its use in sickle cell anaemia; its usual mode of action is on its reduction of production of deoxyribonucleotides via inhibition of the enzyme ribonucleotide reductase. Hydroxycarbamide works by stimulating the production of fetal haemoglobin which protects against sickling.

In HbS the negative charge is lost and this removes the inhibition to polymerise.

HbS polymers interact with the red blood cell membrane creating temporary pores thus increasing permeability.

HbS has a life span of 30 days compared to the normal 120 days.

Vasodilation is caused by nitric oxide (endothelial derived relaxing factor).

Option A is correct, as this is the correct mechanism of action.

Option B is incorrect as this is the incorrect mechanism of action.

Option C is incorrect as this is the incorrect mechanism of action.

Option D is incorrect as this is the incorrect mechanism of action.

Option E is incorrect as this is the incorrect mechanism of action.

[Q: 2720] OnExamination 2012 - Haematology

Which of the following are features of acute chest syndrome?

- 1- Chest pain
- 2- Shortness of breath
- 3- Fever
- 4- Evidence of new infiltration on CXR
- 5- All of the above

Answer & Comments

Answer: 5- All of the above

Acute chest syndrome is defined as a 'new infiltrate consistent with consolidation at least segmental in size, and one of: chest pain, a temperature > 38.5°C, tachypnoeic, wheezing or cough'.

It is important to remember that not all of the above features will be present at the same time, CXR changes often lag behind. The key is to have a high index of suspicion and monitor vital signs particularly oxygen saturations regularly and anticipate development of possible acute chest syndrome. Early recognition and treatment is life saving.

Option A is correct. Chest pain is often a feature of acute chest syndrome, either from the onset or presents later during the course of disease.

Option B is correct. Shortness of breath is an important feature of acute chest syndrome and one of the main markers of deterioration indicating the need for possible exchange transfusion. All sickle patients should have their oxygen saturations measured regularly on air.

Option C is correct. Fever, usually temperature of greater than 38.5°C is another recognised feature of acute chest syndrome. All patients with temperatures more than 38°C should have cultures sent.

Option D is correct. Although new infiltrates are a characteristic feature of acute chest syndromes, it is important to remember that they can lag behind, and treatment should not be delayed in the absence of CXR changes if all other clinical signs suggest acute chest syndrome.

Option E is correct. This is the best answer as acute chest syndrome is a combination of signs and symptoms, not all of them need to be present for a diagnosis to be made.

[Q: 2721] OnExamination 2012 - Haematology

A pregnant woman attends for her booking antenatal appointment. She lives and is being treated within a high prevalence trust.

How will screening for sickle cell disease be undertaken?

- 1- She will automatically be offered chorionic villus sampling at 8-10 weeks gestation
- 2- It will depend on the family origin of herself and her partner
- 3- She will first be screened for sickle cell carrier status. If that test is positive, her partner will be screened, and only if both are positive will she be offered chorionic villus sampling or amniocentesis
- 4- The screening only detects HbS. It does not detect any other haemoglobinopathies
- 5- Amniocentesis cannot distinguish whether the fetus has sickle cell trait or sickle cell disease

Answer & Comments

Answer: 3- She will first be screened for sickle cell carrier status. If that test is positive, her partner will be screened, and only if both are positive will she be offered chorionic villus sampling or amniocentesis

In low prevalence trusts laboratory screening is only carried out if the baby is identified as being at risk of a haemoglobinopathy based

on the family origin questionnaire and a routine full blood count from the mother.

In high prevalence trusts all women undergo the initial laboratory screening to identify if the mother carries the sickle cell gene. The father is tested for carrier status only if the mother is found to be a carrier. If both are found to be carriers this is confirmed by genetic testing before offering chorionic villus sampling (CVS) (8-10 weeks) or amniocentesis (14-16 weeks).

Option A is incorrect because CVS is only offered if both parents are found to carry the sickle cell gene.

Option B is incorrect because in high prevalence trusts all women undergo laboratory testing for carrier status regardless of family origin. However, the family origin questionnaire still needs to be completed to facilitate diagnosis of the type of haemoglobinopathy.

Option C is correct. First the mother is screened for carrier status, and then the father is screened only if the mother is a carrier. Only if both parents are genetically confirmed as carriers is the mother offered chorionic villus sampling or amniocentesis.

Option D is incorrect. The screening will also detect some other haemoglobinopathies, some of which are clinically significant, some of which have no clinical significance.

Option E is incorrect because amniocentesis allows genetic testing, which can distinguish sickle cell disease from sickle cell trait.

[Q: 2722] OnExamination 2012 - Haematology

A 6-month-old baby is noticed to be pale and listless.

His complete blood count shows haemoglobin of 6 g/dL, and his blood picture shows a hypochromic, microcytic picture. Genetic testing shows the ?0?0 genotype.

Which is the correct answer relating to this haematological disorder?

- 1- Iron chelation is only possible with subcutaneous or intravenous infusion of desferrioxamine
- 2- A transfusion programme with iron chelation is the best initial approach
- 3- Transfusion support should be used sparingly considering the risks of transmission of infections and iron overload
- 4- The parents and other siblings should not be screened by genetic testing
- 5- There is no increased risk of gallstone formation or bone deformities

Answer & Comments

Answer: 2- A transfusion programme with iron chelation is the best initial approach

This question relates to the management of severe beta thalassaemia major.

Beta thalassaemia major is characterised by anaemia, splenomegaly, bone deformities and early death if not treated appropriately (option E is incorrect).

Treatment revolves around lifesaving red cell concentrate support (option C is incorrect), with the inherent development of transfusional iron overload, which can be managed with iron chelation, both intravenous/subcutaneous (desferrioxamine) or oral (deferasirox - option B is correct).

The next of kin should be offered screening (option D is incorrect).

Regular transfusion with attention to iron chelation is the mainstay of treatment, although haemopoietic stem cell transplantation has a possible role with curative intent - hence option B is the correct answer.

[Q: 2723] OnExamination 2012 - Haematology

A 25-year-old gentleman with Burkitt's lymphoma is admitted and commenced on induction chemotherapy.

Within 48 hours it is noticed that his urine output is dropping to 20 mls/hr. Further investigation shows potassium of 6.5 mmol/L, calcium of 1.5 mmol/L, phosphate of 4 mmol/L and creatinine of 250 µmol/L.

Which of the following is the most appropriate management of this complication?

- 1- Allopurinol and intravenous hydration
- 2- Intravenous hydration with 3L/m2 and rasburicase.
- 3- Intravenous hydration with 3 litres per day
- 4- Rasburicase only
- 5- Urinary alkalinisation

Answer & Comments

Answer: 2- Intravenous hydration with 3L/m2 and rasburicase.

This question concerns the management of acute tumour lysis syndrome (ATLS).

Acute tumour lysis syndrome is a common complication of haematological tumours which have a high proliferation index, for example, Burkitt's lymphoma, hyperleukocytic acute myelogenous leukaemia (AML), diffuse large B-cell lymphoma.

Management revolves around institution of aggressive hydration, aiming for 3L/m2 control of electrolyte disturbances (typically, hypocalcaemia, hyperphosphataemia, hyperkalaemia and uraemia) and clearance of the increased metabolic load with rasburicase, a specific recombinant enzyme.

Thus options A, C, D and E should not be selected since they omit important aspects of the holistic management of acute tumour lysis syndrome.

[Q: 2724] OnExamination 2012 -
Haematology

A regular donor reports yellow discoloration of his eyes and fevers five days after a blood donation.

What would be the next most appropriate course of action for the blood bank medical officer?

- 1- APlatelets are safe to be released in this situation
- 2- Release all the blood products from this donor if initial testing is negative
- 3- Recall blood products from this donor and arrange for retesting of this donor
- 4- DSelected blood products such as red cell packs may be released as these have a small volume of plasma
- 5- The donor needs to be struck off the donor register

Answer & Comments

Answer: 3- Recall blood products from this donor and arrange for retesting of this donor

Depending on the complications developed by the donor an assessment must be made on how to manage the donor as well as the blood products from the donation.

In this case, the blood products must be recalled till further testing and clarification of the donor illness (option C).

Release of one or any of the blood products must be prevented (hence not options A, B or D).

The donor need not be struck off the register at this stage till further testing results are available (option E).

[Q: 2725] OnExamination 2012 -
Haematology

Which of the following is the blood product with the highest risk of transmission of a

bacterial infection related to transfusion?

- 1- Cryoprecipitate
- 2- Fresh frozen plasma
- 3- Factor VIII concentrates
- 4- Packed red cells
- 5- Platelets

Answer & Comments

Answer: 5- Platelets

Since platelets are stored at room temperature (22°C), the risk of bacterial contamination is highest in this blood product (option E).

In contrast packed red cells are stored at an average of 4°C (option D) while fresh frozen plasma as well as cryoprecipitate are stored at - 20°C (options B and A).

Factor VIII concentrates are heat inactivated freeze dried products with a minimal risk of bacterial contamination (option C).

[Q: 2726] OnExamination 2012 -
Haematology

A pre-transfusion sample shows that a patient has blood group O.

This means that which of the following statements is correct?

- 1- The red cells have absent A /B antigen and plasma has anti A and anti B antibodies
- 2- The red cells have A /B antigen but no antibodies in the plasma
- 3- The red cells may have any antigen but plasma has anti A and anti B antibodies
- 4- The red cells have antigen A and plasma has antiB antibodies
- 5- The red cells have antigen B and plasma has A antibodies

Answer & Comments

Answer: 1- The red cells have absent A /B antigen and plasma has anti A and anti B antibodies

Option A is blood group O as it has no A or B antigen but has the corresponding antibodies

Option B represents blood group AB while

Options D and E represent groups A and B respectively.

Option C does not represent any blood group.

[Q: 2727] OnExamination 2012 - Haematology

Which of the following is a feature of haemoglobin S?

- 1- Has a higher affinity for oxygen than HbA
- 2- It is more negatively charged than HbA and as a result, less soluble
- 3- Is a result of a point mutation
- 4- It has the effect of shifting the oxygen dissociation curve to the left
- 5- It contains two α -like globins and two β -like globins and two haem molecules

Answer & Comments

Answer: 3- Is a result of a point mutation

HbS has the following properties:

It is less negatively charged than HbA (due to the loss of glutamate)

It polymerises with adjacent HbS

It is less soluble than HbA

It has lower affinity for oxygen (right-shift of the oxygen-dissociation curve), which improves the yield of oxygen to the tissues

It is the result of a point mutation.

Option A is incorrect because the statement is false. HbS has a lower affinity for oxygen,

which increases the risk of desaturation, but improves the yield of oxygen to the tissues.

Option B is incorrect because the statement is false. HbS is less negatively charged, due to the loss of glutamate for valine. The loss of the negative charge and the configuration of HbS makes it less soluble.

Option C is correct because the statement is true. HbS is the result of a point mutation substituting glutamate for valine at position 6.

Option D is incorrect because the statement is false. HbS shifts the oxygen dissociation curve to the right.

Option E is incorrect because the statement is false. It contains two α -like globins and two β -like globins and four haem molecules.

[Q: 2728] OnExamination 2012 - Haematology

Which of the following statements is true about the storage conditions and shelf life of blood products?

- 1- Fresh frozen plasma is stored at -30°C for up to 24 months
- 2- Fresh frozen plasma is stored at -30°C for 12 months
- 3- Packed red cells are stored at 4°C for up to 25 days
- 4- Platelets are stored at 22°C for up to 10 days
- 5- Platelets are stored at 4°C for up to five days

Answer & Comments

Answer: 1- Fresh frozen plasma is stored at -30°C for up to 24 months

Fresh frozen plasma can be stored up to 24 months at -30°C (hence option A is correct).

Red cells are stored at 4°C for up to 35 days and platelets at 22°C for five days on a platelet shaker/agitator (hence not options B, C, D and E).

[Q: 2729] OnExamination 2012 -
Haematology

A 32-year-old woman who has been admitted on two previous occasions with hypertension, agitation and severe abdominal pain is brought to the emergency department by her husband.

She has apparently hardly slept over the past few days, staying up all night working and then most recently drinking substantial amounts of alcohol.

On examination, her behaviour strikes you as hypomanic. She has a BP of 155/91 mmHg, and a pulse of 85. Her abdomen is soft, but is diffusely tender with active bowel sounds.

Investigations

Haemoglobin 12.8 g/dl(11.5-16.5)

White cells $11.3 \times 10^9/L$ (4-11)

Platelets $204 \times 10^9/L$ (150-400)

Sodium 131 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 95 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Acute intermittent porphyria
- 2- Hypothyroidism
- 3- Irritable bowel syndrome
- 4- Manic depressive psychosis
- 5- Stimulant abuse

Answer & Comments

Answer: 1- Acute intermittent porphyria

Acute intermittent porphyria (AIP) should be considered in this type of patient, where there are intermittent symptoms characterised by repeated attacks of abdominal pain where no obvious cause is found.

Other features consistent with the diagnosis include

Agitation

Hypertension

Hyponatraemia

Mild leukocytosis.

A range of psychiatric symptoms, including hypomania and delirium may be seen.

Urinary porphobilinogen assay is the optimal way to establish the diagnosis.

Avoidance of precipitants, including alcohol and the oral contraceptive pill, can dramatically reduce the frequency of attacks.

[Q: 2730] OnExamination 2012 -
Haematology

An 18-year-old male presented with excessive bleeding following a tooth extraction.

His investigations showed:

Platelet count $260 \times 10^9/L$ (150-400)

Prothrombin time 13 s(11.5-15.5)

Activated partial thromboplastin time 86 s (30-40)

Factor VIII 110 IU/dl (50-150)

Deficiency of which of the following clotting factors is the most likely explanation for this patient?

- 1- II
- 2- V
- 3- VII
- 4- IX
- 5- X

Answer & Comments

Answer: 4- IX

An elevated APTT could be due to:

- * Treatment with heparin
- * Haemophilia

- * von Willebrand's disease
- * Antiphospholipid syndrome.

A normal factor VIII would suggest haemophilia B where there is lack of factor IX.

A prolonged APTT can be seen in von Willebrand's disease, but factor VIII activity would be low.

The presentation is not consistent with antiphospholipid syndrome and would also, typically, be associated with thrombocytopenia.

[Q: 2731] OnExamination 2012 - Haematology

A 17-year-old girl with mild von Willebrand's disease is scheduled for dental extraction. A previous dental extraction resulted in bleeding that had required two unit transfusion.

What is the most appropriate treatment prior to dental surgery?

- 1- Cryoprecipitate
- 2- DDAVP
- 3- Fresh frozen plasma
- 4- High purity factor VIII concentrate
- 5- Recombinant factor VIII concentrate

Answer & Comments

Answer: 2- DDAVP

DDAVP is the choice treatment for mild von Willebrand disease, which would include type I, and the majority of type II; although there is some controversy in type II B as it is thought that DDAVP can exacerbate thrombocytopenia that can accompany this type of von Willebrand's.

It is of no use in type III - severe von Willebrand's disease. The history tells us that she has mild disease.

You would not use cryoprecipitate or fresh frozen plasma in these patients in this era, due

to potential viral transmission risk from blood products.

For severe disease you would use a Von Willebrand factor concentrate, not factor VIII concentrate.

[Q: 2732] OnExamination 2012 - Haematology

Which of the following statements regarding thrombocytosis is correct?

- 1- Erythropoietin is the key hormone in the regulation of megakaryocyte differentiation
- 2- May occur as a response to exercise
- 3- Occurs exclusively in essential thrombocythaemia
- 4- Secondary thrombocytosis is an indication for hydroxycarbamide therapy
- 5- The most common cause is essential thrombocythaemia

Answer & Comments

Answer: 2- May occur as a response to exercise

The most common cause of thrombocytosis is a reactive thrombocytosis.

Thrombocythaemia may occur in any of the myeloproliferative disorders, particularly polycythaemia rubra vera (PRV).

Thrombopoietin is the key hormone in the regulation of megakaryocyte differentiation.

Secondary thrombocytosis does not place the patient at risk for haemostatic or cardiovascular events.

[Q: 2733] OnExamination 2012 - Haematology

A 60-year-old Chinese man has been started by his general practitioner on quinine for leg cramps.

He presents, a week later, with five days of darkened urine and two days of increasing breathlessness, back pain and fatigue.

Investigations show a haemoglobin of 7.0 g/dL (13.0-18.0) and raised reticulocyte count.

Which of the following best explain this drug reaction?

- 1- Autoimmune haemolytic anaemia
- 2- Glucose-6-phosphate dehydrogenase deficiency
- 3- Hereditary spherocytosis
- 4- Pyruvate kinase deficiency
- 5- Sickle cell disease

Answer & Comments

Answer: 2- Glucose-6-phosphate dehydrogenase deficiency

G6PDH (X linked recessive) is seen in African, Mediterranean, Iraqi, Jew, South East Asian and Chinese people and predisposes to a haemolytic anaemia reaction with drugs or infection.

Implicated drugs include

Aspirin

Sulphonamides

Antimalarials

Quinine/quinidine.

The haemolytic anaemia is non-immune (direct antiglobulin test [DAT] negative).

Pyruvate kinase deficiency is autosomal recessive and presents as a chronic haemolytic anaemia exacerbated by viral infections.

Hereditary spherocytosis is characterised by variable chronic non-immune haemolysis exacerbated by infections.

Further Reading G6PD.org

[Q: 2734] OnExamination 2012 - Haematology

A 70-year-old woman is on multiple medications for various conditions and she is found to have a macrocytic anaemia with a low serum B12.

Which of the following medications is a possible cause of the B12 deficiency?

- 1- Amiodarone
- 2- Ezetimibe
- 3- Metformin
- 4- Nicotinic acid
- 5- Sodium valproate

Answer & Comments

Answer: 3- Metformin

Metformin can lead to reduced B12 absorption but this is not usually a clinical problem.

"The clinician must be aware of the possibility of metformin-associated B12 deficiency in users who suffer cognitive impairment, peripheral neuropathy, subacute combined degeneration of the cord or anaemia." Age Ageing. 2006 Mar;35(2):200-1

[Q: 2735] OnExamination 2012 - Haematology

Which of the following conditions would be expected to be associated with a raised leukocyte alkaline phosphatase (LAP) score?

- 1- Chronic myeloid leukaemia
- 2- Infectious mononucleosis
- 3- Myelofibrosis
- 4- Pernicious anaemia
- 5- Thrombocytopenic purpura

Answer & Comments

Answer: 3- Myelofibrosis

The LAP score aids in the differential diagnosis of chronic myelocytic leukaemia (CML) versus leukaemoid reaction.

It also aids in the evaluation of:

Polycythaemia vera

Myelofibrosis with myeloid metaplasia, and

Paroxysmal nocturnal haemoglobinuria.

Low scores have been associated with:

CML

Paroxysmal nocturnal haemoglobinuria (PNH)

Thrombocytopenic purpura, and

Hereditary hypophosphatasia.

High scores have been seen in:

Polycythaemia vera

Myelofibrosis

Aplastic anaemia

Downs syndrome

Hairy cell leukaemia

Leukaemoid reactions and

Neutrophilia either physiological or secondary to infection.

It is also increased in Hodgkin disease. Read more

[Q: 2736] OnExamination 2012 - Haematology

A 45-year-old lady is found to have thymoma.

Which one of the following conditions is associated with thymoma?

- 1- Acute lymphocytic leukaemia
- 2- Acute myeloid leukaemia
- 3- Myelofibrosis
- 4- Pure red cell aplasia
- 5- Thrombocythaemia

Answer & Comments

Answer: 4- Pure red cell aplasia

"Originally, thymoma was cited as the primary cause of acquired pure red cell aplasia. However, subsequent studies revealed that thymomas caused only 2 of 37 cases of pure red cell aplasia. Conversely, only 7% of patients with thymomas had pure red cell aplasia. T-cell mediated erythroid rejection is considered the mechanism for the production of pure red cell aplasia in patients with thymomas. This is supported by evidence that a subgroup of T cells in B-cell chronic lymphocytic leukemia is responsible for pure red cell aplasia." eMedicine: Pure Red Cell Aplasia

[Q: 2737] OnExamination 2012 - Haematology

A 56-year-old man is found to have a macrocytic anaemia with a megaloblastic bone marrow.

Which of the following causes of macrocytosis is the most likely cause here?

- 1- Alcohol
- 2- Aplastic anaemia
- 3- Folate deficiency
- 4- Myelodysplasia
- 5- Reticulocytosis

Answer & Comments

Answer: 3- Folate deficiency

A megaloblastic bone marrow occurs in Vitamin B₁₂ or folate deficiency and with some cytotoxic drugs.

The other causes of macrocytosis do not cause a megaloblastic bone marrow appearance.

[Q: 2738] OnExamination 2012 -
Haematology

A 55-year-old gentleman presents to his GP with a six month history of lethargy and left upper quadrant abdominal discomfort.

A blood count shows a white cell count of $350 \times 10^9/L$, haemoglobin of 10.5 g/dL and a platelet count of $223 \times 10^9/L$. A bone marrow aspirate shows increased granulocytic precursors and less than 5% blasts. Molecular studies show the patient to be BCR-ABL transcript positive.

Which of the following is the most appropriate therapy?

- 1- Chemotherapy
- 2- Haemopoietic stem cell transplant
- 3- Hydroxycarbamide
- 4- Interferon
- 5- Treatment with tyrosine kinase inhibitor, for example, imatinib

Answer & Comments

Answer: 5- Treatment with tyrosine kinase inhibitor, for example, imatinib

The above presentation and laboratory findings are typical for chronic phase chronic myelogenous leukaemia (CML).

Option A (chemotherapy) is incorrect because chemotherapy is only used in the blast crisis phase of CML.

Options C and D are now outdated treatments for CML.

Option B (stem cell transplant) is not performed first in patients with CML since the advent of specifically targeted therapy for the BCR-ABL transcript positive leukaemias, that is, tyrosine kinase inhibitors, which are now the gold standard therapy for CML.

Hence option E is the correct answer.

[Q: 2739] OnExamination 2012 -
Haematology

A 25-year-old man presents with an enlarged inguinal lymph node with night sweats. The most likely clinical diagnosis is Hodgkin's lymphoma.

An excision biopsy of the lymph node is performed.

Which one of the following findings on histopathology is associated with the best prognosis in Hodgkin's disease?

- 1- Lymphocyte depleted
- 2- Lymphocyte predominant
- 3- Mixed cellularity
- 4- Nodular sclerosing
- 5- Reed-Sternberg cells

Answer & Comments

Answer: 2- Lymphocyte predominant

Hodgkin's disease is characterised by Reed-Sternberg cells and this is, therefore, not a prognostic feature.

Nodular sclerosing is the most common finding and has a good prognosis.

Mixed cellularity also has good prognosis.

Lymphocyte depleted has the worst prognosis.

The best prognosis is lymphocyte predominant.

[Q: 2740] OnExamination 2012 -
Haematology

A 16-year-old boy presents with a haemarthrosis that developed in his left knee following an injury in the garden.

His investigations show:

Platelet count $260 \times 10^9/L$ (150-400)

Prothrombin time 13 s(11.5-15.5)

Activated partial thromboplastin time 80 s(30-40)

Factor VIII 110 IU/dl(50-150)

Which of the following is the most likely diagnosis?

- 1- Antiphospholipid syndrome
- 2- Antithrombin III deficiency
- 3- Haemophilia A
- 4- Haemophilia B
- 5- von Willebrand's disease

Answer & Comments

Answer: 4- Haemophilia B

An elevated activated partial thromboplastin time (APTT) could be due to

Treatment with heparin

Haemophilia

von Willebrand's disease

Antiphospholipid syndrome.

A normal factor VIII would suggest haemophilia B where there is lack of factor IX.

A prolonged APTT can be seen in von Willebrand's disease but factor VIII activity would be low.

The presentation is not consistent with antiphospholipid syndrome which is associated with thrombosis rather than haemorrhage. Antithrombin III deficiency is also associated with thrombosis, and is most commonly acquired in the setting of nephrotic syndrome.

[Q: 2741] OnExamination 2012 - Haematology

Which of the following is the mechanism of action of warfarin?

- 1- Activation of gamma-glutamyl carboxylase
- 2- Chelation of calcium
- 3- Inhibition of activated factor X

4- Inhibition of vitamin K-dependent carboxylase

5- Inhibition of vitamin K epoxide reductase

Answer & Comments

Answer: 5- Inhibition of vitamin K epoxide reductase

The vitamin K epoxide is in turn recycled back to vitamin K and vitamin K hydroquinone by another enzyme, the vitamin K epoxide reductase (VKOR).

Warfarin inhibits epoxide reductase (specifically the VKORC1 subunit), thereby diminishing available vitamin K and vitamin K hydroquinone in the tissues which inhibits the carboxylation activity of the glutamyl carboxylase.

When this occurs, the coagulation factors are no longer carboxylated at certain glutamic acid residues, and are incapable of binding to the endothelial surface of blood vessels, and are thus biologically inactive.

More information

[Q: 2742] OnExamination 2012 - Haematology

A 78-year-old female who is on warfarin for atrial fibrillation presents with melaena.

Her blood pressure is 90/60 mmHg and heart rate is 100 bpm.

Investigations show:

Haemoglobin 9 g/l (12-16)

MCV 87 fl(83-95)

INR 7.2(<1.4)

A PR examination confirms melaena.

Which is the best option for correcting the coagulopathy?

- 1- FFP
- 2- IV vitamin K
- 3- Stop warfarin

4- Stop warfarin and give IV vitamin K

5- Stop warfarin and give IV vitamin K and prothrombin complex concentrate

Answer & Comments

Answer: 5- Stop warfarin and give IV vitamin K and prothrombin complex concentrate

This patient is hypotensive and tachycardic with melaena suggesting a major bleeding episode on warfarin.

In these circumstances current guidelines suggest stopping warfarin, giving IV vitamin K, and either fresh frozen plasma (FFP) or prothrombin complex concentrate.

Local guidelines will be available and if in doubt consult with the haematologist on call. FFP may not completely reverse the effects of warfarin so it may now be preferable to consider prothrombin complex concentrate (PCC) if available.

The rate of fatal haemorrhage in patients receiving warfarin approaches 1%. It is therefore essential that knowledge regarding the reversal of warfarin coagulation is serviceable.

[Q: 2743] OnExamination 2012 - Haematology

A 12-year-old boy was diagnosed with haemophilia A.

His uncle on his mother's side also has the same condition although his mother is well. The parents of the boy are worried about their next child suffering with the same condition.

What is the chance of the next child having the disease?

1- 0%

2- 25%

3- 50%

4- 75%

5- 100%

Answer & Comments

Answer: 2- 25%

Haemophilia is an X linked recessive disease.

The mother is the carrier of the disease.

There will be 50% chance of her sons having the disease and there is a 50% chance of her daughters being carriers.

The sex of the next child it is not mentioned in this question. The overall chance of the next child having the disease will be 25% and phenotypically normal child will be 75%.

[Q: 2744] OnExamination 2012 - Haematology

A patient with AML develops jaundice and spiking pyrexia three weeks into induction chemotherapy.

The patient remained pyrexial after seven days of intravenous antibiotics.

What is the likely diagnosis?

1- CMV

2- Fungal infection

3- Hepatic leukaemic deposits

4- Miliary TB

5- Toxoplasmosis

Answer & Comments

Answer: 1- CMV

The most likely cause for the persisting pyrexia plus hepatitis in this immunocompromised patient treated with appropriate antibiotics would be a Cytomegalovirus (CMV) infection.

Fungal infection would not be expected to cause the jaundice but again may be responsible for the pyrexia.

TB would be most unlikely and hepatic infiltration would not be expected to produce this pyrexia.

[Q: 2745] OnExamination 2012 -
Haematology

A 16-year-old girl presents with bilateral cervical lymphadenopathy. Her lymph node biopsy reveals a nodular sclerosing Hodgkin's disease.

Which one of the following features indicates a poorer prognosis?

- 1- Fatigue
- 2- Mediastinal mass of 3 cm
- 3- Night sweats
- 4- Pruritis
- 5- Recent Epstein-Barr virus infection

Answer & Comments

Answer: 3- Night sweats

Important prognostic features in Hodgkin's disease (HD) are stage B symptoms:

Fever

Night sweats

Weight loss.

A mass of > 10 cm in size is also a poor prognostic factor.

Therefore although fatigue and pruritus are common, they have no prognostic significance.

EBV infection commonly is associated with HD but has no prognostic significance.

[Q: 2746] OnExamination 2012 -
Haematology

A 40-year-old man presents with bleeding gums and ease of bruising. His only medication is omeprazole for dyspepsia.

Investigations show:

Haemoglobin 12.5 g/dL (13.0-18.0)

MCV 90 fL (80-96)

Platelets $20 \times 10^9/L$ (150-400 $\times 10^9$)

Prothrombin time 13.5s (11.5-15.5)

Blood film: occasional giant platelets

What is the most likely diagnosis?

- 1- Amegakaryocytic thrombocytopenia
- 2- Disseminated intravascular coagulation
- 3- Drug-induced thrombocytopenia
- 4- Immune thrombocytopenia
- 5- Thrombotic thrombocytopenic purpura

Answer & Comments

Answer: 4- Immune thrombocytopenia

The only abnormality is the very low platelet count.

The bone marrow is still working as there are giant platelets seen on film, which you see when there is peripheral consumption of the platelets.

The large platelets are a sign that the bone marrow is churning them out prematurely to keep up with demand.

With disseminated intravascular coagulation the prothrombin time would be prolonged.

With thrombotic thrombocytopenic purpura the haemoglobin would be low- as haemolysis is a feature.

Drug-induced thrombocytopenia in itself is an immune mechanism, and while lansoprazole can cause a reduction in platelet count, it is not classically a drug you associate with drug induced thrombocytopenia.

Immune thrombocytopenia is very common and would give this very low platelet count, and by choosing this answer it covers drug induced thrombocytopenia as well.

[Q: 2747] OnExamination 2012 -
Haematology

A 75-year-old woman receives two units of packed red cells following a hip replacement.

One week later her haemoglobin concentration had fallen by 4 g/l.

Which one of the following would be most likely to indicate a delayed transfusion reaction?

- 1- Conjugated hyperbilirubinaemia
- 2- Elevated D dimer concentration
- 3- Haemoglobinuria
- 4- Haemosiderinuria
- 5- Positive direct antiglobulin test

Answer & Comments

Answer: 5- Positive direct antiglobulin test

The features suggest immune haemolysis with direct antiglobulin test (DAT) being diagnostic.

A. Is inappropriate as it is unconjugated bilirubin that is raised in haemolysis.

B, C and D. Are not going to be diagnostic of an immune haemolytic transfusion reaction.

[Q: 2748] OnExamination 2012 - Haematology

Which of the following statements regarding disseminated intravascular coagulation (DIC) is most correct?

- 1- DIC is associated with a rising platelet count
- 2- DIC is associated with an elevated D-dimer
- 3- DIC is associated with rising fibrinogen levels
- 4- Normal clotting parameters effectively exclude a diagnosis of DIC
- 5- Removal of the underlying cause of the DIC will lead to resolution of the manifestations of DIC

Answer & Comments

Answer: 2- DIC is associated with an elevated D-dimer

DIC is caused by the enhanced and abnormally sustained generation of thrombin, and is associated with elevated products of fibrin breakdown, one of these being D-dimer.

Treatment of the underlying cause, for example, sepsis, does not always lead to resolution of the condition, and recombinant human activated protein C has been shown to be effective in reducing mortality from DIC in patients with sepsis.

DIC is associated with a falling platelet count and decreased fibrinogen, but the clotting factors may be normal, especially when one considers that the acute phase response may shorten the activated partial thromboplastin time (APTT) and increase fibrinogen.

For an excellent review see BMJ 2003;327:974-7.

[Q: 2749] OnExamination 2012 - Haematology

A 45-year-old woman being treated for acute myeloid leukaemia fails to get sufficient rises with platelet transfusions.

She is 14 days post chemotherapy, afebrile and apart from minor bruising is otherwise well.

Which of the following would be the next best step in the management of platelet refractoriness?

- 1- Avoid further platelet transfusions
- 2- Continue to monitor for platelet rises with random platelets
- 3- Check for a one hour post platelet transfusion platelet count
- 4- Prescribe HLA matched platelets
- 5- Request directed platelet donations

Answer & Comments

Answer: 3- Check for a one hour post platelet transfusion platelet count

Patients who are refractory to platelet transfusions should first be investigated to check for adequate platelet rises - best done on a one or two hour post platelet transfusion sample (option C).

Further management would include checking for HLA antibodies but requesting HLA matched platelets at this stage would not be appropriate (hence not option D).

Continuing random platelet transfusions or requesting a directed platelet donation are also not appropriate at this stage (options B and E).

Platelets are obviously indicated in this patient until recovery of blood counts and hence cannot be avoided (option A).

[Q: 2750] OnExamination 2012 - Haematology

A 42-year-old man presented with tiredness, breathlessness and nose bleeds for three weeks. On examination there were several bruises on his arms and legs, 2 cm splenomegaly and fundal haemorrhages.

Investigations revealed:

Haemoglobin 7.2 g/dl (13.0-18.0)

White cell count $13.8 \times 10^9/L$ (4-11)

Platelet count $24 \times 10^9/L$ (150-400)

Blood film White cells predominantly myeloblasts and promyelocytes

Which one of the following investigations would be of most prognostic value?

- 1- Bone marrow trephine biopsy
- 2- Cerebrospinal fluid examination
- 3- Cytochemistry
- 4- Cytogenic karyotype
- 5- Immunophenotyping

Answer & Comments

Answer: 4- Cytogenic karyotype

Cytogenetic evaluation of malignant haematological cells may have important implications for the prognosis and treatment options in acute myelogenous leukaemia (AML).

For example t(8;21) confers a good prognosis in adult AML, and about 70% of patients in this low-risk group can be cured with intensive chemotherapy alone, radiotherapy being reserved for patients who relapse.

[Q: 2751] OnExamination 2012 - Haematology

A 60-year-old male presents with bruising and tiredness.

Examination reveals four finger breadth splenomegaly and his results reveal:

Haemoglobin 11 g/dL (13.0-18.0)

White cell count $100 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $900 \times 10^9/L$ (150-400 $\times 10^9$)

Blood film reveals a neutrophilia, basophilia, numerous myelocytes and 4% myeloblasts.

Which of the following is likely to be present in this patient?

- 1- BCR-ABL gene fusion only
- 2- Deletion 11q13
- 3- Deletion chromosome 13
- 4- Normal chromosomal analysis
- 5- Translocation 9;22

Answer & Comments

Answer: 5- Translocation 9;22

The Philadelphia chromosome (translocation 9;22) is present in approximately 90% of subjects with chronic myelocytic leukaemia (CML).

The molecular consequences of this translocation is the generation of the fusion bcr-abl gene which creates an abnormal protein stimulating white cell growth. Only 5%

of cases have the bcr-abl fusion gene only without the typical Philadelphia chromosome.

Deletion of Ch13 is associated with a poorer prognosis in multiple myeloma.

[Q: 2752] OnExamination 2012 - Haematology

Whilst being investigated for infertility, a 30-year-old woman is noted to have some bruising on her limbs with a palpable spleen on abdominal examination.

Investigations reveal:

Haemoglobin 10.0 g/dL (11.5-16.5)

White cell count $110 \times 10^9/L$ (4-11 $\times 10^9$)

Neutrophils $60 \times 10^9/L$ (1.5-7 $\times 10^9$)

Lymphocytes $2 \times 10^9/L$ (1.5-4 $\times 10^9$)

Monocytes $0.8 \times 10^9/L$ (0-0.8 $\times 10^9$)

Eosinophils $0.3 \times 10^9/L$ (0.04-0.4 $\times 10^9$)

Basophils $0.7 \times 10^9/L$ (0-0.1 $\times 10^9$)

Myelocytes $40 \times 10^9/L$

Myeloblasts $4 \times 10^9/L$

Platelet count $900 \times 10^9/L$ (150-400 $\times 10^9$)

What is the most likely diagnosis?

- 1- Acute myeloid leukaemia
- 2- Acute promyelocytic leukaemia
- 3- Chronic myeloid leukaemia
- 4- Essential thrombocythaemia
- 5- Myelofibrosis

Answer & Comments

Answer: 3- Chronic myeloid leukaemia

The features of this blood film are anaemia, thrombocytosis, neutrophilia with roughly 55% neutrophils, 40% myelocytes with less than 5% blast cells.

This is typical of chronic myeloid leukaemia which usually has associated tender

splenomegaly. Usually the Philadelphia chromosome is present in 95% of cases.

Acute leukaemia is defined as blast cells constituting over 30% of cell type present.

Chronic myeloid leukaemia often ends in acute blastic transformation after a mean duration of approximately four years.

[Q: 2753] OnExamination 2012 - Haematology

An 80-year-old woman has a three month history of progressive numbness and unsteadiness of her gait.

On examination, there is a mild spastic paraparesis, with brisk knee reflexes, ankle reflexes are present with reinforcement, extensor plantars, sensory loss in the legs with a sensory level at T10, impaired joint position sense in the toes, and loss of vibration sense below the iliac crests.

Investigations were as follows:

Haemoglobin 12.2 g/dL (12-16)

MCV 95 fL (80-96)

What is the most likely diagnosis?

- 1- Anterior spinal artery occlusion
- 2- Dorsal meningioma
- 3- Multiple sclerosis
- 4- Subacute combined degeneration of the cord
- 5- Tabes dorsalis

Answer & Comments

Answer: 2- Dorsal meningioma

The presence of a sensory loss at T10 indicates a thoracic myelopathy.

Subacute combined degeneration of the cord is unlikely as the haemoglobin concentration and mean corpuscular volume (MCV) are normal.

Anterior spinal artery occlusion is unlikely as the history is progressive and chronic.

[Q: 2754] OnExamination 2012 - Haematology

Which of the following is a feature of hereditary haemorrhagic telangiectasia?

- 1- A good response to oestrogen therapy
- 2- Cerebral arteriovenous malformations
- 3- GI haemorrhage is the usual presenting feature
- 4- Telangiectasia of the mucous membranes, but not the skin
- 5- Tendency of lesions to become less obvious with age

Answer & Comments

Answer: 2- Cerebral arteriovenous malformations

Hereditary haemorrhagic telangiectasia (HHT) is a multisystem vascular dysplasia characterised by the presence of multiple arteriovenous malformations (AVMs) that lack intervening capillaries and result in direct connections between arteries and veins. Small AVMs, called telangiectases, close to the surface of skin and mucous membranes often rupture and bleed. It is inherited as an autosomal dominant trait.

The most common clinical manifestations of HHT are spontaneous and recurrent epistaxis and multiple telangiectases, which commonly appear on the lips, face, tongue or hands in adulthood. A minority of individuals with HHT have symptomatic gastrointestinal (GI) bleeding, which most commonly begins after age 50 years. Large AVMs often cause symptoms when they occur in the brain or lung; complications from bleeding or shunting may be sudden and catastrophic. It is estimated at least 30% of HHT patients have pulmonary involvement, 30% hepatic

involvement and 10-20% cerebral involvement.

The manifestations of HHT generally develop with age, and are usually not present at birth. Epistaxis is usually the earliest sign of disease, often occurring in childhood. Pulmonary AVMs can become apparent from puberty. By the age of 16 years 71% of patients will have developed signs of HHT, rising to over 90% by 40 years.

The Curacao criteria can be used to aid diagnosis:

The diagnosis is:

- Definite if three criteria are present.
- 'Possible' or 'suspected' if two criteria are present
- 'Unlikely' if fewer than two criteria are present

Criteria:

- Epistaxis: spontaneous, recurrent nose bleeds
- Telangiectases: multiple, characteristic sites (lips, oral cavity, fingers, nose)
- Visceral lesions, such as gastrointestinal telangiectasia, pulmonary AVM, hepatic AVM, cerebral AVM, spinal AVM
- Family history of a first degree relative with HHT

Cerebral involvement can be in the form of telangiectasias, cerebral AVMs, aneurysms or cavernous angiomas. Cerebral AVMs are thought to affect 10% of patients, and can result in headaches, seizures, surrounding ischaemia (steal) or haemorrhage. These lead to significant mortality and morbidity.

Management of epistaxis and gastrointestinal haemorrhage should be symptomatic initially. Whilst it is generally regarded that pulmonary AVMs should be screened for (and treated with prophylactic antibiotics and

embolisation), screening for cerebral and hepatic AVMs remains controversial and is not currently offered in the UK. Oestrogen therapy is sometimes advocated but their efficacy is unclear. They may be beneficial in heavily transfusion dependent patients.

[Q: 2755] OnExamination 2012 -
Haematology

An 18-year-old Asian female is noted by her dentist to have gingival hypertrophy.

Which of the following is most likely to be responsible for her presentation?

- 1- Carbamazepine
- 2- Lead poisoning
- 3- Phenytoin
- 4- Scurvy
- 5- Sodium valproate

Answer & Comments

Answer: 3- Phenytoin

The inclusion of 'Asian' descent in this question is intended as a distractor.

Gum hypertrophy may be seen in conditions such as acute myeloid leukaemias and with drugs such as phenytoin.

Scurvy (vitamin C deficiency) is associated with bleeding gums.

Lead toxicity is associated with pigmentation of the gingiva.

Carbamazepine is not associated with gingival hyperplasia but recognised side effects include ataxia, drowsiness and blood dyscrasias.

[Q: 2756] OnExamination 2012 -
Haematology

A 68-year-old woman was admitted to hospital with severe acute dyspnoea. She denied having any chest pain but said that she

had become progressively breathless over the past three months.

On examination her pulse was 120 beats per minute and regular. Her blood pressure was 95/55 mmHg and her jugular venous pressure was elevated to the angle of the jaw. Her heart sounds were normal. Auscultation of her chest revealed bilateral fine inspiratory crackles to the mid zones. She had haemorrhages in both fundi.

Investigations revealed:

Haemoglobin 5.6 g/dL(11.5-16.5)

Haematocrit 0.19(0.36-0.47)

MCV 118 fL(80-96)

MCH 33.0 pg(28-32)

White cell count $3.4 \times 10^9/L$ (4-11)

Platelets $95 \times 10^9/L$ (150-400)

Serum Vitamin B₁₂ Result pending

Serum folate Result pending

The electrocardiogram (ECG) showed left bundle branch block, which had been documented previously.

She is given 80 mg of intravenous furosemide which results in an excellent diuresis.

What is the next most appropriate immediate step in her management?

- 1- Blood transfusion
- 2- Bone marrow aspiration
- 3- Start intramuscular Vitamin B₁₂ and oral folic acid
- 4- Start oral ferrous sulphate
- 5- Thrombolyse with t-PA

Answer & Comments

Answer: 1- Blood transfusion

The clinical picture represents severe megaloblastic anaemia with cardiac failure.

The questions asks about immediate management. Although the anaemia has been

developing slowly, she has become acutely haemodynamically compromised. In such circumstances it would be most appropriate to transfuse the patient. This would need to be done very cautiously with diuretic cover.

She will clearly need to start an intensive course of intramuscular Vitamin B₁₂ and oral folic acid as well, but this is less important in the hyperacute situation where there is a risk of the patient dying from anaemia.

Giving oral folic acid without Vitamin B₁₂ would be hazardous and could precipitate subacute combined degeneration of the spinal cord. Transfusion may also be hazardous in a patient with severe cardiac congestive failure (CCF).

[Q: 2757] OnExamination 2012 - Haematology

Heinz bodies in red blood cells in haemolytic anaemia are present in which of the following?

- 1- Clostridium welchii septicaemia
- 2- Cold agglutinin disease
- 3- Glucose 6 phosphate dehydrogenase deficiency
- 4- Paroxysmal nocturnal haemoglobinuria
- 5- Post splenectomy

Answer & Comments

Answer: 3- Glucose 6 phosphate dehydrogenase deficiency

Heinz bodies are oxidised denatured Hb.

Post splenectomy causes:

Target cells

Pappenheimer bodies (siderotic granules) and

Howell-Jolly bodies (DNA remnants).

[Q: 2758] OnExamination 2012 - Haematology

A 20-year-old Caucasian student returns from Ghana with a spiking temperature and nocturnal sweats. She has 0.5% of red blood cells infected with Plasmodium falciparum.

Select one of the following answers relating to quinine therapy in this case.

- 1- Glucose levels should be monitored in those being treated with quinine
- 2- Pregnancy is a contraindication for quinine
- 3- Quinine is contraindicated in those taking mefloquine prophylactically
- 4- Quinine must always be given parenterally initially
- 5- The dose of quinine should be reduced in liver impairment

Answer & Comments

Answer: 1- Glucose levels should be monitored in those being treated with quinine

Severe malaria is indicated by more than 1% of RBC infected.

Hypoglycaemia is an important side effect of quinine therapy and should be monitored in those having intravenous quinine.

Intravenous infusion of quinine is reserved for severe or cerebral malaria (most deaths from M. falciparum occur in first 96 hours of starting treatment).

The initial dose should not be reduced in those severely ill with renal/hepatic impairment.

High doses of quinine in pregnancy are teratogenic in the first trimester. However in malaria, the benefit of treatment outweighs the risk. Current WHO Guidelines (2006) recommend artemisinins are first line in the second and third trimester. In the first trimester, both artesunate and quinine are considered treatment options. In severe

malaria, any available treatment should be started without delay as both the mother and foetus' life are in danger.

[Q: 2759] OnExamination 2012 - Haematology

A 56-year-old female presents at the general practitioner with weakness.

A full blood count (FBC) reveals a haemoglobin concentration of 10.5 g/dL (11.5-16.5) and a mean cell volume (MCV) of 104 fL (80-96), but no other abnormality.

Which of the following may account for this?

- 1- Hormone replacement therapy (HRT)
- 2- Scurvy
- 3- Thyrotoxicosis
- 4- Ulcerative colitis
- 5- Zollinger-Ellison syndrome

Answer & Comments

Answer: 2- Scurvy

This is a tricky question. However, if you bear in mind this patient's symptoms and her FBC you should come to the correct conclusion.

She has weakness and in association with a mild anaemia and her increased MCV a vitamin C deficiency is most probable. Anaemia of this level should not cause weakness in itself.

Scurvy should not be thought of as a disease of the past, as cases continue to be diagnosed in children and adults. Clinical manifestations vary, and can be seen within 8-12 weeks of irregular or inadequate dietary intake. The early stages are characterised by malaise, fatigue and lethargy. Continued deficiency leads to anaemia, myalgia, bone pain, bruising, petechial and perifollicular haemorrhages, corkscrew hairs, gum disease, poor wound healing and mood changes. Late stages can lead to generalised oedema, severe jaundice, haemolysis, haemorrhage,

neuropathy, convulsions and death. Treatment for scurvy is vitamin C supplementation, and recovery is usually complete within three months.

HRT can affect folate storage and absorption, but not usually to an extent to cause these biochemical changes. is more likely to be associated with iron (Fe) deficiency anaemia as is Zollinger-Ellison syndrome and ulcerative colitis are both associated with iron-deficiency anaemia, and therefore a microcytosis.

Hypothyroidism, not thyrotoxicosis, is associated with macrocytosis.

[Q: 2760] OnExamination 2012 - Haematology

A mild lymphocytosis of $15 \times 10^9/L$ with a few smear cells is reported on a full blood count result in a 70-year-old asymptomatic man attending clinic for an annual review.

Which of the following would be the most essential investigation to establish a diagnosis of chronic lymphocytic leukaemia (CLL)?

- 1- CT scan of chest abdomen and pelvis
- 2- Lactic dehydrogenase (LDH) levels
- 3- Presence of smear cells on the blood film
- 4- Presence of palpable cervical lymphadenopathy
- 5- Peripheral blood flow cytometry

Answer & Comments

Answer: 5- Peripheral blood flow cytometry

Flow cytometry (option E) showing a specific pattern of monoclonal B cell proliferation (CD19/5 coexpressing, CD23 positive, light chain restricted B cell population) is diagnostic of CLL.

CT scan (option A) and LDH (option B) are investigations needed to complete staging but not essential for diagnosis.

Smear cells (option C) are reported in other lymphoproliferative as well as benign lymphocytosis and merely indicate fragile lymphocytes which are artefactually smeared on the glass slide.

Cervical lymphadenopathy (option D) may be seen in CLL but can also be seen in any other cause of lymphadenopathy (for example, viral infections, adenopathy secondary to local dental infection).

[Q: 2761] OnExamination 2012 - Haematology

A 19-year-old woman presents for the third time in the past eight months with acute abdominal pain and severe agitation. On the two previous occasions she was admitted by the surgeons and discharged without significant intervention.

She has started the oral contraceptive pill within the last year. According to her mother the local GP has considered medicating her because of increasing anxiety.

On examination her BP is 155/82 mmHg, pulse is 90 and regular, BMI 22. Her abdomen is generally tender although there are active bowel sounds.

Investigations show:

Haemoglobin 12.0 g/dl(11.5-16.0)

White cell count $9.3 \times 10^9/L$ (4-11)

Platelets $182 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 92 micromol/l (79-118)

You give her opiates for pain.

Which of the following is the most important additional therapy during this acute attack?

- 1- IV cefuroxime and metronidazole
- 2- IV glucose
- 3- Oral chlorpromazine
- 4- Oral diazepam

5- Oral propranolol

Answer & Comments

Answer: 2- IV glucose

The history of three recent attacks of acute anxiety and abdominal pain coupled with starting the oral contraceptive pill, raises the possibility of acute intermittent porphyria. Use of IV or oral glucose during an attack can lead to more rapid resolution of symptoms, as such that would be the favoured approach here. The pill should of course be withdrawn if possible.

There is no indication of acute sepsis, so use of IV antibiotics is inappropriate.

Phenothiazines may be used for restlessness, nausea and anxiety, and beta blockers have a role in the management of sympathetic activation.

It is glucose however that will have most impact in shortening the duration and severity of symptoms.

[Q: 2762] OnExamination 2012 - Haematology

Which of the following chemotherapeutic agents inhibits topoisomerase?

- 1- Bleomycin
- 2- Cisplatin
- 3- Docetaxel
- 4- Etoposide
- 5- Vincristine

Answer & Comments

Answer: 4- Etoposide

The topoisomerase inhibitors are a major class of chemotherapeutic agents and work by arresting the cell in S phase, and thereby inducing apoptosis.

Etoposide inhibits DNA topoisomerase II, thereby inducing errors in DNA synthesis at the pre-mitotic stage of cell division.

Bleomycin binds directly to DNA, inducing strand breaks and therefore degradation.

Cisplatin cross-links DNA, activating several signal transduction pathways which culminate in cell apoptosis.

Docetaxel prevents microtubule disassembly, and therefore limits the amount of free tubulin available for cell replication.

Vincristine is a vinca alkaloid, which inhibits microtubule formation during metaphase of mitosis.

[Q: 2763] OnExamination 2012 - Haematology

Mutation in codon 12 of the Ras oncogene often results in which of the following?

- 1- Decreased GTP binding
- 2- Decreased GTP hydrolysis
- 3- Increased GTP binding
- 4- Increased GTP hydrolysis
- 5- Increased interaction with SOS

Answer & Comments

Answer: 2- Decreased GTP hydrolysis

The Ras family of oncogenes are important intracellular signalling proteins which transmit signals from receptor tyrosine kinase proteins in the cell membrane down to the nucleus.

Ras is controlled by the activity of a GTPase binding site; when guanosine triphosphate (GTP) is bound Ras is active and it slowly hydrolyses the GTP to guanosine diphosphate (GDP) resulting in an inactive state.

Mutations in codon 12 result in decreased GTPase activity and a Ras protein which is 'always on' resulting in increased proliferation of the cell.

[Q: 2764] OnExamination 2012 - Haematology

A 40-year-old woman with early breast cancer is referred to the oncology clinic for consideration of radiotherapy to her breast following wide local excision.

What is the role of adjuvant radiotherapy in this case?

- 1- To improve wound healing
- 2- To increase overall survival
- 3- To reduce keloid scarring
- 4- To reduce local recurrence
- 5- To reduce skin metastasis

Answer & Comments

Answer: 4- To reduce local recurrence

Adjuvant radiotherapy is given after wide local excision of a breast tumour to reduce the risk of local recurrence; following meta-analysis there is no increased survival benefit largely due to complications of radiotherapy treatment.

Radiotherapy does improve the appearance of scars and can reduce keloid scarring but it is only rarely given for this indication.

[Q: 2765] OnExamination 2012 - Haematology

Which tumour marker is most commonly raised in ovarian cancers?

- 1- AFP
- 2- Beta-HCG
- 3- CA125
- 4- CA19-9
- 5- CEA

Answer & Comments

Answer: 3- CA125

CEA is used to monitor colorectal and breast carcinoma

CA19-9 is used primarily to monitor pancreatic carcinoma response

Beta-HCG and AFP are used to monitor testicular carcinoma, and are also raised in germ cell tumours of the ovary

AFP by itself is useful in monitoring liver carcinoma

CA125 is most commonly used to monitor epithelial ovarian carcinoma but can also be raised in endometrial, lung, breast and gastrointestinal carcinoma.

[Q: 2766] OnExamination 2012 - Haematology

A 60-year-old woman presents with a gradual onset of lumbar spine pain over the past two weeks associated with a gradual deterioration in her mobility. She has a past history of metastatic breast cancer to her bones currently controlled on anastrozole.

An emergency MRI reveals widespread metastatic deposits in her spine with encroachment at L2 causing a moderate degree of spinal cord compression.

What is the best course of action?

- 1- Emergency chemotherapy
- 2- Emergency radiotherapy
- 3- Emergency surgical decompression
- 4- Emergency surgical decompression and chemotherapy
- 5- Emergency surgical decompression and radiotherapy

Answer & Comments

Answer: 5- Emergency surgical decompression and radiotherapy

Spinal cord compression is a devastating complication of metastatic disease which needs to be treated promptly.

The patient needs to be nursed in bed and given high dose steroids until the MRI result is known.

Surgical decompression is best for expansile soft tissue masses which have fractured the bone and are forcing this against the spinal cord. This should then be followed up by post-operative radiotherapy to reduce the soft tissue component.

Chemotherapy has no role in spinal cord compression from breast cancer; it is used in highly chemotherapy-responsive tumours such as germ cell malignancies and lymphoma.

[Q: 2767] OnExamination 2012 - Haematology

A 60-year-old woman presents with a gradual onset of lumbar spine pain over the past two weeks associated with a gradual deterioration in her mobility. She has a past history of metastatic breast cancer to her bones currently controlled on anastrozole.

An emergency MRI reveals widespread metastatic deposits in her spine with encroachment at L2 causing a moderate degree of spinal cord compression.

What is the best course of action?

- 1- Emergency chemotherapy
- 2- Emergency radiotherapy
- 3- Emergency surgical decompression
- 4- Emergency surgical decompression and chemotherapy
- 5- Emergency surgical decompression and radiotherapy

Answer & Comments

Answer: 5- Emergency surgical decompression and radiotherapy

Spinal cord compression is a devastating complication of metastatic disease which needs to be treated promptly.

The patient needs to be nursed in bed and given high dose steroids until the MRI result is known.

Surgical decompression is best for expansile soft tissue masses which have fractured the bone and are forcing this against the spinal cord. This should then be followed up by post-operative radiotherapy to reduce the soft tissue component.

Chemotherapy has no role in spinal cord compression from breast cancer; it is used in highly chemotherapy-responsive tumours such as germ cell malignancies and lymphoma.

[Q: 2768] OnExamination 2012 - Haematology

A 25-year-old man is diagnosed with a testicular seminoma and treated with BEP chemotherapy.

His staging CT scan reveals para-aortic lymphadenopathy and he is referred from the multi-disciplinary meeting for external beam radiotherapy.

He is admitted after his third fraction of radiotherapy with severe community acquired pneumonia and isolated in a lead-lined side-room on an oncology ward.

Unfortunately he deteriorates and you are fast-bleeped to attend as he is peri-arrest due to impending respiratory failure.

What radiation precautions should you take before entering the room?

- 1- Consult the local rules for radiation protection
- 2- Do not enter the room unless the patient arrests
- 3- None
- 4- Wear a disposable apron and gloves
- 5- Wear a lead-lined apron and disposable gloves

Answer & Comments

Answer: 3- None

Much confusion surrounds the use of radiotherapy, especially how patients are cared for on the ward.

It is critical to distinguish between whether the patient has had external beam radiotherapy, brachytherapy or use of an unsealed source.

External beam radiotherapy or use of targeted intraoperative radiotherapy does not render the patient radioactive.

Use of brachytherapy methods can involve insertion of radioactive seeds or beads which may require some radiation protection precautions depending on the site.

Use of an unsealed source, for example radioiodine treatment of thyroid cancer, has substantial need for precautions and patients need to be isolated in a lead-lined side room, often for several days.

In this case the patient is not radioactive and needs emergency care immediately. It is likely he is in a lead-lined side room as this is the only room available on the ward - it has no bearing on whether he is radioactive or not.

[Q: 2769] OnExamination 2012 - Haematology

Small molecule kinase inhibitors for cancer:

A 44-year-old woman presents to the clinic with increasing lethargy and fatigue. She has been treated previously with interferon alpha and has a diagnosis of chronic myeloid leukaemia.

Her white blood cell count has risen to 22×10^3 cells per microlitre, and she is anaemic with a recent haemoglobin of 8.9 g/dl.

You decide to start her on imatinib.

Which of the following correctly describes the mode of action of imatinib?

- 1- Bcr-abl tyrosine kinase inhibitor
- 2- Epidermal growth factor receptor (EGFR) kinaseinhibitor
- 3- Fibroblast growth factor receptor inhibitor
- 4- HER2 receptor inhibitor
- 5- Vascular endothelial growth factor (VEGF)inhibitor

Answer & Comments

Answer: 1- Bcr-abl tyrosine kinase inhibitor

The answer is A, Bcr-abl tyrosine kinase inhibitor.

In chronic myeloid leukaemia (CML) this particular kinase is stuck chronically in the "on" position.

By targeting the kinase, imatinib inhibits the unregulated cell division which occurs in CML and can maintain many patients in remission for a number of years.

There is also a role for imatinib in the treatment of gastrointestinal stromal tumours, where targeting of Bcr-abl tyrosine kinase has been shown to impact on progression of tumour size.

Other small molecules used in the treatment of cancer include trastuzumab which targets the human epidermal growth factor 2, used in the treatment of breast cancer, and sunitinib, which inhibits multiple kinases which are stimulated by agonism of a number of receptors including VEGF receptors, RET and platelet-derived growth factor (PDGF) receptors.

[Q: 2770] OnExamination 2012 - Haematology

Approximately 1% of pregnant women develop clinically important red cell antibodies, the most common being rhesus antibodies.

The women negative for D antigen develop antibodies on exposure to D positive blood (such as fetomaternal haemorrhage, abortions and transfusions).

This increases the risk of haemolytic disease of the newborn (HDN) in subsequent pregnancies.

From the following, choose the correct statement about rhesus antibodies in pregnancy:

- 1- D positive women are less likely than D negativewomen to form antibodies to other red cell antigens (such as Kelland Duffy)
- 2- Following delivery, the degree of FMH should be calculated on a blood sample from a D negative mother
- 3- Maternal antibody titres do not predict haemolytic disease of new born
- 4- Pregnant women should be checked for antibodies at 28 weeks as fetomaternal haemorrhage (FMH) occurs only after the second trimester.
- 5- The fetal Rh type is not dependent on the paternal Rh grouping

Answer & Comments

Answer: 2- Following delivery, the degree of FMH should be calculated on a blood sample from a D negative mother

Following delivery, the degree of FMH should be calculated on a blood sample from a D

negative mother to adjust the dose of antiD in the D negative mother delivering a D positive child (option B).

D positive women and D negative women have the same chances of developing antibodies to other red cell antigens.

All pregnant women should have a blood group and antibody screen in their first trimester or at presentation, whichever is earlier (option D).

The fetal Rh type depends on the paternal and maternal Rh typing (option E).

Maternal antibody titres correlate with the degree of HDN.

[Q: 2771] OnExamination 2012 - Haematology

A 34-year-old man with normal baseline cardiac and respiratory function starts on the ABVD (Adriamycin, bleomycin, vinblastine and dacarbazine) chemotherapy regimen for his stage IIB Hodgkin's lymphoma.

He tolerated the first three cycles of the chemotherapy well.

After completion of the fourth cycle he presents with exertional dyspnoea and a dry cough. He is afebrile, a chest x ray and ECG are normal.

Which of the following is the most likely diagnostic possibility?

- 1- Adriamycin related cardiomyopathy
- 2- Bleomycin related pulmonary fibrosis
- 3- Hyperemesis and reflex cough related to dacarbazine
- 4- Pneumocystis carinii pneumonia
- 5- Vinblastine related neurotoxicity

Answer & Comments

Answer: 2- Bleomycin related pulmonary fibrosis

Bleomycin related pulmonary fibrosis (option B) is a major toxicity of the widely used ABVD regimen for treatment of Hodgkin's disease.

Although Adriamycin can cause cardiotoxicity (option A) this is unusual at the doses used in this regimen and one would expect abnormalities on the ECG.

He is afebrile so Pneumocystis (option D) is less likely though needs to be considered in the differential.

There is no history of hyperemesis (option C) given and a vinblastine neuropathy (option E) is unlikely to present an acute shortness of breath.

[Q: 2772] OnExamination 2012 - Haematology

The risk of a viral infection transmitted via a transfusion is widely variable.

In the UK, the risk of transmission of hepatitis B would be best described as which of the following?

- 1- 0.05 per million donations
- 2- 0.2 per million donations
- 3- 1 per million donations
- 4- Slightly more than 2 per million donations
- 5- Slightly less than 0.01 per million donations

Answer & Comments

Answer: 4- Slightly more than 2 per million donations

The common viral infections considered in the infective risks of a blood transfusion are hepatitis B, hepatitis C and HIV.

The risks are variable depending on the source of donation and the type of testing employed but generally in the United Kingdom the risks for hepatitis B are in the order of 2.2/ million donations (hence option D) while those for HIV and hepatitis C are 0.2 and 0.05/ million donations (hence not options A, B, C and E).

A broad knowledge of the risks may be required while consenting a patient for blood transfusion.

[Q: 2773] OnExamination 2012 - Haematology

A patient on a medical ward received a transfusion 48 hours ago for symptomatic anaemia on background of chronic renal disease and obstructive airways disease. He gives a history of previous transfusions in the last year. The patient has now actually dropped his Hb by 2g/L compared to his pretransfusion level and reports a dark coloured urine. The LDH and bilirubin are elevated.

The is most likely to represent:

- 1- acute hepatitis as an infective complication
- 2- acute haemolytic transfusion reaction
- 3- delayed haemolytic transfusion reaction
- 4- non haemolytic febrile transfusion reaction
- 5- transfusion related graft versus host disease

Answer & Comments

Answer: 3- delayed haemolytic transfusion reaction

This case is an example of delayed haemolytic transfusion reaction which occurs 24 hrs after the transfusion (hence option c as explained further). This happens in a patient who has been previously immunized by transfusions or pregnancy. The antibodies are not detectable initially but becomes obvious as a secondary immune response to the antigen exposure during the transfusion occurs. A haemoglobin level, blood film, LDH, direct antiglobulin test, renal profile, serum bilirubin, haptoglobin and urinalysis for haemoglobinuria should be checked. The group and antibody screen should be repeated. A transfusion associated graft versus host disease and an acute hepatitis is unlikely given the time frame - both would be expected to occur in a week or

two (hence not options a or e). This is also not an acute hemolysis which would be expected to occur during the transfusion (hence not option b). Given the rise in Bilirubin and LDH this is a haemolytic reaction (hence not option d).

[Q: 2774] OnExamination 2012 - Haematology

Which of the following is the minimum dataset for identifying a patient and a sample for purpose of a blood transfusion request?

- 1- The full name and gender
- 2- The full name, gender, date of birth, address and patient identity number
- 3- The full name , gender and patient identity number
- 4- The full name, gender, address and patient identity number
- 5- The full name, gender, previous blood grouping details, address and patient identity number

Answer & Comments

Answer: 2- The full name, gender, date of birth, address and patient identity number

Given that maximum errors and near misses occur because of mislabelling or mistaken identity of the patient or the sample a minimum dataset is prescribed for transfusion requests.

This involves recording the full name, gender, date of birth, address (in some areas) and patient identity number (option B is correct).

Previous blood grouping details are not required and missing elements of this minimum dataset are not acceptable in the transfusion service (options A, C, D and E).

[Q: 2775] OnExamination 2012 - Haematology

You are taking ward referrals on behalf of the

renal team and are asked to see a 24-year-old woman who has been undergoing chemotherapy for acute myeloid leukaemia.

Unfortunately over the past 24 hours her condition has deteriorated and she is now oliguric; this is associated with a rise in her creatinine to 420 $\mu\text{mol/l}$ (79-118).

Which of the following treatments would have been most effective in preventing this episode?

- 1- Colchicine
- 2- IV normal saline
- 3- Naproxen
- 4- Prednisolone
- 5- Rasburicase

Answer & Comments

Answer: 5- Rasburicase

Tumour lysis syndrome is recognised after the onset of chemotherapy in patients with acute leukaemia.

Whilst ensuring adequate hydration and alkalinisation of urine is of value, rasburicase, (recombinant urate oxidase) is effective when used both pre and post the onset of chemotherapy in reducing urate accumulation.

The commonest reported side effect of rasburicase therapy is fever associated with administration and rasburicase overdose may lead to accumulation of hydrogen peroxide.

Other options for the management of tumour lysis syndrome include

Prophylactic allopurinol

Acetazolamide to drive urine alkalinisation.

[Q: 2776] OnExamination 2012 - Haematology

A 32-year-old woman presented to the Emergency department with right upper quadrant pain related to cholecystitis. The

pain settled with conservative management, but the surgeons noticed when they admitted her that she appears to have splenomegaly.

You examine her and confirm that she has an enlarged spleen. On further questioning she tells you that her father had his spleen removed.

Investigations show

Haemoglobin 10.9 g/dl

Spherocytes and reticulocytes seen on film (11.5-16.5)

Mean corpuscular volume 102 fl(80-96)

White cell count $7.9 \times 10^9/\text{L}$ (4-11)

Platelets $180 \times 10^9/\text{L}$ (150-400)

Serum Sodium 141 mmol/l (135-146)

Serum Potassium 4.4 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Which of the following is the most appropriate next investigation?

- 1- Autoimmune profile
- 2- Bone marrow biopsy
- 3- Coombs' test
- 4- Osmotic fragility test
- 5- Ultrasound scan abdomen

Answer & Comments

Answer: 4- Osmotic fragility test

This patient has a history which is strongly suggestive of hereditary spherocytosis, with increased haemolysis leading to increased risk of gallstones as seen here.

Spherocytosis occurs because of inherited defects in the membrane of red blood cells, leading to reduced cell deformability and this leads to the cells being removed by the spleen, which is the cause of progressive splenic enlargement.

Twenty to 30% of patients have mild disease, and, as in this case, can present later in life,

but 60-70% have more severe anaemia and splenic enlargement which leads to presentation in childhood.

Elective splenectomy is often required in severe cases, but patients with mild hereditary spherocytosis (HS) may require no intervention at all.

[Q: 2777] OnExamination 2012 - Haematology

A 54-year-old man comes to the endocrine clinic for review.

He has a history of type 2 diabetes which is currently managed with gliclazide 80 mg BD.

Most recently he has been diagnosed with abnormal liver function which the GP suspects is cirrhosis, although he claims he does not drink more than three to four glasses of wine per week.

He has split from his partner and admits to erectile dysfunction problems going back over the past three years.

On examination he looks tanned and has signs of chronic liver disease. There is sparse secondary sexual hair.

Investigations show

Haemoglobin 14.8 g/dl(13.5-18)

White cell count $6.0 \times 10^9/L$ (4-10)

Platelets $222 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (134-143)

Potassium 4.7 mmol/l (3.5-5)

Creatinine 130 $\mu\text{mol/l}$ (60-120)

ALT 230 u/l (5-40)

Glucose 10.5 mmol/l (<6.0)

Which of the following is the most appropriate single test with respect to revealing the underlying diagnosis?

- 1- Hepatitis serology
- 2- Serum ferritin
- 3- Serum iron

4- Serum testosterone

5- Transferrin saturation

Answer & Comments

Answer: 5- Transferrin saturation

The clinical presentation here is highly suspicious for genetic haemochromatosis. The best way to measure iron overload is via transferrin saturation which is calculated from the serum iron and the serum total iron binding capacity.

If the saturation is greater than 55% then genetic testing for the two commonest mutations, C282Y and H63D should be considered. Liver biopsy is indicated where there is evidence of liver damage, as indicated here by the raised alanine aminotransferase (ALT).

Treatment is with venesection, which is indicated until transferrin saturation falls to below 16%. Diabetes mellitus and hypogonadism may respond in some patients to venesection.

[Q: 2778] OnExamination 2012 - Haematology

A 23-year-old man with a teratoma of the testis attended for review following chemotherapy.

Which one of the following serum tumour markers is of most value in monitoring the clinical progression of his disease?

- 1- Alpha-fetoprotein
- 2- Carbohydrate antigen CA 15-3
- 3- Carbohydrate antigen CA 19-9
- 4- Carbohydrate antigen CA 125
- 5- Carcinoembryonic antigen

Answer & Comments

Answer: 1- Alpha-fetoprotein

Alpha-fetoprotein (AFP), beta-hCG and PLAP (placental like isoenzyme of alkaline phosphatase) are the major tumour markers in use for the monitoring of testicular teratoma.

CA 125, 15-3 and 19-9 are useful in bowel, pancreatic and ovarian tumours, and carcinoembryonic antigen (CEA) in large bowel tumours.

[Q: 2779] OnExamination 2012 - Haematology

A 17-year-old girl underwent emergency splenectomy after a domestic accident.

Which one of the following organisms is most likely to cause life-threatening infection in the future?

- 1- Actinomyces
- 2- Haemophilus influenzae
- 3- Pseudomonas aeruginosa
- 4- Staphylococcus aureus infection
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 5- Streptococcus pneumoniae

Following splenectomy a person is at risk of Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis, Escherichia coli and Pseudomonas aeruginosa.

By far the most common is Streptococcus pneumoniae, which can cause life-threatening infection.

[Q: 2780] OnExamination 2012 - Haematology

You are asked to provide advice on a 35-year-old woman who is admitted under the maxillo-facial surgeons for extraction of wisdom teeth.

The only concern was that she had developed prolonged bleeding following a tooth

extraction 10 years previously and had required suturing. Besides this, she gave no other history of bleeding.

What is the most likely diagnosis?

- 1- Factor V Leiden
- 2- Factor IX deficiency
- 3- Factor XII deficiency
- 4- Primary antiphospholipid syndrome
- 5- von Willebrand's disease

Answer & Comments

Answer: 5- von Willebrand's disease

Not that much is given away by this history, just the issue of a prolonged bleed after prior dental extraction.

The most likely diagnosis when considering this patient is von Willebrand's disease which is an autosomal dominant condition and is one of the commonest bleeding disorders. Most cases are mild, with bleeding after only mild injury, particularly mucosal membrane injuries.

The condition is due to a reduction or structural abnormality of von Willebrand's factor, which has the dual role of promoting normal platelet function and stabilising coagulation factor VIII.

Von Willebrand's disease can give normal results on screening tests, and diagnosis may require specialist investigation.

Most patients with mild disease respond to desmopressin (DDAVP), but clotting factor concentrates are needed for a minority.

[Q: 2781] OnExamination 2012 - Haematology

Which of the following haematological disorders is inherited as an autosomal recessive condition?

- 1- Antithrombin III deficiency

- 2- Protein C deficiency
- 3- Glucose-6-phosphate dehydrogenase deficiency
- 4- Pyruvate kinase deficiency
- 5- Acute intermittent porphyria

Answer & Comments

Answer: 4- Pyruvate kinase deficiency

A. Anti-thrombin 3 (AT3) is a plasma inhibitor protein that blocks the enzymatic activity of some serine proteases coagulation factors. The activity of this inhibitor is increased by heparin.

AT3 is synthesised by the liver, is not vitamin K dependent, and can be consumed during disseminated intravascular coagulation (DIC). Normal newborns have a reduced activity. Congenital AT3 deficiency is an autosomal dominant. Treatment of thrombotic events in these patients may be difficult.

B. Protein C is an inhibitor that, once activated, inhibits clot formation and enhances fibrinolysis. It is liver synthesised and vitamin K dependent. Protein C is converted to an active enzyme by a thrombin-thrombomodulin complex on the endothelial cell surface.

Activated protein C inhibits a plasminogen activator inhibitor, which results in enhanced fibrinolysis, and, with protein S as a co-factor, inhibits the clotting of the activated factors 5 and 8 by limited proteolysis. Activated protein C thus controls the conversion of factor 10 to 10a and prothrombin to thrombin.

Congenital deficiency is an autosomal dominant trait. Acquired deficiency may occur in association with infection.

C. Glucose-6-phosphate dehydrogenase deficiency is the most important disease of the pentose phosphate pathway, and is responsible for two clinical syndromes:

An episodic haemolytic anaemia induced by infections or certain drugs

A spontaneous chronic non-spherocytic haemolytic anaemia.

The deficiency is X linked, and heterozygous females are resistant to falciparum infections. There are a large number of abnormal alleles causing disease of vastly different severity.

D. Pyruvate kinase deficiency is a rare congenital haemolytic anaemia inherited as an autosomal recessive. Generation of adenosine triphosphate (ATP) within the red cell is impaired, resulting in an abnormally high concentration of 2,3,DPG in the red cell, which inhibits the enzymes of the pentose phosphate pathway.

Clinical manifestations vary from severe neonatal haemolysis, to a mild, well compensated haemolysis first noted in adulthood.

E. Acute intermittent porphyria is an autosomal dominant disorder resulting from partial porphobilinogen deaminase deficiency in the cytosol of all tissues including erythrocytes. Clinical expression of the disease is linked to environmental or acquired factors such as

Nutritional status

Drugs

Steroids

Chemicals.

The major abnormality is of the peripheral, autonomic or central nervous system (CNS).

Major symptoms are abdominal pain, nausea, vomiting, constipation or diarrhoea. In severe cases the urine develops a port wine colour due to the high content of porphobilin, an auto-oxidation product of PBG.

Hypertension and neuropathy are common, with muscle weakness, cranial nerve abnormality and seizures.

[Q: 2782] OnExamination 2012 -
Haematology

A 42-year-old man presents with increasing abdominal pain and a feeling of fullness and nausea when he eats. He has also felt constitutionally unwell over the past few weeks and months with some night sweats and gradual weight loss.

On examination his BMI is 21, his BP is 126/82 mmHg, pulse 80 and regular, his temperature is 37.4°C. He has an abdominal fullness with some evidence of ascites.

Investigations show

Haemoglobin 10.9 g/dl(13.5-17.7)

White cell count $8.9 \times 10^9/L$ (4-11)

Platelets $188 \times 10^9/L$ (150-400)

ESR 67 mm/hr(<10)

Serum Sodium 137 mmol/l (135-146)

Serum Potassium 4.9 mmol/l (3.5-5)

Creatinine 115 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 85 U/l (5-40)

Colonoscopy Caecal mass, suggestive of Burkitt's lymphoma

Which translocation is likely to be found in the Burkitt's cells?

1- 2:5

2- 8:14

3- 8:21

4- 9:21

5- 14:11

Answer & Comments

Answer: 2- 8:14

Burkitt's lymphoma is associated with a t(8;14)(q24;q32) translocation, which is observed in approximately 80% of patients with the disease. What this does is to juxtapose c-Myc, which is a transcription factor responsible for initiating the cell cycle,

with the locus for the immunoglobulin heavy chain.

Burkitt's lymphoma, particularly sporadic lymphoma, may be seen in adults and commonly involves the abdominal organs, usually the caecum as seen here, or the distal ileum.

Localised Burkitt's is associated with around a 90% survival rate, although the prognosis is less good in adults.

[Q: 2783] OnExamination 2012 -
Haematology

Which one of the following is true of IgE?

1- Crosses the normal placenta

2- Is increased acutely in an asthmatic attack

3- Is increased in the serum of atopic individuals

4- Is involved in type 2 hypersensitivity

5- Is present in plasma in the same concentration as IgG

Answer & Comments

Answer: 3- Is increased in the serum of atopic individuals

IgG is the predominant form of immunoglobulin in plasma at a concentration around 10,000 times that of IgE.

IgG crosses the placenta to confer immunity to the fetus but IgE does not.

IgE is involved in arming mast cells and basophils. IgE causes mast cells to release vasoactive amines, such as histamine, producing an inflammatory response which can result in a type I hypersensitivity reaction.

IgE is responsible for allergen-mediated diseases such as anaphylaxis, asthma and atopy.

Total serum IgE is frequently increased in those with atopy but serum IgE does not rise acutely during an asthmatic attack.

[Q: 2784] OnExamination 2012 - Haematology

Which of the following malignancies is associated with HTLV-1 infection?

- 1- Adult T cell leukaemia
- 2- Burkitt's lymphoma
- 3- Chronic lymphocytic leukaemia
- 4- Pancreatic cancer
- 5- Transitional cell carcinoma

Answer & Comments

Answer: 1- Adult T cell leukaemia

Between 1:10 and 1:20 are believed to develop malignancy associated with human T lymphotropic virus 1 (HTLV-1); adult T cell leukaemia/lymphoma.

[Q: 2785] OnExamination 2012 - Haematology

A 29-year-old man is starting a chemotherapy regime that includes cisplatin.

Which of the following is the mechanism of action of cisplatin?

- 1- Causes crosslinking in DNA
- 2- Degrades preformed DNA
- 3- Inhibits purine synthesis
- 4- Reduces the formation of microtubules
- 5- Stabilises DNA-topoisomerase II complex

Answer & Comments

Answer: 1- Causes crosslinking in DNA

"Cisplatin acts by crosslinking DNA in several different ways, making it impossible for rapidly dividing cells to duplicate their DNA for mitosis." Wikipedia: cisplatin

[Q: 2786] OnExamination 2012 - Haematology

A 20-year-old man presented to hospital two days after returning from visiting his family in Bangladesh.

Within a day of his return to the United Kingdom he suddenly developed profuse watery diarrhoea. He says there had been an outbreak of diarrhoea in his family's village in the week before his return.

Stool culture revealed a growth of *Vibrio cholerae*.

Which one of the following blood types is associated with the greatest susceptibility to severe cholera?

- 1- Blood Group A
- 2- Blood Group AB
- 3- Blood Group B
- 4- Blood Group O
- 5- Rhesus -ve

Answer & Comments

Answer: 4- Blood Group O

"Individuals with blood group O are more susceptible than other individuals to severe cholera, although the mechanism underlying this association is unknown." Infect Immun. 2005 Nov; 73(11): 7422-7.

[Q: 2787] OnExamination 2012 - Haematology

A 52-year-old woman presents with tiredness and weight gain. She is confirmed to have autoimmune thyroiditis.

Which of the following tumours is she at increased risk of developing?

- 1- Anaplastic carcinoma of the thyroid
- 2- Follicular carcinoma of the thyroid
- 3- Medullary carcinoma of the thyroid
- 4- Papillary carcinoma of the thyroid

5- Thyroid lymphoma

Answer & Comments

Answer: 5- Thyroid lymphoma

There is a small but recognised risk of developing thyroid lymphoma associated with autoimmune thyroiditis (also known as Hashimoto's disease or lymphocytic thyroiditis).

The risk is small and would certainly not be screened for, nor should it in patients with autoimmune thyroid disease.

[Q: 2788] OnExamination 2012 - Haematology

A 70-year-old male is diagnosed with multiple myeloma and is treated with melphalan and prednisolone.

Which of the following when added to this chemotherapeutic regime would be expected to improve survival?

- 1- Cyclosporin
- 2- Interferon alpha
- 3- Methotrexate
- 4- Simvastatin
- 5- Thalidomide

Answer & Comments

Answer: 5- Thalidomide

Significant improvements in survival may be expected through the addition of thalidomide to standard chemotherapeutic regimes.

Studies suggest a significant improvement at both two years and five years with thalidomide.

NEJM 2006; 367:825-31.

Lancet 2006 354:1021-1-30

[Q: 2789] OnExamination 2012 - Haematology

A 55-year-old asymptomatic woman with mild splenomegaly was found to have a platelet count of $650 \times 10^9/L$ ($150-400 \times 10^9$) on blood investigation. White blood cells and haemoglobin are within the normal range.

What is the next step in management?

- 1- Anagrelide
- 2- Hydroxycarbamide
- 3- Low dose aspirin
- 4- Observation
- 5- Plateletpheresis

Answer & Comments

Answer: 4- Observation

In essential thrombocythosis low risk patients have a risk of thrombosis similar to that of the age and sex-matched population and a very low risk of life-threatening bleeding, supporting close observation as the most sensible approach.

Hydroxycarbamide is an adequate choice for patients 60 years of age or older who are otherwise in good health.

For elderly patients with limited projected survival (less than 10 years) and who have problems with other drug compliance, 32P administration might be appropriate.

Anagrelide should be offered to younger patients (less than 60) who are at high risk by virtue of a prior history of thrombosis.

In patients who suffer from thrombotic episodes, especially episodes involving the microcirculation or large vessels, low-dose aspirin (100 mg/day) is usually administered.

In severe life-threatening episodes rapid cyto-reduction may be achieved by plateletpheresis or by the administration of a single dose of 0.4 mg/kg of nitrogen mustard.

[Q: 2790] OnExamination 2012 -
Haematology

A 59-year-old male is referred with an abnormal full blood count (FBC).

He had presented to his general practitioner with a flu-like illness which has since subsided but a FBC revealed a platelet count of $800 \times 10^9/L$ ($150-400 \times 10^9$) which has remained persistently elevated but with no other abnormality on the FBC.

He is otherwise entirely asymptomatic and no abnormalities are noted on examination.

Which of the following is the most appropriate treatment for this patient?

- 1- Anagrelide
- 2- Aspirin
- 3- Hydroxycarbamide
- 4- Observation
- 5- Plateletpheresis

Answer & Comments

Answer: 4- Observation

There are a number of adverse prognostic markers for essential thrombocythaemia (ET):

Age above 60

Symptomatology - particularly thrombosis and

Platelet count above 1500.

Generally the prognosis is extremely good in ET with survival of over two decades expected.

This patient would be regarded as low risk and hence observation only employed.

The risk of bleeding can also be a problem and although you may think that aspirin would be appropriate the evidence is conflicting.

[Q: 2791] OnExamination 2012 -
Haematology

A 62-year-old female with colonic carcinoma is

treated with chemotherapy and is receiving ondansetron for intractable nausea and vomiting.

Which of the following best describes the pharmacological actions of ondansetron?

- 1- Anticholinergic
- 2- Cannabinoid
- 3- Dopaminergic antagonists
- 4- H1 antihistamine
- 5- 5-HT3 antagonist

Answer & Comments

Answer: 5- 5-HT3 antagonist

Ondansetron is a selective 5-HT3 antagonist both centrally and peripherally and as such is a potent antiemetic.

[Q: 2792] OnExamination 2012 -
Haematology

A man presents with generalised fatigue and weakness. A diagnosis of Eaton-Lambert syndrome is made.

An antibody to what cellular component is found in this condition?

- 1- Anticholinesterase
- 2- Mitochondria
- 3- Potassium channels
- 4- Sodium channels
- 5- Voltage gated calcium channels

Answer & Comments

Answer: 5- Voltage gated calcium channels

The EL syndrome is rare and unlike myasthenia gravis which affects mostly women primarily affects men over the age of 40 and is usually associated with an underlying bronchial neoplasm.

Strength usually is reduced in proximal muscles of the legs and arms producing a waddling gait and difficulty elevating the arms.

The disorder is associated with the presence of antibodies against the voltage dependent calcium channels.

[Q: 2793] OnExamination 2012 - Haematology

A 24-year-old female student presented with fever and rigors for two days, fatigue, headache especially retro-orbital and diarrhoea. In particular she complained of a weakness of the left side of her face and drooping of the lip.

She had recently returned from a sabbatical in Uganda four weeks previously.

She was febrile (39.9°C), had a mild left facial nerve palsy, lymphadenopathy in her axillae and groin and she had an erythematous, maculopapular rash.

Laboratory investigations showed:

Haemoglobin 12.0 g/dl (11.5-16.5)

WBC $3.0 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $150 \times 10^9/L$ (150-400 $\times 10^9$)

Blood film Lymphopenia, some atypical lymphocytes seen

Which of the following is the most likely diagnosis?

- 1- Acute HIV infection (seroconversion illness)
- 2- Dengue fever
- 3- Infectious mononucleosis
- 4- Typhoid fever
- 5- Viral hepatitis

Answer & Comments

Answer: 1- Acute HIV infection (seroconversion illness)

Acute human immunodeficiency virus (HIV) seroconversion illness should be suspected where there has been a risk of exposure.

The symptoms and signs are often vague but the clinical presentation here is consistent. The median time from exposure to presentation is 25 days.

More than three quarters of patients who become infected with HIV develop symptoms consistent with primary HIV infection.

Symptoms typically appear a few days to a few weeks after exposure to HIV, and generally include several of the following:

Fever

Rash, often erythematous maculopapular

Fatigue

Pharyngitis

Generalised lymphadenopathy

Urticaria

Myalgia/arthritis

Anorexia

Mucocutaneous ulceration

Headache, retro-orbital pain

Neurologic symptoms, e.g.

aseptic meningitis

radiculitis

myelitis.

Source: AETC National Resource Center

[Q: 2794] OnExamination 2012 -
Clinical pharmacology

Which of the following is correct regarding lead poisoning?

- 1- Can only result from lead ingestion
- 2- Causes a peripheral neuropathy due to demyelination
- 3- Causes adrenal suppression
- 4- Commonly presents with diarrhoea
- 5- Is associated with a macrocytic anaemia

Answer & Comments

Answer: 2- Causes a peripheral neuropathy due to demyelination

Lead can also be absorbed through the skin and by inhalation.

It is associated with iron deficiency and a microcytic anaemia.

The most common gastrointestinal symptoms are abdominal colic and constipation.

[Q: 2795] OnExamination 2012 -
Clinical pharmacology

You are asked to review a 71-year-old woman who comes to the clinic complaining that her hearing is not as good as it was after a prolonged period of treatment in hospital for infective endocarditis.

On examination you find that she has significant sensorineural hearing impairment and you suspect this may be gentamicin related.

What is the mechanism of ototoxicity associated with gentamicin?

- 1- Cell wall integrity disruption
- 2- DNA toxicity
- 3- Interruption of cell division
- 4- Nitric oxide reduction
- 5- Oxygen free radical generation

Answer & Comments

Answer: 5- Oxygen free radical generation

Gentamicin is toxic to cochlear hair cells, and it is known to disrupt mitochondrial protein synthesis, which leads to increased oxygen free radical generation via inducible nitric oxide synthase activity.

Peroxynitrite radicals are formed, which then leads to apoptosis.

It is thought that aminoglycosides take longer to clear from inner ear fluids, which may account for the site specific toxicity seen with this class of antibiotics.

A switch from BD dosing to OD dosing has reduced the susceptibility of patients to toxicity, and once daily regimes are now the preferred method of gentamicin administration.

Peak (one hour post dose), and trough, (pre-dose levels) are assayed to determine dose adjustments. A dose of 3 mg/kg/day is the usual starting level in adults with normal renal function.

Gentamicin may be used in patients with impaired renal function, but dose level and interval between doses needs to be adjusted to avoid toxicity.

[Q: 2796] OnExamination 2012 -
Clinical pharmacology

A 21-year-old nurse comes to the clinic requesting contraception. She works shifts including nights, and so often wakes up at odd times of the day. She has recently married and may want to start a family during the next two years.

Her mother suffered a DVT three years ago.

On further questioning she has some problems with libido and has heard that progesterone only based preparations may impact on this. On examination she looks well, her BMI is 21, and her BP is 100/70 mmHg.

Which of the following is likely to be the most appropriate medication for her?

- 1- Combined oral contraceptive pill
- 2- Diaphragm
- 3- Mirena coil
- 4- Progesterone implant
- 5- Progesterone only pill

Answer & Comments

Answer: 1- Combined oral contraceptive pill

The fact that her mother suffered a deep vein thrombosis (DVT) is largely irrelevant with respect to assessing her DVT risk.

For the progesterone only pill, it must be taken within three hours of the time the pill was taken on the previous day; given she works shifts this is likely to have a significant impact and increase the chances of a missed pill.

The time window for a missed pill with respect to the combined pill is 12 hours.

Given that she may decide to start a family at any time, the progesterone implant or Mirena coil do not seem to be ideal options, and progesterone only preparations may be associated with a reduced libido.

The diaphragm has a higher failure rate and should definitely not be the first choice in this patient.

The primary action of the combined oral contraceptive pill is inhibition of ovulation, although there are also alterations to the cervical mucus and endometrium which may contribute to effectiveness.

In contrast the progesterone only pill does not necessarily affect ovulation and its primary mode of action is on cervical mucus and implantation.

Long acting progesterone preparations prevent proliferation of the endometrium,

thicken cervical mucus and suppress ovulation in some women.

The major risk of the combined oral contraceptive pill is thromboembolic disease; with respect to long acting progesterone, the major concerns are around irregular menstrual bleeding and changes in libido.

[Q: 2797] OnExamination 2012 -
Clinical pharmacology

A 23-year-old woman presents to the Emergency department with low grade fever and dysuria. Her only medication is the oral contraceptive pill.

On examination her temperature is 37.8°C, and she has suprapubic and left loin tenderness consistent with a urine infection and possible pyelonephritis.

Investigations show:

Haemoglobin 12.5 g/dl 11.5-16.5

White cell count $12.8 \times 10^9/L$ 4-11

Platelets $209 \times 10^9/L$ 150-400

Serum Sodium 139 mmol/l 135-146

Serum Potassium 3.9 mmol/l 3.5-5

Creatinine 82 $\mu\text{mol/l}$ 79-118

Which of the following antibiotics do SIGN guidelines recommend for this patient?

- 1- Amoxicillin
- 2- Ciprofloxacin
- 3- Co-trimoxazole
- 4- Nitrofurantoin
- 5- Trimethoprim

Answer & Comments

Answer: 2- Ciprofloxacin

Upper urinary tract infection is one area where resistance to antimicrobials is increasing.

For this reason trimethoprim and amoxicillin are not recommended for treatment of upper urinary tract infections, and even resistance to quinolones such as ciprofloxacin is now beginning to prove problematic.

Nitrofurantoin is not used for the treatment of upper urinary tract infections because of difficulty in achieving sufficient plasma concentration, and co-trimoxazole is a second line choice due to problems with blood dyscrasias.

HPA suggests patients started on ciprofloxacin should have urine sent for culture and patients admitted to hospital if there is no response to treatment in 24 hours.

<http://www.sign.ac.uk/pdf/sign88.pdf>

[Q: 2798] OnExamination 2012 - Clinical pharmacology

A 61-year-old man presents to the emergency department complaining of lethargy and muscle weakness. He has begun therapy for hypertension with bendroflumethiazide a few weeks earlier. Blood testing reveals a potassium of 2.5 mmol/l.

Which of the following is the most likely cause of his hypokalaemia?

- 1- Increased sodium within the ascending loop of Henle
- 2- Increased sodium within the descending loop of Henle
- 3- Increased sodium within the distal collecting duct
- 4- Increased sodium within the distal convoluted tubule
- 5- Increased sodium within the proximal convoluted tubule

Answer & Comments

Answer: 4- Increased sodium within the distal convoluted tubule

Thiazides block sodium reabsorption in the proximal segment of the distal convoluted tubule. This promotes increased delivery of sodium to the distal segment of the distal convoluted tubule. There the aldosterone sensitive sodium potassium exchange pump is presented with increased luminal sodium, which leads to increased excretion of potassium and hydrogen ions.

Often thiazide diuretics are combined in the treatment of hypertension with an ACE inhibitor or angiotensin receptor blocker (ARB), in which case hypokalaemia does not normally present itself as a problem.

[Q: 2799] OnExamination 2012 - Clinical pharmacology

A 60-year-old lady presented with heartburn. She is known to have osteoporosis and has been taking alendronate for a number of years.

Which of the following is the most likely cause of her symptoms?

- 1- Achalasia
- 2- Calcification of lower oesophageal sphincter
- 3- Crush fracture
- 4- Ischaemic heart disease
- 5- Oesophagitis

Answer & Comments

Answer: 5- Oesophagitis

"Oral bisphosphonates seem to induce serious esophagitis in some patients, may result in gastritis and cause diarrhoea. When used as recommended, serious esophageal complications are few. Patients with known esophageal disease (e.g. achalasia, stricture, Barrett's esophagus, severe reflux and scleroderma) should avoid taking oral bisphosphonates." American Family Physician 2000;61:2731-6

[Q: 2800] OnExamination 2012 -
Clinical pharmacology

A 59-year-old male with type 2 diabetes is attending the foot clinic regularly.

He has a neuropathic ulcer complicated by osteomyelitis. A deep wound swab has grown *Staphylococcus aureus* and *Escherichia coli*.

He also takes warfarin for atrial fibrillation.

Which of the following antibiotics will reduce the anticoagulant effect of warfarin?

- 1- Ciprofloxacin
- 2- Co-trimoxazole
- 3- Erythromycin
- 4- Metronidazole
- 5- Rifampicin

Answer & Comments

Answer: 5- Rifampicin

The anticoagulant effect of warfarin can be affected by drugs, which induce or inhibit the action of enzymes involved in the metabolism of warfarin.

Rifampicin is known to induce the action of such enzymes, therefore increasing the metabolism of warfarin and so reducing its anticoagulant effect.

Erythromycin and ciprofloxacin inhibit the effect of these enzymes, therefore enhancing the anticoagulant effect of warfarin.

Metronidazole and co-trimoxazole inhibit the clearance of the active S isomer of warfarin, therefore enhancing its anticoagulant effect.

[Q: 2801] OnExamination 2012 -
Clinical pharmacology

A 56-year-old female who is taking warfarin for atrial fibrillation and has had a stable INR of between 2-2.5 over the last one year is noted to have an INR on the last visit of 7.8 (>1.4).

Consumption of which of the following may be responsible for this?

- 1- Carrot juice
- 2- Cranberry juice
- 3- Oil of evening primrose
- 4- Orange juice
- 5- St John's wort

Answer & Comments

Answer: 2- Cranberry juice

Cranberry juice has been recognised to be responsible for a deranged INR, it being postulated that it inhibits cytochrome p450.

St John's wort induces cytoP450 and therefore reduces INR.

[Q: 2802] OnExamination 2012 -
Clinical pharmacology

A 45-year-old male takes lithium for a bipolar affective disorder.

Which of the following drugs would be contraindicated in conjunction with lithium?

- 1- Atenolol
- 2- Bendroflumethiazide
- 3- Codeine phosphate
- 4- Flucloxacillin
- 5- Thyroxine

Answer & Comments

Answer: 2- Bendroflumethiazide

Caution should be exercised when taking lithium and diuretics as the latter may reduce renal clearance of lithium and increase serum lithium concentrations.

Non-steroidal anti-inflammatory drugs (NSAIDs) also increase lithium concentrations.

Metronidazole, angiotensin-converting enzyme inhibitors (ACEis) and calcium channel

blockers also increase serum lithium concentrations.

[Q: 2803] OnExamination 2012 -
Clinical pharmacology

Which of the following statements regarding Antabuse (disulfiram) is/are correct?

- 1- Antabuse acts by promoting the metabolism of acetaldehyde
- 2- Can be used in patients with a history of psychosis in order to limit alcohol excess
- 3- Can be used to assist abstinence from alcohol in patients with heart disease
- 4- Patients using alcohol based perfumes may develop serious reactions
- 5- Requires regular dose titration once initiated

Answer & Comments

Answer: 4- Patients using alcohol based perfumes may develop serious reactions

Antabuse inhibits the breakdown of acetaldehyde, which is a major metabolite of alcohol.

It is the accumulation of acetaldehyde which causes the flushing, sweating, palpitations, nausea, and vomiting seen in patients taking Antabuse who imbibe alcohol.

These reactions may also occur with alcohol based products, for example, perfume.

Antabuse is contraindicated in cirrhosis and heart disease, and psychosis is a relative contraindication for its use.

[Q: 2804] OnExamination 2012 -
Clinical pharmacology

A 57-year-old man with a history of stable coronary artery disease comes to the clinic for review.

He suffered an inferior myocardial infarction some seven years earlier, but has been

troubled with only relatively minor chest pain since this time.

He takes a number of medications for control of blood pressure, cholesterol and his angina. On examination his BP is 145/72 mmHg, pulse is 70 and regular. His chest is clear and there is no ankle swelling.

He tells you that he has been buying sildenafil over the internet for erectile dysfunction.

Which of the following medications would concern you most with respect to possible drug interaction?

- 1- Atorvastatin
- 2- Bisoprolol
- 3- Indapamide
- 4- Nicorandil
- 5- Ramipril

Answer & Comments

Answer: 4- Nicorandil

Sildenafil leads to significant hypotension with nitrates and drugs such as nicorandil which act as nitrate donors. As such it is contraindicated for use with these agents.

Atorvastatin, bisoprolol, indapamide and ramipril are all commonly prescribed in patients with erectile dysfunction and no significant interaction with PDE-5 inhibitors is recognised.

Alpha blockers may lead to hypotension in patients prescribed sildenafil and caution is therefore advised where co-prescription is considered.

Sildenafil is metabolised via the CYP3A4 pathway, as such caution is also advised when co-prescribing agents such as erythromycin and increased consumption of grapefruit juice.

[Q: 2805] OnExamination 2012 -
Clinical pharmacology

In which of the following would the first drug

be associated with increased pharmacological action of the second drug?

- 1- Erythromycin : theophylline
- 2- Phenytoin : ethinyloestradiol
- 3- Ranitidine : corticosteroid
- 4- Rifampicin : warfarin
- 5- Valproate : phenobarbitone

Answer & Comments

Answer: 1- Erythromycin : theophylline

Erythromycin would inhibit the metabolism of theophylline.

Ranitidine unlike cimetidine is not an enzyme inhibitor.

Phenytoin would speed up metabolism of ethinyloestradiol making the pill less effective.

Rifampicin is a well recognised enzyme inducer.

[Q: 2806] OnExamination 2012 - Clinical pharmacology

A 71-year-old man is treated for paroxysmal atrial fibrillation with 200 mg of amiodarone per day.

He is finding extreme problems with photosensitivity and wants to discontinue the medication.

Which of the following is true of amiodarone therapy?

- 1- It has a half life of 36 hours so stopping the medication will be associated with an immediate improvement
- 2- Photosensitivity is a rare occurrence
- 3- Purple skin discoloration is seen independent of photosensitivity
- 4- Skin sensitivity can be prevented by using a sun block

- 5- Thyroid dysfunction is seen more commonly in patients who experience photosensitivity

Answer & Comments

Answer: 4- Skin sensitivity can be prevented by using a sun block

Photosensitivity is seen very commonly in those patients who are prescribed amiodarone therapy. It is distinct from the slate grey skin discolouration which can occur with prolonged amiodarone use and can be prevented by using a total sun block preparation.

The half life of amiodarone has a mean of around 50 days, and may be as short as 20 days in some individuals and as long as 100 days in others. Slate grey or blue skin appearance is the commonest pigmentation change seen in association with treatment.

The incidence of amiodarone induced thyroid dysfunction has no relationship at all to photosensitivity.

[Q: 2807] OnExamination 2012 - Clinical pharmacology

A 49-year-old woman presents to the Emergency department with right sided pleuritic chest pain. She has had two previous pulmonary emboli (PE) and is on lifelong warfarin therapy.

On examination she is short of breath and in pain. Her BP is 105/70 mmHg and her pulse is 92. Auscultation of the chest is normal. She has a swollen left leg, but she tells you this is chronic since an extensive DVT a few years earlier.

Investigations reveal:

Haemoglobin 12.5 g/dl (11.5-16.5)

White cell count $7.2 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Serum Sodium 137 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Creatinine 82 µmol/l (79-118)

INR 2.22-3

CXR No focal changes

paO₂ 8.2 kPa10-13.3

paCO₂ 4.2 kPa4.8-6.1

Which of the following is the most appropriate next step?

- 1- Add aspirin to her therapy
- 2- Add clopidogrel to her therapy
- 3- Increase the INR target to 3-4
- 4- Increase the INR target to 4-5
- 5- Refer for an IVC filter

Answer & Comments

Answer: 5- Refer for an IVC filter

In this situation, where she is anticoagulated yet has sustained a further PE, there are two potential choices, either to consider increasing her INR target to 3-4, or considering an IVC filter.

Contraindications to anticoagulation where an IVC filter may be considered include

Haemorrhagic stroke

Recent neurosurgery or other major surgery

Major trauma and

Evidence of active internal bleeding.

Other contraindications include

Pregnancy

Frequent falls and

Poor potential compliance with warfarin.

In these situations an IVC filter may be the most appropriate option. Given her young age and the potential for further PEs, a filter may be considered ahead of increased warfarin dose.

IVC filters may also be considered for prophylaxis in patients who have a diagnosis of cancer or who have a DVT and are about to undergo surgery. In this case, anticoagulation may result in more problems than filter placement.

A previous relative contraindication to filter placement was the need to undergo MRI, but now, MRI proof filters are available and this is no longer a problem.

www.bcsghguidelines.com/documents/vena_cava_filters_bjh_2006.pdf

[Q: 2808] OnExamination 2012 - Clinical pharmacology

You are investigating a new anti-platelet agent which may have additional effects on top of clopidogrel. To investigate the effects of the new therapy you need to be aware of the mode of action of clopidogrel.

Which of the following best describes the action of clopidogrel?

- 1- 5HT-2 receptor inhibition
- 2- Cox-1 inhibition
- 3- Cox-2 inhibition
- 4- IIb IIIa inhibition
- 5- Inhibition of the platelet ADP receptor

Answer & Comments

Answer: 5- Inhibition of the platelet ADP receptor

The answer is inhibition of the platelet ADP receptor, which leads to decreased propensity to platelet aggregation and is complementary to cyclo-oxygenase inhibition, which of course is the action of aspirin.

5HT-2 receptor inhibition also reduces platelet aggregation; one example is sarpogrelate developed in North East Asia primarily as an alternative to aspirin because of its association with a lower risk of haemorrhage.

IIb IIIa inhibitors are used in patients with unstable angina/NSTEMI, an example being abciximab.

[Q: 2809] OnExamination 2012 -
Clinical pharmacology

A 55-year-old woman, who has a history of atrial fibrillation and is receiving warfarin and digoxin, informs you that she has been feeling down of late and has been self medicating with St John's wort which she obtained from a health shop.

Which of the following interactions may be expected between St John's Wort and her current medication?

- 1- Digoxin concentrations are unlikely to be affected
- 2- INR is likely to be increased
- 3- INR is likely to be reduced
- 4- INR is likely to be unaffected
- 5- There is an increased risk of digoxin toxicity

Answer & Comments

Answer: 3- INR is likely to be reduced

St John's wort is now commonly taken for depressive symptoms, yet it is a liver enzyme inducer and therefore has interactions with medications typically reducing the efficacy.

In this regard, St John's wort may reduce the efficacy of warfarin, requiring increased dose to maintain the INR and it may also reduce the efficacy of digoxin.

[Q: 2810] OnExamination 2012 -
Clinical pharmacology

The nurse bleeped you because an obese patient is feeling nauseous and is vomiting. He is also complaining of seeing green and yellow halos.

He has recently been treated with a standard intravenous bolus of digoxin for fast atrial

fibrillation. His creatinine clearance is normal. Digoxin toxicity is suspected.

What do you think is the cause of his symptoms?

- 1- Decreased hepatic excretion
- 2- Decreased protein binding
- 3- Decreased renal clearance
- 4- Decreased volume of distribution
- 5- Increased half life

Answer & Comments

Answer: 4- Decreased volume of distribution

Digoxin is concentrated in tissues and therefore has a large apparent volume of distribution. Serum digoxin concentrations are not significantly altered by large changes in fat tissue weight so that its distribution space correlates best with lean (that is, ideal) body weight, not total body weight.

In this case a higher dose than necessary was given due to calculation on the patient total body weight, resulting in digoxin toxicity. In other words his distribution space had been overestimated. Ideal body weight should be used, rather than total body weight, when calculating doses.

Approximately 25% of digoxin in the plasma is bound to protein.

[Q: 2811] OnExamination 2012 -
Clinical pharmacology

A 90-year-old man with chronic leukaemia presents with gout which his general practitioner treats with allopurinol.

How does allopurinol prevent the accumulation of uric acid?

- 1- By competing for its transporter to the kidney
- 2- By enhancing its solubility
- 3- By inhibiting purine synthesis

- 4- By inhibiting pyrimidine synthesis
- 5- By inhibiting the inflammatory response it causes

Answer & Comments

Answer: 3- By inhibiting purine synthesis

Allopurinol is a xanthine oxidase inhibitor and is converted by this enzyme to alloxanthine.

In this form it inhibits the conversion of hypoxanthine to xanthine and the conversion of xanthine to uric acid, therefore inhibiting the formation of uric acid.

[Q: 2812] OnExamination 2012 - Clinical pharmacology

A 50-year-old male has a blood pressure of 160/90 mmHg on two consecutive days.

You decide that you are going to initiate drug therapy.

Which of the following statements regarding your decision is correct?

- 1- ACE inhibitors should not be used as first line treatment in Afro-Caribbean patients
- 2- An alpha-blocker would be a first line agent in this patient
- 3- If the patient is non-caucasian a beta-blocker would be an appropriate first line treatment
- 4- Potassium monitoring is not required if an ACE inhibitor is prescribed without the addition of spironalactone
- 5- Spironalactone would be an appropriate second line agent in this patient

Answer & Comments

Answer: 1- ACE inhibitors should not be used as first line treatment in Afro-Caribbean patients

ACE inhibitors have low efficacy in black patients in the clinical trials of ACE inhibitors.

According to the British Hypertension Society guidelines (J Hum Hypertension 2003;17:81-86) first line treatment in black patients and patients older than 55 years of age should be with a diuretic or a calcium channel blocker.

An alpha blocker or spironalactone should only be used as an adjunct treatment in resistant hypertension.

[Q: 2813] OnExamination 2012 - Clinical pharmacology

A 52-year-old woman takes lithium carbonate for manic depression and also takes codeine and diclofenac prescribed by her GP for osteoarthritis.

Which one of the following statements is correct?

- 1- Codeine will reduce the bioavailability of lithium
- 2- The analgesic effect of codeine will be reduced by co-administration of diclofenac
- 3- The nephrotoxicity of diclofenac will be increased in this patient
- 4- Plasma lithium concentration will be increased by codeine
- 5- Plasma lithium concentrations will be raised by diclofenac

Answer & Comments

Answer: 5- Plasma lithium concentrations will be raised by diclofenac

Diclofenac decreases renal lithium clearance and increases lithium concentrations.

Codeine and diclofenac are frequently co-prescribed.

[Q: 2814] OnExamination 2012 - Clinical pharmacology

A 68-year-old lady with mitral valve disease and atrial fibrillation is taking warfarin. Lately her international normalised (INR) has fallen

and the dose of warfarin has had to be increased.

Which of the following new treatments may account for this change?

- 1- Allopurinol
- 2- Amiodarone
- 3- Clarithromycin
- 4- Sertraline
- 5- St John's wort

Answer & Comments

Answer: 5- St John's wort

The metabolism of warfarin has been increased since it is becoming less effective.

St John's wort is an enzyme inducer.

The other drugs are enzyme inhibitors.

[Q: 2815] OnExamination 2012 - Clinical pharmacology

A 52-year-old man has been started on regular diclofenac for back pain. He is concerned as over the past few days he has been suffering from deteriorating vision.

On examination his BP is 142/82 mmHg, pulse is 72 and regular. There is bilateral decreased visual acuity and loss of colour vision. The rest of the neurological examination is unremarkable.

Which of the following is most likely to have occurred?

- 1- Cataract formation
- 2- Closed angle glaucoma
- 3- Open angle glaucoma
- 4- Optic neuritis
- 5- Retinal detachment

Answer & Comments

Answer: 4- Optic neuritis

Optic neuritis is described as being rarely associated with diclofenac therapy. A range of other CNS side effects has also been noted on the summary of product characteristics, these include headache, dizziness, vertigo and in rare circumstances drowsiness.

Cataract formation would not lead to loss of colour vision or to a sudden deterioration in sight over the course of a few days.

Glaucoma and retinal detachment are not thought to be associated with diclofenac treatment.

[Q: 2816] OnExamination 2012 - Clinical pharmacology

Which of the following is correct with regard to poisoning / overdose?

- 1- Aspirin causes acidosis due to hypoventilation
- 2- Chlormethiazole causes hyperthermia and hypertension
- 3- Ethylene glycol causes a metabolic alkalosis and renal failure
- 4- Methanol causes a metabolic acidosis with an increased anion gap
- 5- Phenobarbitone causes a metabolic acidosis

Answer & Comments

Answer: 4- Methanol causes a metabolic acidosis with an increased anion gap

Aspirin causes hyperventilation which may result in a respiratory alkalosis; massive overdose may cause a metabolic acidosis.

Phenobarbitone and chlormethiazole both suppress the central nervous system causing hypoventilation, hypotension and hypothermia.

Ethylene glycol causes a metabolic acidosis.

Methanol is metabolised to formaldehyde and formic acid.

[Q: 2817] OnExamination 2012 -
Clinical pharmacology

You are examining the mechanisms of various agents used in either platelet inhibition or anticoagulation in the management of cardiovascular disease.

Which of the following correctly describes a mechanism of action associated with warfarin therapy?

- 1- 2b3a receptor inhibition
- 2- Cyclo-oxygenase inhibition
- 3- P2Y12 inhibition
- 4- Reduced levels of factor X
- 5- Selective COX-2 inhibition

Answer & Comments

Answer: 4- Reduced levels of factor X

Warfarin inhibits production of factors II, VII, IX and X, and it does this by restricting the activity and availability of vitamin K. This accounts for vitamin K administration being the treatment for warfarin toxicity.

2b3a receptor inhibitors are used in the treatment of acute coronary syndrome and they inhibit platelet aggregation.

P2Y12 is an adenosine diphosphate (ADP) dependent receptor involved in platelet aggregation which is inhibited by clopidogrel.

Cyclo-oxygenase inhibition is the mechanism of action of aspirin.

Selective COX-2 inhibitors have fallen out of favour due to potential increased risk of cardiovascular events.

[Q: 2818] OnExamination 2012 -
Clinical pharmacology

A 45-year-old woman presents to the oncology clinic with metastatic carcinoma of the breast.

She wants to take an active role in deciding on the optimal chemotherapy regime for herself, and wants to discuss the relative advantages of capecitabine versus 5-fluorouracil (5-FU).

What would you advise her about capecitabine?

- 1- Can be orally administered
- 2- Has a greater period of progression free survival than 5-FU
- 3- Is associated with less blood dyscrasias than 5-FU
- 4- Is not dependent on renal function
- 5- Is not usually associated with diarrhoea

Answer & Comments

Answer: 1- Can be orally administered

The major difference between capecitabine and 5-FU is that capecitabine is an oral prodrug of 5-FU. The final step in metabolism to 5-FU is thymidine phosphorylase, higher activity of thymidine phosphorylase occurring in tumour tissues.

Evidence suggests that efficacy of capecitabine versus 5-FU is broadly similar, with minor, insignificant differences occurring in progression free survival in comparative studies across a range of primary tumour types.

Whilst activation of capecitabine to 5-FU occurs after a number of steps, metabolites are still renally excreted, so in this sense, no significant advantage over 5-FU is conferred.

[Q: 2819] OnExamination 2012 -
Clinical pharmacology

A patient is suspected of having taken a substance with anticholinesterase effects.

Which of the following combinations of signs, if present, would be the most likely to confirm this effect?

- 1- Bradycardia and miosis

- 2- Bradycardia and mydriasis
- 3- Bradycardia and urinary retention
- 4- Tachycardia and diarrhoea
- 5- Tachycardia and lacrimation

Answer & Comments

Answer: 1- Bradycardia and miosis

An acetylcholinesterase inhibitor or anti-cholinesterase is a chemical that inhibits the cholinesterase enzyme from breaking down acetylcholine (ACh), so increasing both the level and duration of action of the neurotransmitter acetylcholine.

ACh can stimulate postganglionic receptors to produce effects such as salivation, lacrimation, defecation, micturition, sweating, miosis, bradycardia, and bronchospasm. Muscarine produces these effects, and hence they are referred to as muscarinic effects, and the postganglionic receptors are called muscarine receptors. (eMedicine)

SLUD (salivation, lacrimation, urination, defecation [and emesis]) is a syndrome of pathological effects indicative of massive discharge of the parasympathetic nervous system.

Unlikely to occur naturally, SLUD is usually encountered only in cases of drug overdose or exposure to nerve gases. Nerve gases irreversibly inhibit the enzyme acetylcholinesterase; this results in a chronically high level of acetylcholine at cholinergic synapses throughout the body, thus chronically stimulating acetylcholine receptors throughout the body.

[Q: 2820] OnExamination 2012 - Clinical pharmacology

A 60-year-old female suffers from bipolar affective disorder and is being treated with lithium. She also has a long history of hypertension for which she is on treatment.

During a recent clinic visit her blood pressure was noted to be 170/94 mmHg and a new antihypertensive agent was added. A week later she presents with features of lithium toxicity including tremor, nausea and weakness.

The addition of which one of the following drugs was likely to have precipitated the lithium toxicity?

- 1- Doxazosin
- 2- Hydralazine
- 3- Lisinopril
- 4- Minoxidil
- 5- Moxonidine

Answer & Comments

Answer: 3- Lisinopril

The precipitation of lithium toxicity by diuretics is well appreciated. Yet ACE inhibitors [log-in required for full text] and angiotensin antagonists are also capable of precipitating lithium toxicity through reduced lithium clearance.

Other drugs that may precipitate lithium toxicity include

NSAIDs

Tetracycline

Phenytoin

Ciclosporin.

[Q: 2821] OnExamination 2012 - Clinical pharmacology

Which of the following antiemetics functions through inhibition of neurokinin (NK) 1 receptor?

- 1- Aprepitant
- 2- Domperidone
- 3- Hyoscine
- 4- Granisetron

5- Ondansetron

Answer & Comments

Answer: 1- Aprepitant

Aprepitant is a neurokinin receptor blocker used in the prevention of chemotherapy induced nausea.

Ondansetron and granisetron are 5HT₃ antagonists.

Hyoscine is an anticholinergic/antihistaminergic.

Domperidone is an antidopaminergic agent.

[Q: 2822] OnExamination 2012 - Clinical pharmacology

A middle-aged lady presents with cervical and inguinal lymphadenopathy. She is also experiencing pins and needles in a glove and stocking distribution, and has gum hypertrophy. She has a previous history of epilepsy and is on regular medication.

Which of the following drugs is most likely to cause her symptoms?

- 1- Carbamazepine
- 2- Phenobarbitone
- 3- Phenytoin
- 4- Sodium valproate
- 5- Vigabatrin

Answer & Comments

Answer: 3- Phenytoin

Recognised side effects of phenytoin include

Drowsiness

Ataxia

Confusion

Blurred vision

Dizziness

Nystagmus

Permanent cerebellar ataxia

Peripheral neuropathy

Rashes

Gum hypertrophy

Thickening of the facial features

Lymphadenopathy

Chorea

Sleep disturbance.

Remarkable side effects of other anti-epileptic drugs are:

Drowsiness

Blurred vision

Dizziness

Leukopenia

SIADH and rash (carbamazepine)

Liver toxicity (sodium valproate)

Severe rash (lamotrigine)

Retinal damage (vigabatrin)

Aplastic anaemia (felbamate).

[Q: 2823] OnExamination 2012 - Clinical pharmacology

Which term best describes the affinity of a drug for its receptor?

- 1- Efficacy
- 2- Intrinsic activity
- 3- Potency
- 4- Selectivity
- 5- Therapeutic effect

Answer & Comments

Answer: 3- Potency

Affinity is the measure of the net molecular attraction between a drug (or neurotransmitter or hormone) and its receptor.

The receptor's affinity for binding a drug determines the concentration of drug required to form a significant number of drug-receptor complexes.

Affinity and intrinsic activity are determinants of potency.

Efficacy contributes both to potency and to the maximum effect of the agonist. Efficacy is a measure of the efficiency of the drug-receptor complex in initiating the signal transduction process.

[Q: 2824] OnExamination 2012 - Clinical pharmacology

A 16-year-old female is admitted with a severe paracetamol overdose. She is treated with IV N-acetylcysteine (NAC).

By replenishing which of the following compounds does N-acetylcysteine function as an antidote in paracetamol overdose?

- 1- Arginine
- 2- Cysteine
- 3- Cystine
- 4- Glutathione
- 5- Methionine

Answer & Comments

Answer: 4- Glutathione

Paracetamol is predominantly metabolised to glucuronide and sulphate conjugates, which are excreted in the urine.

Hepatotoxicity is related to the conversion of a small proportion of the ingested dose to N-acetyl-p-benzoquinoneimine.

In therapeutic doses N-acetyl-p-benzoquinoneimine is detoxified by

conjugation with glutathione in the liver, but once the protective intracellular glutathione stores are depleted hepatic and renal damage may ensue.

NAC and methionine replenishes glutathione stores in the liver and may also act through its sulphhydryl (-SH) group as a direct reducing agent.

[Q: 2825] OnExamination 2012 - Clinical pharmacology

A 60-year-old retired nurse with idiopathic Parkinson's disease presented with motor oscillations and on-off periods.

She had received co-beneldopa for five years. Selegiline was added to her treatment.

On which one of the following enzymes does selegiline act to cause this adjuvant action?

- 1- Catechol-o-methyltransferase
- 2- Dopa decarboxylase
- 3- Dopamine hydroxylase
- 4- Monoamine oxidase
- 5- Tyrosine hydroxylase

Answer & Comments

Answer: 4- Monoamine oxidase

Selegiline is a MAO-B inhibitor.

[Q: 2826] OnExamination 2012 - Clinical pharmacology

You are asked to see a 42-year-old man who complains of a cough at night. He also tells you that he has wheeze when he has a cold, and he smokes 20 cigarettes per day. He works as a landscaper on a housing development.

On examination his BP is 152/91 mmHg, his pulse is 70 and his BMI is 21. There is no significant wheeze.

You assess him at intermediate risk of having a diagnosis of asthma.

According to BTS guidelines, which FEV₁/FVC ratio triggers asthma therapy?

- 1- 0.5
- 2- 0.6
- 3- 0.7
- 4- 0.8
- 5- 0.9

Answer & Comments

Answer: 3- 0.7

Features described by the BTS guidelines as increasing the likelihood of asthma include

Worse symptoms at night and in the early morning

Nocturnal cough or wheeze

Symptoms after exercise

Allergen exposure

Beta blockers or

Aspirin.

A history of asthma or atopy in the family and wheeze on examination also increase the likelihood of an asthma diagnosis.

Prominent dizziness or tingling of the hands and feet associated with shortness of breath may be a pointer towards hyperventilation, and chronic cough without wheeze is also a pointer against a diagnosis of asthma.

Where the FEV₁/FVC is greater than 0.7, referral for specialist advice is recommended if significant chest disease is suspected.

2011 Asthma guidelines

[Q: 2827] OnExamination 2012 - Clinical pharmacology

Which of the following is not a cause of drug-induced hepatitis?

- 1- Amiodarone

- 2- Ethambutol
- 3- Isoniazid
- 4- Methyldopa
- 5- Pyrazinamide

Answer & Comments

Answer: 2- Ethambutol

Side effects of ethambutol are largely confined to visual disturbances in the form of

Loss of acuity

Colour blindness

Restriction of visual fields.

It does not cause hepatitis and is renally excreted.

Causes of drug-induced hepatitis include

Isoniazid

Amiodarone

Pyrazinamide

Methyldopa.

[Q: 2828] OnExamination 2012 - Clinical pharmacology

A 17-year-old boy is diagnosed with asthma and comes to the clinic for review. He is currently managed with 100 mcg BD of inhaled beclomethasone and salbutamol PRN.

His mother wants to enrol him in a class teaching the Buteyko technique.

What would you advise about its success?

- 1- It is associated with improved FEV₁
- 2- It is associated with improved FVC
- 3- It is associated with improved symptoms
- 4- It should not be recommended to adults who require inhaled steroids
- 5- Patients enrolled tend to use more short acting beta agonists

Answer & Comments

Answer: 3- It is associated with improved symptoms

The Buteyko technique controls chronic hyperventilation, as such patients perceive less symptoms of shortness of breath, and their use of short acting bronchodilators is reduced.

This does not however have any impact on lung function including FEV₁ and FVC.

It may be particularly valuable in patients who complain of symptoms of shortness of breath significantly in excess of those expected when you review their lung function.

British Thoracic Society's asthma guidelines

[Q: 2829] OnExamination 2012 - Clinical pharmacology

A mother brings her 3-year-old child to the casualty department because she is complaining of earache. You collect her from the waiting room where she is happily playing with toys. This is the second episode over the past year.

On examination her temperature is 37.4°C and her right ear drum is pink and bulging consistent with otitis media.

According to the SIGN national guidelines, how will you manage the child?

- 1- Advise paracetamol and or ibuprofen to relieve her pain
- 2- Prescribe clarithromycin for the child and advise her to start it immediately
- 3- Prescribe penicillin V for the child and advise she starts it immediately
- 4- Prescribe penicillin V for the child and advise she starts it in 24 hours if the pain does not improve
- 5- Refer to the ENT surgeons as this is the second episode

Answer & Comments

Answer: 1- Advise paracetamol and or ibuprofen to relieve her pain

Advise her to take paracetamol and or ibuprofen to relieve her pain.

SIGN guidelines point out that in children without significant systemic features of infection such as fever and generalised illness apart from pain, there is no significant benefit of antibiotics. The guidelines state that if all children were treated with antibiotics, then the number needed to treat (NNT) would be 17 to avoid one clinical failure.

Unfortunately practice in the management of otitis media in children varies considerably in children across the world, from 31% in the Netherlands to 98% in the USA and Australia.

Additionally, for a very common condition, the number of well conducted clinical trials is small. This is one area which could have benefited from better randomised controlled trials of antibiotics at the outset, but on available evidence, rationalisation of antibiotic use to guard against the development of resistance is sensible.

Reference:

<http://www.sign.ac.uk/guidelines/fulltext/66/section3.html>

[Q: 2830] OnExamination 2012 - Clinical pharmacology

A 68-year-old man with a history of type 2 diabetes, chronic renal failure and epilepsy is admitted to the emergency department with anorexia, nausea, and increasing lethargy.

He also developed tremor and nystagmus, with truncal ataxia and strange choreoathetoid movements. He takes BD mixed insulin for his diabetes, phenytoin for his epilepsy, ramipril and amlodipine for his hypertension.

On examination his BP is 159/88 mmHg, his pulse is 90. He has bilateral crackles on

auscultation of his chest consistent with fluid overload.

Investigations show

Haemoglobin 10.5 g/dl(13.5-17.7)

White cells $7.8 \times 10^9/L$ (4-11)

Platelets $182 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 5.7 mmol/l (3.5-5)

Creatinine 231 $\mu\text{mol/l}$ (79-118)

HbA1c 53 mmol/mol(<35)

Phenytoin levels Within the therapeutic range

Which of the following is the most likely reason for his phenytoin toxicity?

- 1- Decreased GI absorption of phenytoin
- 2- Decreased hydroxylation of phenytoin
- 3- Decreased protein binding of phenytoin
- 4- Increased protein binding of phenytoin
- 5- Increased renal cycling of phenytoin metabolites

Answer & Comments

Answer: 3- Decreased protein binding of phenytoin

This patient has renal failure, a state in which drugs that are usually highly protein bound, such as phenytoin, lose some of their affinity for protein binding. This results in increased availability of free drug at any given dose, which then increases the risk of toxicity.

Because laboratory assays for phenytoin usually measure total drug concentration, this gives a degree of false reassurance.

In patients with renal failure, dose reduction of phenytoin is therefore required.

Other drugs where this may be a problem include sodium valproate and warfarin.

[Q: 2831] OnExamination 2012 - Clinical pharmacology

A 45-year-old publican is brought to the Emergency department by ambulance.

He is extremely agitated and says that he can see a number of dogs at the door of the side room and they are barking fiercely. On further questioning his wife tells you that he drinks some eight to ten pints of beer and glasses of wine and whisky each day. They have recently had an argument about his drinking and he has not touched any alcohol for the past 12-18 hours.

On examination he is agitated and sweating, his BP is 145/84 mmHg, his pulse is 85 and regular. He has changes consistent with chronic liver disease and is tender in the right upper quadrant of his abdomen.

Investigations show:

Haemoglobin 10.1 g/dl(13.5-17.7)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $151 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 92 IU/l (5-40)

Bilirubin 54 $\mu\text{mol/l}$ (<17)

Which of the following is the most likely diagnosis?

- 1- Alcoholic hallucinosis
- 2- Delirium tremens
- 3- Hypomanic episode
- 4- Minor alcohol withdrawal symptoms
- 5- Stimulant overdose

Answer & Comments

Answer: 1- Alcoholic hallucinosis

Alcoholic hallucinosis is known to appear some 12-24 hours after the last alcoholic drink

has been taken and hallucinations may be visual, auditory or tactile in nature.

More minor withdrawal symptoms which patients experience may include

A degree of agitation and restlessness

Sweating

Nausea and vomiting

Feelings of depression.

Withdrawal seizures are seen 24-48 hours after alcohol withdrawal, and two to three days after stopping drinking withdrawal delirium (delirium tremens 'DTs') is seen.

Management includes the use of anti-withdrawal medication such as chlordiazepoxide, and thiamine replacement.

[Q: 2832] OnExamination 2012 - Clinical pharmacology

A 28-year-old car mechanic is admitted to the hospital having taken an overdose of methanol after splitting up from his wife.

On admission to the Emergency department he is drowsy and intoxicated. His BP is 134/82 mmHg, and he has a tachycardia with a pulse of 95.

Investigations show:

Haemoglobin 14.0 g/dl (13.5-17.7)

White cell count $8.1 \times 10^9/L$ (4-11)

Platelets $190 \times 10^9/L$ (150-400)

Serum Sodium 137 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Bicarbonate 17 mmol/l (22-30)

Creatinine 130 $\mu\text{mol/l}$ (79-118)

Which of the following is the most appropriate antidote for methanol poisoning?

1- Atenolol

2- Ethanol

3- Glucagon

4- Insulin

5- Polyethylene glycol

Answer & Comments

Answer: 2- Ethanol

Methanol, like ethanol, is metabolised by alcohol dehydrogenase to form formaldehyde. Formaldehyde is then further metabolised by aldehyde dehydrogenase to formic acid.

Formate formation leads to a severe metabolic acidosis, and crystals forming within the eye can lead to so called 'snow field' cataract formation.

Inhibition of metabolism of methanol by alcohol dehydrogenase with either ethanol or fomepizole is the treatment of choice.

[Q: 2833] OnExamination 2012 - Clinical pharmacology

A 38-year-old man is admitted with an hour history of chest pain, confusion and agitation after taking a recreational drug.

On examination, he is confused, has a temperature of 38.3°C and a blood pressure of 188/102 mmHg.

Which of the following drugs is most likely to be responsible for his presentation?

1- Cocaine

2- Ecstasy (MDMA)

3- Gamma hydroxybutyrate (GHB)

4- LSD

5- Opiates

Answer & Comments

Answer: 1- Cocaine

In this scenario, the young male presents with confusion and agitation following drug abuse.

The most likely agent is cocaine.

Through central effects, cocaine induces sweating, pyrexia and also adrenergic mediated hypertension.

It may also be responsible for coronary and cerebral artery spasm causing chest pain and/or infarction.

The main differential for this question would be ecstasy however cocaine is far more likely to present with chest pain and in this age group.

[Q: 2834] OnExamination 2012 - Clinical pharmacology

A 58-year-old male presents with painful breast tissue.

Six weeks previously he was treated for atrial fibrillation and had a number of drugs commenced.

Which one of the following drugs may have caused this problem?

- 1- Aspirin
- 2- Digoxin
- 3- Flecainide
- 4- Spironolactone
- 5- Warfarin

Answer & Comments

Answer: 4- Spironolactone

Digoxin may cause gynaecomastia but usually only on prolonged use.

Spironolactone is well known to cause gynaecomastia due to its well described anti-androgen effects.

[Q: 2835] OnExamination 2012 - Clinical pharmacology

A 70-year-old man presents with an episode of syncope.

On subsequent investigation he is found to have marked postural hypotension. He has

been taking felodipine for hypertension for a number of years and he also takes aspirin. On further questioning he appears to have taken up a new healthier lifestyle on his seventieth birthday.

Which of the following health supplements is he most likely to have taken that would have contributed to the calcium-channel blocker induced hypotension?

- 1- Cod liver oil capsules
- 2- Cranberry juice
- 3- Ginseng
- 4- Grapefruit juice
- 5- Vitamin C

Answer & Comments

Answer: 4- Grapefruit juice

Grapefruit juice interacts with drugs.

The basis for this interaction has been diligently explored and appears to relate to both flavanoid and nonflavanoid components of grapefruit juice interfering with enterocyte CYP3A4 activity.

Of the calcium channel blockers felodipine in particular is affected.

Am J Hypertens (2006) 19: 768-73

[Q: 2836] OnExamination 2012 - Clinical pharmacology

A 30-year-old patient with learning difficulties is admitted as a medical emergency.

The patient complains of headache, anorexia and vomiting.

On examination she is febrile with a temperature of 38°C, pulse 110 bpm and is clinically jaundiced.

Investigations reveal:

Bilirubin 60 µmol/L (1-22)

Albumin 28 g/L (37-49)

AST 400 IU/L(5-40)

Alkaline phosphatase 400 IU/L(45-105)

Prothrombin time 35 seconds(<14)

She was commenced on a new medication within the last three months.

Which do you suspect may be contributing to the presentation?

- 1- Cabergoline
- 2- Carbamazepine
- 3- Lamotrigine
- 4- Metformin
- 5- Sodium valproate

Answer & Comments

Answer: 5- Sodium valproate

Sodium valproate can occasionally have an idiosyncratic response leading to severe or even fatal hepatic toxicity.

This is more common if the patient has a metabolic or degenerative disorder, organic brain disease or severe seizures associated with mental retardation. Usually this reaction occurs within the first three months of therapy.

Carbamazepine can be associated with jaundice occasionally, however the history of mental retardation and short history of drug use point to sodium valproate as the cause.

Lamotrigine can disrupt liver function tests (LFTs).

Metformin and cabergoline do not affect liver function however caution is advised when using these drugs in patients with hepatic disease.

[Q: 2837] OnExamination 2012 - Clinical pharmacology

A 72-year-old woman comes to the emergency department complaining of nausea and vomiting. Apparently she saw the on-call

GP a few days earlier and was prescribed clarithromycin for a respiratory tract infection.

Past medical history of note includes COPD for which she takes high dose Seretide, tiotropium and oral theophylline, ischaemic heart disease for which she takes ramipril, amlodipine and indapamide and chronic renal failure.

On examination her BP is 132/70 mmHg, and her pulse is 105 (atrial fibrillation). She has bibasal crackles consistent with mild LVF.

Investigations show

Haemoglobin 11.4 g/dl11.5-16.5

White cell count $7.0 \times 10^9/L$ 4-11

Platelets $197 \times 10^9/L$ 150-400

Serum Sodium 139 mmol/l135-146

Serum Potassium 4.0 mmol/l3.5-5

Creatinine 145 $\mu\text{mol/l}$ 79-118

Which of the following medications is likely to have resulted in her presentation?

- 1- Amlodipine
- 2- Indapamide
- 3- Ramipril
- 4- Theophylline
- 5- Tiotropium

Answer & Comments

Answer: 4- Theophylline

Clarithromycin is a potent inhibitor of CYP3A4, and as such may interfere significantly with metabolism of a number of medications, including theophylline, simvastatin, and cyclosporine as the most important drug interactions.

The effect of warfarin and digoxin may also be potentiated by clarithromycin.

<http://www.medicines.org.uk/emc/medicine/16945/SPC/#INTERACTIONS>

[Q: 2838] OnExamination 2012 -
Clinical pharmacology

A 33-year-old woman with a history of alcoholism and self-neglect, presents with an episode of blood streaked vomiting. This is attributed to minor Mallory-Weiss tear.

She is admitted to hospital and given an intravenous infusion of 5% dextrose. Her serum potassium concentration is noted the following day to have fallen to 1.9 mmol/L (3.5-4.9) on admission.

What is the likely mechanism for the fall in potassium concentration?

- 1- Cortisol release in response to stress increasing renal potassium loss
- 2- Decompensated liver failure causing aldosterone secretion
- 3- Intracellular re-uptake in response to re-feeding with glucose
- 4- Metabolic acidosis increasing renal potassium excretion
- 5- Potassium levels falling following gastric loss in vomiting

Answer & Comments

Answer: 3- Intracellular re-uptake in response to re-feeding with glucose

This neglected person is being fed with dextrose, which will cause an elevation of circulating insulin to maintain glycaemic control.

This will consequently drive potassium intracellularly so reducing extracellular potassium concentration.

[Q: 2839] OnExamination 2012 -
Clinical pharmacology

A 64-year-old gentleman consults you in clinic because he is having trouble putting his shoes on due to swelling.

He has COPD, hypertension and angina.

Which medication is likely to be causing this problem?

- 1- Diltiazem
- 2- Eplerenone
- 3- Isosorbide mononitrate
- 4- Nicorandil
- 5- Propranolol

Answer & Comments

Answer: 1- Diltiazem

Diltiazem, as with nearly all the calcium channel blockers, causes gravitational/ankle oedema.

Eplerenone is an aldosterone antagonist and therefore is used to treat ankle oedema.

Isosorbide mononitrate commonly causes headaches and hypotension.

Nicorandil rarely causes angioedema, but not ankle swelling.

Propranolol does not cause ankle oedema although it may worsen decompensated heart failure, so is usually avoided until the patient has been diuresed appropriately.

[Q: 2840] OnExamination 2012 -
Clinical pharmacology

A 72-year-old woman comes to the Emergency department.

She takes warfarin, an anticoagulant for chronic atrial fibrillation, and is usually on a stable warfarin dose of 5 mg every morning. She has had a number of trips to the GP over past weeks for management of her hypertension, a respiratory tract infection, and for treatment of depression.

On examination her BP is 142/72 mmHg, her pulse is 80 bpm and regular, she has extensive bruising over her arms and legs.

Investigations show:

Haemoglobin 13.1 g/dl 11.5-16.5

White cell count $8.1 \times 10^9/L$ 4-11

Platelets $160 \times 10^9/L$ 150-400

Serum Sodium 140 mmol/l 135-146

Serum Potassium 4.7 mmol/l 3.5-5

Creatinine 106 $\mu\text{mol/l}$ 79-118

INR 6.12-3

Which of the following medications is most likely to have caused an increased propensity to bruising?

- 1- Azithromycin
- 2- Digoxin
- 3- Fluoxetine
- 4- Ramipril
- 5- Simvastatin

Answer & Comments

Answer: 3- Fluoxetine

Warfarin is subject to both pharmacodynamic and pharmacokinetic interactions which may lead to increased INR.

Pharmacodynamic interactions are those which may increase the propensity to bleeding without actually altering the absorption, metabolism, distribution or excretion of warfarin. Examples include concomitant use of clopidogrel or aspirin in combination with warfarin, or concomitant use of acute therapies like 2b3a receptor antagonists.

Pharmacokinetic interactions are those which impact on the absorption, metabolism, distribution or excretion of the drug.

Fluoxetine is a CYP450 enzyme inhibitor. Both inhibitors and inducers of CYP450 enzymes may lead to changes in the anti-coagulant effect of warfarin.

Co-prescription of antibiotics often inadvertently leads to increases in INR; examples of antibiotic P450 inhibitors include clarithromycin and erythromycin.

[Q: 2841] OnExamination 2012 - Clinical pharmacology

A 71-year-old man with a history of hypertension, type 2 diabetes and erectile dysfunction comes to the clinic for review complaining of blue vision.

He takes amlodipine and ramipril for hypertension, digoxin for atrial fibrillation, sitagliptin and metformin for diabetes, and sildenafil for erectile dysfunction.

Which of the following is most likely to be responsible for his blue vision?

- 1- Amlodipine
- 2- Digoxin
- 3- Metformin
- 4- Sildenafil
- 5- Sitagliptin

Answer & Comments

Answer: 4- Sildenafil

Digoxin is associated with yellow/green visual disturbance.

Sildenafil is a PDE-5 inhibitor, but at high dose it inhibits the activity of PDE-6, which is essential for the functioning of retinal rods cells. Inhibition of the enzyme leads to patients reporting blue tinged vision, particularly in low light conditions.

The condition may be improved by reducing the dose of sildenafil, but of course this may limit efficacy with respect to improving erectile dysfunction.

[Q: 2842] OnExamination 2012 - Clinical pharmacology

A 24-year-old female who has previously suffered with severe depression presents with secondary amenorrhoea.

She is found to have a prolactin of 645 mU/L (normal 50-350).

Which of the drugs which she takes may cause this?

- 1- Becotide
- 2- Montelukast
- 3- Omeprazole
- 4- Risperidone
- 5- Sertraline

Answer & Comments

Answer: 4- Risperidone

Antipsychotic medications are known to elevate prolactin levels, due to dopamine antagonist effects.

Sertraline is not thought to exert dopamine antagonist effects and thus does not result in hyperprolactinaemia.

The other medications on her list have not been associated with hyperprolactinaemia.

[Q: 2843] OnExamination 2012 - Clinical pharmacology

A 48-year-old man is admitted with nausea and excessive drowsiness after taking an antihistamine tablet. He has previously used the antihistamine but on this occasion he has recently been drinking large amounts of grapefruit juice for his health.

Grapefruit juice is suspected of causing a drug interaction in this man.

Which of the following liver enzyme systems is affected by grapefruit juice?

- 1- Cytochrome p450 3A4
- 2- Glucuronidation
- 3- Glutathione S-transferase
- 4- Glycine decarboxylase
- 5- Sulfation

Answer & Comments

Answer: 1- Cytochrome p450 3A4

Bergamottin is a constituent of grapefruit juice and is metabolised by the cytochrome p450 3A4 pathway.

[Q: 2844] OnExamination 2012 - Clinical pharmacology

Which of the following are centrally acting antihypertensive therapies?

- 1- Hydralazine
- 2- Minoxidil
- 3- Moxonidine
- 4- Phenoxybenzamine
- 5- Verapamil

Answer & Comments

Answer: 3- Moxonidine

Moxonidine and alpha-methyl dopa are centrally acting antihypertensives and modify blood pressure through central action modifying sympathetic activity.

Verapamil is a calcium antagonist, minoxidil and hydralazine both vasodilators and phenoxybenzamine an alpha blocker.

[Q: 2845] OnExamination 2012 - Clinical pharmacology

Which of the following pharmacological agents acts through the opening of potassium channels?

- 1- Amiloride
- 2- Glibenclamide
- 3- Lidocaine
- 4- Nicorandil
- 5- Phenytoin

Answer & Comments

Answer: 4- Nicorandil

Nicorandil is a potent potassium channel activator. It relaxes vascular smooth muscle

through membrane hyperpolarisation via increased transmembrane potassium conductance and, like nitrates, through an increase in intracellular cyclic guanosine monophosphate (GMP).

Glibenclamide blocks potassium channels.

Amiloride inhibits the action of aldosterone on the distal convoluted tubule producing potassium reabsorption.

[Q: 2846] OnExamination 2012 - Clinical pharmacology

A 22-year-old male is admitted after drinking engine coolant in an apparent suicide attempt after finding his wife in bed with the postman.

Investigations reveal:

pH 7.1(7.36-7.44)

pO₂ 15.3 kPa(11.3-12.6)

pCO₂ 3.2 kPa(4.7-6.0)

Standard Bicarbonate 2.2 mmol/L(20-28)

Serum calcium 1.82 mmol/L(2.2-2.6)

After replacing calcium which of the following is the most urgent treatment for this man?

- 1- 8.4% bicarbonate infusion
- 2- Alcohol infusion
- 3- Fomepizole infusion
- 4- Gastric lavage
- 5- Haemodialysis

Answer & Comments

Answer: 1- 8.4% bicarbonate infusion

Engine coolant contains ethylene glycol. Ingestion of as little as 30-60 ml is capable of causing death.

Traditional management of poisoning includes the use of ethanol, with or without haemodialysis.

Activated charcoal is not indicated and gastric lavage may be beneficial only in the first hour after ingestion.

However fomepizole has recently been approved for use and is a competitive inhibitor of alcohol dehydrogenase. However it is very expensive and the evidence supporting its use over alcohol is lacking. Also, this patient already has a severe metabolic acidosis.

In these circumstances, antidotal therapy to block alcohol dehydrogenase with ethanol or 4-MP alone is insufficient to treat the poisoning. Data suggest that a severe lactic acidosis needs initial correction and in this patient the most appropriate treatment would be IV fluids with bicarbonate to correct the metabolic acidosis.

Then haemodialysis is probably required.

[Q: 2847] OnExamination 2012 - Clinical pharmacology

A 42-year-old man presents with gingival hypertrophy.

Which of his cardiac medications is likely to be responsible?

- 1- Amlodipine
- 2- Atenolol
- 3- Digoxin
- 4- GTN
- 5- Simvastatin

Answer & Comments

Answer: 1- Amlodipine

Calcium channel blockers and drugs like phenytoin and cyclosporin are associated with gingival hypertrophy.

[Q: 2848] OnExamination 2012 -
Clinical pharmacology

A 76-year-old man is reviewed in clinic having recently been diagnosed with severe heart failure (HF) associated with very limiting breathlessness. He was formerly a heavy smoker with a medical history of COPD. His lung function test demonstrates mild to moderate obstructive airways disease and he has 5% airways reversibility.

On clinical examination his heart rate is 95 bpm and BP 156/90 mmHg. No wheeze is present. He has an elevated JVP +5 cms but no clinical signs of fluid congestion. He is already taking aspirin 75 mg od, ramipril 10 mg od, furosemide 40 mg od and simvastatin 40 mg nocte.

You decide to add in a beta-blocker as the next step.

Which would be the most appropriate choice?

- 1- Atenolol 25 mg od
- 2- Bisoprolol 5 mg od
- 3- Bisoprolol 1.25 mg od
- 4- Carvedilol 6.25 mg bd
- 5- Carvedilol 12.5 mg bd

Answer & Comments

Answer: 3- Bisoprolol 1.25 mg od

NICE recommends β blockers in all HF patients.

In chronic obstructive pulmonary disease (COPD) patients with HF, cardioselective β blockers appear safer at lower doses than higher doses or non-selective β blockers (refs in DTB article).

Bisoprolol 5 mgs is too high an initial starting dose, a low dose can always be titrated up later, if tolerated.

Carvedilol though effective treatment for heart failure is not selective and therefore

carries a greater risk of causing bronchospasm.

Atenolol though cardioselective has no clinical evidence for prognostic benefit in heart failure.

The patient should be closely monitored for deterioration in lung function post-administration.

[Q: 2849] OnExamination 2012 -
Clinical pharmacology

A 63-year-old female presents with dry mouth of three months duration.

She is taking medication for hypertension, stress incontinence and reflux oesophagitis.

Which of the following may be responsible for her dry mouth?

- 1- Bendroflumethiazide
- 2- Cimetidine
- 3- Doxazosin
- 4- Hydralazine
- 5- Oxybutinin

Answer & Comments

Answer: 5- Oxybutinin

Oxybutinin is an effective treatment for detrusor instability and is a parasympathetic muscarinic antagonist. Consequently dry mouth is a problem in up to 70% of cases.

Bendroflumethiazide, the thiazide diuretic, at a dose of 2.5 mg per day is not associated with dry mouth.

Cimetidine is an H₂ antagonist and is not associated with dry mouth.

[Q: 2850] OnExamination 2012 -
Clinical pharmacology

A 42-year-old woman was taking an antibiotic for a urinary tract infection when she suffered a left Achilles tendon rupture whilst playing

badminton. She is very fit, exercising and doing stretching work up to four times per week, and feels the antibiotic may have been responsible.

Which of the following antibiotics is the most likely cause?

- 1- Amoxicillin
- 2- Cephalexin
- 3- Co-amoxiclav
- 4- Ofloxacin
- 5- Trimethoprim

Answer & Comments

Answer: 4- Ofloxacin

The whole class of quinolone antibiotics is associated with case reports of tendon rupture. This may in part be related to decreased cellular proliferation and tendon fibroblast turnover.

In animal models where quinolones are continued post tendon rupture, it is associated with delayed healing.

Juvenile toxicity models also show increased rates of tendon abnormalities, and for this reason use of quinolones is not recommended in children or in pregnancy.

[Q: 2851] OnExamination 2012 - Clinical pharmacology

A 75-year-old patient being treated for heart failure presents with hyperkalaemia, the potassium being 6.9 mmol/l (NR 3.5-5.0).

He was recently commenced on amiloride.

The interaction of amiloride with which of his drugs listed below is likely to have caused the hyperkalaemia?

- 1- Bisoprolol
- 2- Digoxin
- 3- Metolazone
- 4- Perindopril

5- Warfarin

Answer & Comments

Answer: 4- Perindopril

The co-administration of a potassium-sparing diuretic and an ACE inhibitor, in this case perindopril, may result in profound hyperkalaemia as has occurred in this patient.

Thus patients on both these drugs should have their potassium monitored closely.

Metolazone may result in profound hypokalaemia.

[Q: 2852] OnExamination 2012 - Clinical pharmacology

This symbol appears next to a drug in the BNF.

What does this signify?

- 1- A drug less suitable for prescribing
- 2- A drug that requires closer surveillance for possible side effects
- 3- Controlled drug
- 4- Over the counter medication
- 5- Prescription only therapy

Answer & Comments

Answer: 1- A drug less suitable for prescribing

This symbol indicates those preparations that are considered by the Joint Formulary Committee to be less suitable for prescribing.

Although such preparations may not be considered first choice agents their use may be justifiable in certain circumstances.

[Q: 2853] OnExamination 2012 - Clinical pharmacology

This symbol appears next to a drug that you have looked up in the BNF:

What does this signify?

- 1- Not available for prescription on the NHS

- 2- Not recommended for NHS use
- 3- Only available for specialist use and not for the wider NHS use
- 4- Over the counter only therapy
- 5- Specialist licence required for prescription on the NHS

Answer & Comments

Answer: 1- Not available for prescription on the NHS

This symbol signifies that the drug is not available for NHS prescription but may be available as a private script.

[Q: 2854] OnExamination 2012 - Clinical pharmacology

Which of the following antiemetics functions as a cholinergic muscarinic antagonist?

- 1- Aprepitant
- 2- Domperidone
- 3- Hyoscine
- 4- Metoclopramide
- 5- Ondansetron

Answer & Comments

Answer: 3- Hyoscine

Scopolamine is named after the genus Scopolia.

The name 'hyoscine' is from the scientific name for henbane, Hyoscyamus niger.

It acts as a competitive antagonist at muscarinic acetylcholine receptors; it is thus classified as an anticholinergic or as an antimuscarinic drug.

[Q: 2855] OnExamination 2012 - Clinical pharmacology

Which of the following antiemetics functions through antagonism of the 5-

hydroxytryptamine 3A receptor?

- 1- Aprepitant
- 2- Domperidone
- 3- Hyoscine
- 4- Metoclopramide
- 5- Ondansetron

Answer & Comments

Answer: 5- Ondansetron

Ondansetron is a serotonin 5-HT₃ receptor antagonist used mainly to treat nausea and vomiting following chemotherapy.

Its effects are thought to be on both peripheral and central nerves. One part is to reduce the activity of the vagus nerve, which is a nerve that activates the vomiting center in the medulla oblongata, the other is a blockage of serotonin receptors in the chemoreceptor trigger zone.

It does not have much effect on vomiting due to motion sickness.

This drug does not have any effect on dopamine receptors or muscarinic receptors.

[Q: 2856] OnExamination 2012 - Clinical pharmacology

A 17-year-old boy is admitted with a severe paracetamol overdose following an argument with his girlfriend.

He is treated with intravenous N-acetylcysteine.

Paracetamol is normally metabolised to harmless compounds except in overdose.

Which of the following compounds is the toxic metabolite that accumulates during paracetamol overdose and is reduced by treatment with N-acetylcysteine?

- 1- Glucuronide
- 2- Homocysteine
- 3- Methionine

4- N-acetyl-p-benzoquinoneimine

5- N-hydroxyacetaminophen

Answer & Comments

Answer: 4- N-acetyl-p-benzoquinoneimine

Paracetamol is predominantly metabolised to glucuronide and sulphate conjugates which are excreted in the urine.

Hepatotoxicity is related to the conversion of a small proportion of the ingested dose to N-acetyl-p-benzoquinoneimine. In therapeutic doses N-acetyl-p-benzoquinoneimine is detoxified by conjugation with glutathione in the liver, but once the protective intracellular glutathione stores are depleted hepatic and renal damage may ensue.

NAC and methionine replenish glutathione stores in the liver and may also act through its sulphhydryl (-SH) group as a direct reducing agent.

[Q: 2857] OnExamination 2012 - Clinical pharmacology

A 16-year-old female is admitted after taking an overdose of her mother's propranolol tablets approximately two hours ago.

On examination she is drowsy and has a pulse of 40 beats per minute with a blood pressure of 80/40 mmHg. She is treated with activated charcoal, IV fluids and IV atropine but her bradycardia and hypotension fail to respond.

Which of the following would be the most appropriate next stage in her management?

- 1- IV adrenaline
- 2- IV amiodarone
- 3- IV glucagon
- 4- IV phenytoin
- 5- Insertion of temporary pacemaker

Answer & Comments

Answer: 3- IV glucagon

In those in whom initial atropine is unsuccessful, IV glucagon is a recommended treatment for β -blocker overdose, with some evidence indicating improvement in bradycardia and blood pressure.

[Q: 2858] OnExamination 2012 - Clinical pharmacology

You are asked to advise on analgesia for a 44-year-old woman with acute intermittent porphyria who has undergone wisdom teeth extraction.

Which of the following drugs is safe for use in her treatment?

- 1- Cephalexin
- 2- Cetirizine
- 3- Diclofenac
- 4- Erythromycin
- 5- Ibuprofen

Answer & Comments

Answer: 5- Ibuprofen

Many drugs may induce acute porphyric crises thus great care must be taken when prescribing for patients with acute porphyria.

Drugs unsafe for use in acute porphyria include:

- Barbiturates
- Tricyclic antidepressants
- Monoamine oxidase inhibitor (MAOIs)
- Amphetamines
- Anabolic steroids
- Hormone replacement therapy
- Benzodiazepines
- Diuretics
- Captopril
- Cephalosporins
- Erythromycin
- Isoniazid
- Sulphonamides

Sulphonylureas
Theophylline
Antihistamines
Nifedipine
Verapamil
Amiodarone
Simvastatin.

Ibuprofen is safe for use in acute intermittent porphyria, but diclofenac should be avoided.

[Q: 2859] OnExamination 2012 -
Clinical pharmacology

This symbol appears next to a drug in the BNF:

What does it signify?

- 1- Clinical directive needs to be entered on the prescription to facilitate prescription
- 2- Clinically licensed practitioners only can prescribe this drug
- 3- Control dependent prescribing by licensed practitioners only
- 4- Controlled dispensing from certain pharmacies only
- 5- Controlled drug requiring licensed prescribing

Answer & Comments

Answer: 5- Controlled drug requiring licensed prescribing

The CD symbol signifies a controlled drug, that is, a substance which when requested must be on a prescription signed and dated by a qualified practitioner and specify the prescriber's address.

Also the prescriber must write in his own handwriting the name and address of the patient, the preparation; dose - the total quantity to be prescribed in figures and words; also if prescribed by a dentist then it should state 'for dental use only'.

Such substances include opiates.

[Q: 2860] OnExamination 2012 -
Clinical pharmacology

An 18-year-old woman is admitted after taking drugs at a night club.

Which of the following features suggest she had taken ecstasy (MDMA)?

- 1- A pyrexia of 40°C
- 2- Hypernatraemia
- 3- Hypokalaemia
- 4- Metabolic acidosis
- 5- Respiratory depression

Answer & Comments

Answer: 1- A pyrexia of 40°C

The following are features of the amphetamine MDMA abuse:

Hyponatraemia
Tachycardia
Hyperventilation and
Hyperthermia.

[Q: 2861] OnExamination 2012 -
Clinical pharmacology

You are discussing the optimal medication for use in a patient who needs to withdraw from heroin. He seems motivated and would like to try tablet therapy. He failed to stay clean during the last month, having used street heroin on up to five occasions.

Which of the following is the most appropriate agent for him to combat symptoms of withdrawal?

- 1- Buprenorphine
- 2- Buprenorphine and naloxone combination tablets
- 3- Codeine phosphate
- 4- Dihydrocodeine
- 5- Morphine

Answer & Comments

Answer: 2- Buprenorphine and naloxone combination tablets

Buprenorphine is a partial opiate agonist which binds mu and kappa opiate receptors in the brain. A partial agonist occupies and modulates the receptor without exerting the euphoric effects that would be gained by injecting IV heroin, a full agonist, because it does not exert the full effect.

Naloxone is an opioid antagonist which binds at mu opioid receptors. This means that it blocks the action of opioid agonists such as morphine.

The purpose of combining buprenorphine and naloxone for the treatment of opioid action is that it prevents addicts from achieving a high if they try to create an IV preparation from the tablets for injection.

[Q: 2862] OnExamination 2012 - Clinical pharmacology

A 53-year-old woman is started on a capecitabine based regime for the treatment of metastatic carcinoma.

Which of the following is true of capecitabine?

- 1- Diarrhoea is rarely seen with therapy
- 2- It is a way to deliver cisplatin orally
- 3- It is a way to deliver 5 fluorouracil orally
- 4- It is not effective in the treatment of colon carcinoma
- 5- Capecitabine is more effective than IV agents

Answer & Comments

Answer: 3- It is a way to deliver 5 fluorouracil orally

The answer is option C, it is a way to deliver 5 fluorouracil orally.

Capecitabine is a prodrug which is metabolised to produce 5-fluorouracil, a chemotherapeutic agent used intravenously in the treatment of cancer.

Damage to rapidly dividing cells in the gastrointestinal tract leads to symptoms of diarrhoea and vomiting as a result of capecitabine treatment.

Studies of efficacy suggest no major differences in clinical remission when capecitabine is compared to 5-fluorouracil given IV.

[Q: 2863] OnExamination 2012 - Clinical pharmacology

A patient is treated with hydralazine for the management of her blood pressure. Unfortunately she suffers profound hypotension after only five doses of medication.

Which of the following characteristics does she most likely possess?

- 1- CYP 2D6 polymorphism
- 2- Fast acetylation
- 3- HLA-DR2 genotype
- 4- G6-PD deficiency
- 5- Slow acetylation

Answer & Comments

Answer: 5- Slow acetylation

Slow acetylators often experience toxicity from drugs such as isoniazid, sulfonamides, procainamide, and hydralazine, whereas fast acetylators may not respond to isoniazid and hydralazine in the management of tuberculosis and hypertension.

Sulphonamides are now rarely used due to problems with blood dyscrasias.

Patients with G6-PD deficiency suffer from toxicity when they are prescribed drugs which

are also oxidising agents, such as anti-malarials.

[Q: 2864] OnExamination 2012 - Clinical pharmacology

A 49-year-old woman with a history of hypertension comes to the clinic for review.

She has noticed that she has become jaundiced and is concerned one of her medications may be responsible. She has recently had a second anti-hypertensive added to her regime, and is taking an antibiotic for a respiratory tract infection.

Investigations show

Haemoglobin 12.3 g/dl(11.5-16.0)

White cell count $6.2 \times 10^9/L$ (4-11)

Platelets $195 \times 10^9/L$ (150-400)

Serum Sodium 138 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 105 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 85 U/l (5-40)

Alkaline phosphatase 420 U/l (39-117)

Bilirubin 189 $\mu\text{mol/l}$ (<17)

Which of the following medications is the most likely cause?

- 1- Amlodipine
- 2- Co-amoxiclav
- 3- Enalapril
- 4- Paracetamol
- 5- Penicillin V

Answer & Comments

Answer: 2- Co-amoxiclav

Amoxicillin clavulanate is an important cause of cholestatic jaundice.

Other common drugs associated with cholestatic jaundice include:

Chlorpromazine

Ciprofloxacin

Ofloxacin

Cimetidine

Phenytoin

Naproxen

Captopril

Erythromycin

Azithromycin.

In this case the co-amoxiclav should be withdrawn, and the combination avoided in future.

Because of cholestatic jaundice, prescription of co-amoxiclav is not recommended for longer than 14 days.

[Q: 2865] OnExamination 2012 - Clinical pharmacology

A 45-year-old female is admitted with fatigue, nausea and weight loss.

She is known to have abused alcohol for many years and has previously developed delirium tremens. She stopped drinking alcohol two days ago.

On examination, she is thin, alert and orientated. She is slightly icteric, with features of chronic liver disease but there is no flapping tremor.

Pulse is 88 bpm regular, blood pressure is 106/74 mmHg and temperature is 37°C. She is treated with IV thiamine.

Which of the following agents would be recommended for the prevention of acute alcohol withdrawal?

- 1- IM haloperidol
- 2- IV diazepam
- 3- Oral diazepam
- 4- Oral quetiapine
- 5- No preventative treatment required.

Answer & Comments

Answer: 3- Oral diazepam

This patient with features of alcoholic chronic liver disease would be regarded at high risk of developing acute alcohol withdrawal, particularly in view of her past history of delirium tremens.

Benzodiazepines are appropriate agents in preventing acute alcohol withdrawal and oral agents such as lorazepam and diazepam are recommended.

[Q: 2866] OnExamination 2012 - Clinical pharmacology

A 62-year-old male presented to the urologists with symptoms of urinary hesitancy and dribbling.

They diagnose benign prostatic hyperplasia and he is commenced on finasteride.

Through which of the following mechanisms does finasteride function?

- 1- 5-alpha-reductase inhibitor
- 2- Alpha receptor antagonist
- 3- LHRH analogue
- 4- LHRH antagonist
- 5- Testosterone receptor antagonist

Answer & Comments

Answer: 1- 5-alpha-reductase inhibitor

Finasteride is a 5-alpha-reductase inhibitor preventing the conversion of testosterone to the active dihydrotestosterone (DHT).

Consequently this agent opposes testosterone, so gynaecomastia and reduced libido are common side effects.

It is also taken orally (under the brand name Propecia) for the treatment of male pattern hair loss.

[Q: 2867] OnExamination 2012 - Clinical pharmacology

What does this symbol signify?

- 1- Controlled drug
- 2- Intense monitoring required for any adverse events
- 3- Medication only available as prescription by licensed practitioner
- 4- Pharmacist prescribable drug
- 5- Prescribing can be optional and medication can be obtained over the counter

Answer & Comments

Answer: 3- Medication only available as prescription by licensed practitioner

Prescription Only Medicine - POM - and can be prescribed only by licensed medical or dental practitioners.

[Q: 2868] OnExamination 2012 - Clinical pharmacology

A 29-year-old man who is a keen amateur photographer with his own development studio presented to the Emergency department with confusion. His partner said he had been under a great deal of stress recently and she found him foolishly drinking a developer solution with a poison symbol on it. He is hypoxic and hypotensive.

The local poisons unit suggests a diagnosis of cyanide poisoning.

Which of the following would be the most appropriate treatment?

- 1- Desferrioxamine
- 2- Dicobalt EDTA
- 3- Gastric lavage with Fuller's earth
- 4- Haemodialysis
- 5- Penicillamine

Answer & Comments

Answer: 2- Dicobalt EDTA

Potassium ferricyanide is used chiefly for blueprints in photography, for staining wood, in calico printing, and in electroplating.

Kelocyanor (dicobalt EDTA), given by intravenous injection has been proven to be of use when administered to seriously ill victims of confirmed cyanide poisoning. It is itself toxic, however, and can kill if used wrongly.

HSE knows of several cases of inappropriate use resulting in hospital treatment. Its administration is beyond the scope of first aid and a recommendation has been made in the past that a 'Kelocyanor kit' should be kept by users of cyanide and transported to hospital with the patient.

Unfortunately we are aware of cases where this has misled doctors to treat patients for cyanide poisoning when this diagnosis was not correct.

UK guidelines for the first aid of cyanide poisoning.

[Q: 2869] OnExamination 2012 - Clinical pharmacology

A 59-year-old male presents with a three day history of marked muscle aches and weakness.

He has ischaemic heart disease for which he takes a number of drugs including simvastatin and has been taking these drugs for a number of years without any problem. On this occasion his CPK confirms a diagnosis of rhabdomyolysis with a level of 4200 iu/l (<200).

Which of the following health supplements is he most likely to have taken that would have contributed to the statin-induced rhabdomyolysis?

- 1- Cod liver oil capsules
- 2- Cranberry juice

- 3- Ginseng
- 4- Grapefruit juice
- 5- Vitamin C

Answer & Comments

Answer: 4- Grapefruit juice

Grapefruit juice significantly increases serum concentrations of some statins. This is achieved by reducing the CYP3A4-mediated first-pass metabolism in the small intestine. Concomitant use of atorvastatin and large amounts of grapefruit juice should be avoided, or the dose of atorvastatin should be reduced accordingly. CYP3A4 is a member of the cytochrome P450 system.

Whilst an interaction is increasingly being recognised between cranberry juice and warfarin, there has as yet been no interaction with other drugs metabolised via the P450 system.

No interaction has been shown between statins, omega-3 fish oils, ginseng or vitamin C

[Q: 2870] OnExamination 2012 - Clinical pharmacology

A 58-year-old woman presented with unsteadiness and ataxia and gave a recent history of nausea and epigastric pain for which she had been prescribed an antacid and cimetidine.

She was an epileptic and had been well controlled with phenytoin for eight years. She had been also been prescribed amitriptyline for depression, was receiving post-menopausal hormone replacement therapy and was self-medicating with St John's wort.

Which of the following drugs is most likely to be responsible for her presentation?

- 1- Amitriptyline
- 2- Antacid
- 3- Cimetidine

4- Estradiol

5- St John's wort

Answer & Comments

Answer: 3- Cimetidine

This patient has developed phenytoin toxicity which has been precipitated by cimetidine which inhibits cytochrome P450 metabolism of phenytoin.

Phenytoin concentration is reduced by St John's wort and is unaffected by amitriptyline which would however reduce seizure threshold; antacids may reduce phenytoin absorption and oestradiol metabolism may be increased by phenytoin.

[Q: 2871] OnExamination 2012 - Clinical pharmacology

A 72-year-old man presents with painful lumps in his feet and is diagnosed with gout.

Following initial treatment with nonsteroidal anti-inflammatory agents he is started on allopurinol.

How does this work?

- 1- Increases urinary uric acid excretion
- 2- Inhibits cyclooxygenase II
- 3- Inhibits macrophage tubular formation
- 4- Inhibits nitric oxide synthase
- 5- Inhibits xanthine oxidase

Answer & Comments

Answer: 5- Inhibits xanthine oxidase

Allopurinol inhibits xanthine oxidase, the enzyme involved in the conversion of purines into uric acid.

[Q: 2872] OnExamination 2012 - Clinical pharmacology

A 16-year-old boy reports palpitations, excessive sweating and tremor occurring

almost daily when he walks past a car park where he was mugged four weeks ago.

He is finding the symptoms very troublesome and has started missing school to avoid the car park.

Which of the following psychiatric illnesses does he have?

- 1- Adjustment disorder
- 2- Agoraphobia
- 3- Anorexia nervosa
- 4- Cynophobia
- 5- Generalised anxiety disorder

Answer & Comments

Answer: 1- Adjustment disorder

Adjustment disorder occurs within three months of an identifiable stressor and lasts six months from the withdrawal of the stressor. The patient will show either distress in excess of that expected or a disruption of their day to day life.

The criteria for diagnosing generalised anxiety disorder are anxiety/tension, occasionally accompanied by physical symptoms, on more days than not for more than six months. It is more a diagnosis of exclusion however, as it may be due to prescription medication or another psychiatric illness.

Anxiety disorders can be treated with selective serotonin reuptake inhibitors (SSRIs) or monoamine oxidase inhibitor (MAOI).

Benzodiazepines and beta blockers can be used on a PRN basis for patients who suffer with panic attacks.

Cognitive behavioural therapy can also be of help.

Anorexia nervosa is an eating disorder with altered body image.

Agoraphobia is phobia of open spaces.

Cynophobia is phobia of dogs.

[Q: 2873] OnExamination 2012 -
Clinical pharmacology

A 68-year-old woman comes to the cardiology clinic for review.

She complains of pitting oedema of both ankles and is concerned that some of her medication for heart disease or hypertension may be responsible.

On examination her blood pressure is 142/72 mmHG, pulse is 78 and regular. Her chest is clear, but there is pitting oedema of both lower legs, which she says gets worse towards the end of each day.

Which of the following medications is most likely to be responsible?

- 1- Diltiazem
- 2- Isosorbide dinitrate
- 3- Indapamide
- 4- Nicorandil
- 5- Ramipril

Answer & Comments

Answer: 1- Diltiazem

Diltiazem, like dihydropyridine calcium channel antagonists is associated with ankle swelling due to peripheral venous dilatation.

Swelling is seen to worsen during the course of the day, and is recognised to improve when patients keep their legs up.

Peripheral oedema is not a common problem in patients prescribed nitrates such as isosorbide dinitrate or nitrate donors such as nicorandil.

It is not reported with indapamide, a thiazide-like diuretic, or with ramipril, an ACE inhibitor.

[Q: 2874] OnExamination 2012 -
Clinical pharmacology

A 22-year-old woman attends the GP concerned that she has a positive pregnancy

test. She maintains that she never missed a pill over the course of the last three months.

Which of the following, when taken concurrently with the combined contraceptive pill, is most likely to increase the risk of pregnancy?

- 1- Cimetidine
- 2- Erythromycin
- 3- Fluconazole
- 4- Fluoxetine
- 5- St John's wort

Answer & Comments

Answer: 5- St John's wort

St John's wort is a potent CYP-450 inducer, and use can lead to rapid decreases in sex steroids administered as the combined pill.

Fluconazole is a 2C9 inhibitor

Fluoxetine a 2C19 inhibitor

Erythromycin a 3A4 inhibitor

Cimetidine an inhibitor of 1A2 and 2D6.

As such all four of the other potential choices should not affect contraceptive effectiveness because they do not lead to a decrease in sex steroid levels.

Potent enzyme inducers which may cause significantly decreased pill effectiveness include rifampicin and carbamazepine.

Other antibiotics such as the tetracyclines which may be used in this population for example in the treatment of acne, are known to lead to decreased pill efficacy.

[Q: 2875] OnExamination 2012 -
Clinical pharmacology

A 74-year-old woman with chronic renal failure is admitted to the unit with infective endocarditis. You elect to begin treatment with IV benzylpenicillin and gentamicin.

On examination her temperature is 38.2°C, and she has a pansystolic murmur loudest at the left sternal edge, her BP is 125/82 mmHg, her pulse is 80 bpm and regular and she weighs 80 kg.

Investigations show

Haemoglobin 10.5 g/dl 11.5-16.5

White cell count $7.0 \times 10^9/L$ 4-11

Platelets $202 \times 10^9/L$ 150-400

Serum Sodium 138 mmol/l 135-146

Serum Potassium 4.8 mmol/l 3.5-5

Creatinine 190 $\mu\text{mol/l}$ 79-118

Which of the following is likely to represent the most appropriate dosing regime for the gentamicin?

1- 0.75 mg/kg OD

2- 1 mg/kg BD

3- 1 mg/kg OD

4- 1 mg/kg TDS

5- 1.5 mg/kg OD

Answer & Comments

Answer: 3- 1 mg/kg OD

Where gentamicin is concerned both ototoxicity and nephrotoxicity are potential concerns.

In patients with low creatinine clearance the data sheet recommends a dosing regimen of 80 mg once per day. Given this woman's creatinine is 190 it seems likely she will fall into this group, (10-30 ml/min GFR), although this should be formally calculated either using the Cockcroft-Gault or MDRD equations available on the internet.

Where weight is less than 60 kg it is better to reduce the dose to 60 mg daily.

Studies have compared potential risk of ototoxicity versus efficacy for the OD and BD dosing regimens. It has become apparent that

once daily dosing is associated with reduced risk of toxicity.

Peak levels of gentamicin should however still be assayed, aiming for a level one hour after dosing of between 4 and 10 mg/l. With respect to pre-dose levels the gentamicin SPC recommends not exceeding 2 mg/l.

Three other drugs which require therapeutic monitoring are phenytoin, warfarin and clozapine.

Phenytoin is a highly effective anti-epileptic but is associated at toxic levels with neurological dysfunction including dizziness and nystagmus.

Most warfarin therapy is directed towards a narrow therapeutic window between an INR of 2-3. Ineffective anticoagulation and excess coagulation can both be associated with significant adverse effects.

Clozapine is effective in the treatment of psychotic disorders but is associated with blood cell dyscrasias, for this reason regular monitoring of full blood count is recommended.

Whereas monitoring of gentamicin and phenytoin involves PK monitoring (measuring the level of the drug in plasma), monitoring of warfarin and clozapine is essentially pharmacodynamic monitoring, looking for either over anticoagulation or abnormalities in the white blood cell count.

[Q: 2876] OnExamination 2012 - Clinical pharmacology

You are asked to see a 27-year-old woman on the oncology ward. She has been admitted for a course of chemotherapy and has been taking high dose steroids for a few days. The nurses report that she is very agitated and talks about trying to open the window of her room and jump out from the fourth floor.

You review her notes and see that she admits to drinking a few glasses of wine per week and has smoked cannabis on a few occasions.

On examination her BP is 145/88 mmHg, her pulse is 80 and regular and she looks agitated and upset.

Investigations show:

Haemoglobin 12.1 g/dl(11.5-16.5)

White cell count $16.2 \times 10^9/L$ (4-11)

Platelets $200 \times 10^9/L$ (150-400)

C-reactive protein 9 nmol/l (<10)

Sodium 140 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 92 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely diagnosis?

- 1- Alcohol withdrawal
- 2- Cannabis-related psychosis
- 3- Corticosteroid-related psychosis
- 4- Manic depressive psychosis
- 5- Personality disorder

Answer & Comments

Answer: 3- Corticosteroid-related psychosis

Corticosteroid-related psychosis is seen within a few days of starting high dose oral or intravenous corticosteroids, although some patients have been diagnosed with the condition up to 12 weeks or more after commencing therapy.

Symptoms which are seen include

Agitation

Hypomania

Suicidal intent.

Given the close proximity of her symptoms to the onset of steroid therapy this is much more likely to be the diagnosis than cannabis or alcohol related psychiatric disorder.

In severe cases, typical or atypical antipsychotics or benzodiazepines to manage agitation may be required.

[Q: 2877] OnExamination 2012 - Clinical pharmacology

A 44-year-old woman is taking lithium for bipolar disorder. She also suffers from hypertension and angina and recently underwent a medication review at her GP. She also suffers from osteoarthritis of her knees and has suffered a recent respiratory tract infection.

Over the past few days she has become increasingly drowsy, with ataxia, dizziness and slurred speech. A lithium level is measured at 4 mmol/l.

Which of the following is most likely to have resulted in her presentation with lithium toxicity?

- 1- Amoxicillin
- 2- Atenolol
- 3- Paracetamol
- 4- Ramipril
- 5- Verapamil

Answer & Comments

Answer: 4- Ramipril

ACE inhibitors are known to increase serum lithium levels, as are dihydropyridine calcium antagonists.

Atenolol, in contrast, is a relatively safer option for the treatment of hypertension in association with long term lithium use.

Verapamil in combination with lithium leads to neurotoxicity; this is independent of any increase in serum lithium levels.

If patients have poorly controlled hypertension and they are taking lithium, it may be better to discuss the case with the psychiatrist to see if they can be changed to

another mood stabilising agent, such as sodium valproate.

[Q: 2878] OnExamination 2012 -
Clinical pharmacology

A 55-year-old woman is attending clinic a number of months after having had a myocardial infarction.

She has been commenced on appropriate drugs to reduce cardiovascular risk and has made dietary modifications for healthy living. Recently, however, she complains of muscle aches and pains and is found to have an elevated CPK.

Consumption of which of the following is likely to have contributed to increased statin-associated myotoxicity?

- 1- Carrot juice
- 2- Cranberry juice
- 3- Garlic cloves
- 4- Grapefruit juice
- 5- Omega-3 fish oils

Answer & Comments

Answer: 4- Grapefruit juice

Grapefruit juice significantly increases serum concentrations of some statins. This is achieved by reducing the CYP3A4-mediated first-pass metabolism in the small intestine. Concomitant use of atorvastatin and large amounts of grapefruit juice should be avoided, or the dose of atorvastatin should be reduced accordingly. CYP3A4 is a member of the cytochrome P450 system.

Whilst a interaction is increasingly being recognised between cranberry juice and warfarin, there has as yet been no interaction with other drugs metabolised via the P450 system.

No interaction has been shown between statins, carrot juice, garlic or omega-3 fish oils.

[Q: 2879] OnExamination 2012 -
Clinical pharmacology

A 45-year-old female attends the clinic complaining of headache and vomiting for five days. She has a history of scleroderma complicated by stage V chronic kidney disease.

On examination, she is tachycardic and has a blood pressure of 240/130 mmHg. Fundoscopy reveals grade 3 hypertensive retinopathy.

Which of the following is a centrally acting antihypertensive agent?

- 1- Diazoxide
- 2- Hydralazine
- 3- Minoxidil
- 4- Moxonidine
- 5- Sodium nitroprusside

Answer & Comments

Answer: 4- Moxonidine

Moxonidine is centrally acting and is licensed for mild to moderate hypertension not controlled by β -blockers, ACE inhibitors, calcium channel antagonists and thiazides. Moxonidine is a selective agonist at the imidazoline subtype 1 receptor. This receptor subtype is found in the medulla oblongata. Moxonidine causes a decrease in sympathetic nervous system activity and therefore a decrease in blood pressure.

The other drugs listed are vasodilator in action.

Diazoxide and sodium nitroprusside can be used intravenously in hypertensive emergencies.

Minoxidil is reserved for when hypertension is resistant to other treatments; it causes fluid retention and oedema, however it is effective in combination with a β -blocker and loop diuretic.

Hydralazine can be given orally also in combination with a diuretic and β -blocker. Side effects include reflex tachycardia and fluid retention.

[Q: 2880] OnExamination 2012 - Clinical pharmacology

Which of the following drugs interacts with cranberry juice?

- 1- Amiodarone
- 2- Digoxin
- 3- Propranolol
- 4- Simvastatin
- 5- Warfarin

Answer & Comments

Answer: 5- Warfarin

This theme has apparently been asked in the examination.

I suspect that the authors of this paper were responsible for composing this question.

The answer is warfarin.

[Q: 2881] OnExamination 2012 - Clinical pharmacology

A 35-year-old man is admitted following a serious attempt at paracetamol overdose. Despite efforts to treat him he develops liver failure.

Which of the following is most likely with the ensuing liver failure?

- 1- Better prognosis in older patients
- 2- Better prognosis in those with high alcohol consumption
- 3- Hypoglycaemia rarely happens within 12 hours of onset of encephalopathy
- 4- It is harmful to give N-acetylcysteine
- 5- Lactic acidosis is recognised complication

Answer & Comments

Answer: 5- Lactic acidosis is recognised complication

Use of intravenous N-acetylcysteine reduces morbidity and mortality in fulminant hepatic failure.

Severe hypoglycaemia affects 40% of patients with fulminant liver failure, which exacerbates encephalopathy. It may develop rapidly and recur with sepsis.

Lactic acidosis is due to decreased hepatic lactate clearance, compounded by poor peripheral perfusion and increased lactate production.

There is a poor prognosis in those with blood PH<7.0, prolonged prothrombin time (>100s) and serum creatinine >300uM.

Mortality is greater if the patient is more than 40 years of age.

[Q: 2882] OnExamination 2012 - Clinical pharmacology

A 60-year-old man who has been prescribed lisinopril for hypertension presents with an irritating cough.

What is the mechanism responsible for ACE-induced cough?

- 1- Angiotensin I accumulation
- 2- Asthma
- 3- Bradykinin accumulation
- 4- Laryngeal irritation
- 5- Renin accumulation

Answer & Comments

Answer: 3- Bradykinin accumulation

The enzyme ACE is also responsible for the metabolism of bradykinin in mast cells.

The accumulation of this substance is responsible for the cough found in up to 30% of subjects taking ACE-inhibitors.

This phenomenon is not seen in subjects taking angiotensin receptor blockers such as losartan.

[Q: 2883] OnExamination 2012 - Clinical pharmacology

Miss L is a 25-year-old woman attending the general medical clinic.

For the last six months she has felt generally fatigued and has noticed abdominal bloating and occasional diarrhoea. She has multiple symptoms that have been troubling her for the last few years and her GP would like some advice on diagnosis and management.

She has also been troubled by large, painful mouth ulcers that can be so severe that she is unable to eat. She says that she has had mouth ulcers since she was a teenager and gets them at least once per week.

She complains of joint pains affecting her hands and knees, and reports one brief episode of swelling of the right knee that resolved after a week or so of painkillers.

Last year, she was seen urgently by the ophthalmologists when she developed an acutely red and painful left eye associated with blurred vision and photophobia. She cannot remember what the diagnosis was, but was treated with steroid drops and this has not bothered her since.

On further questioning, you find out that she has also been seen in the GUM clinic complaining of painful vulval ulceration. Swabs and blood samples were taken, but no diagnosis was reached. The symptoms have recurred twice since the first episode two years ago.

You read the referral letter from her GP who describes an episode of erythema nodosum last year. He also mentions that she was

treated for a DVT following a trip to Cyprus when she was 17.

What is the likely unifying diagnosis?

- 1- Crohn's disease
- 2- Brucellosis
- 3- Fibromyalgia
- 4- Behcet's disease
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 4- Behcet's disease

The combination of venous ulceration, iritis, mouth ulceration and arthritis is typical of Behcet's disease.

Behçet's syndrome is a systemic vasculitis with an unknown aetiology, which affects small and large vessels (venous and arterial). More than 60% of patients are HLA-B51, and there is an increased prevalence in the Mediterranean countries. It is commonly associated with mucocutaneous manifestations (oro-genital ulceration, erythema nodosum), ocular disease, gastrointestinal involvement and neurological features. Venous thrombosis is a common complication, but arterial occlusion can also occur.

The International Study Group criteria for classification of Behcet's disease requires the presence of recurrent oral ulceration (minor aphthous, major aphthous or herpetiform ulceration observed by physician or patient, which have recurred at least three times in a 12 month period), and two of the following:

- Recurrent genital ulceration: aphthous ulceration or scarring, observed by physician or patient
- Eye lesions: anterior uveitis, posterior uveitis, or cells in vitreous on slit lamp examination; or retinal vasculitis observed by ophthalmologist

- Skin lesions: erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; or acneiform nodules observed by the physician in post-adolescent patients not on corticosteroid treatment
- Positive pathergy test: read by physician at 24-48 hours.

Pathergy is the non-specific hyper-reactivity of the skin following minor trauma, and is specific to Behcet's disease. It involves intradermal injection of skin with a 20-gauge needle under sterile conditions. It is considered positive if an erythematous sterile papule develops within 48 hours.

- A. This presentation is not typical of Crohn's disease - one would expect a history of diarrhoea, abdominal pain and/or PR bleeding.
- B. Brucellosis is an infective condition which presents most commonly with fever and malaise. It does not fit with the above scenario.
- C. Fibromyalgia presents with pain and tenderness in a number of muscles. Extra-articular features such as genital ulceration are not seen.
- D. Behcet's disease is the most appropriate diagnosis.
- E. Whilst a number of the features described in this scenario could fit with SLE and/or antiphospholipid syndrome the history of oral and genital ulceration is much more typical of Behcet's disease.

[Q: 2884] OnExamination 2012 - Clinical pharmacology

An 18-year-old woman is brought to the Emergency department with shortness of breath, stridor, and an urticarial rash.

On examination her BP is 90/50 mmHg and she has a tachycardia of 95 beats per minute. You give her hydrocortisone and an IV fluid

challenge but her BP fails to improve. You decide to administer adrenalin.

Which of the following is the most appropriate method of administration and dosage?

- 1- 0.5 ml of 1:1000 adrenalin IM
- 2- 0.5 ml of 1:10000 adrenalin IV
- 3- 1 mcg/min IV adrenalin infusion
- 4- 1 ml of 1:10000 adrenalin IM
- 5- 4 mcg/min IV adrenalin infusion

Answer & Comments

Answer: 1- 0.5 ml of 1:1000 adrenalin IM

Multimodal therapy involving use of an IV corticosteroid, IV antihistamine and fluid loading is usually employed in the treatment of anaphylaxis.

IV corticosteroids are designed to modulate downstream release of cytokines from inflammatory cells, they reduce the duration and severity of anaphylaxis.

IV antihistamine is designed to block the effects of histamine on the vascular tree, which ameliorates hypotension, and on the airways, reducing shortness of breath and stridor. Fluid loading is designed to raise blood pressure.

Adrenalin is used for its alpha-agonist effects that include increased peripheral vascular resistance and reversed peripheral vasodilatation, systemic hypotension, and vascular permeability.

Beta-agonist effects include bronchodilatation, chronotropic cardiac activity, and positive inotropic effects.

IM administration is preferred because of a superior safety profile with respect to cardiac adverse events compared with the IV route, although 1:10000 adrenalin IV may be used in a life-threatening situation.

Reference:

<http://www.resus.org.uk/pages/reaction.pdf>

[Q: 2885] OnExamination 2012 -
Clinical pharmacology

You have a 23-year-old female patient who suffers from complex partial epilepsy.

When she comes to her clinic appointment she tells you she is worried because her fit frequency has increased and wants more medication. On examination you also notice that she has a significant fungal infection. Medication includes the oral contraceptive pill.

Which of the following agents is likely significantly to increase her risk of getting pregnant?

- 1- Fluconazole
- 2- Ketoconazole
- 3- Lamotrigine
- 4- Levetiracetam
- 5- Phenytoin

Answer & Comments

Answer: 5- Phenytoin

Phenytoin is a potent enzyme inducer of the cytochrome P450 system; as such it reduces plasma levels of agents which undergo hepatic metabolism, including sex steroids given in the oral contraceptive pill.

Fluconazole and ketoconazole are all inhibitors of the CYP450 system and would lead to increased levels of other agents.

Lamotrigine is metabolised principally by UDP-glucuronyl transferases, as such there is not significant interaction with the OCP.

Levetiracetam does not alter the pharmacokinetics of the oral contraceptive.

[Q: 2886] OnExamination 2012 -
Clinical pharmacology

A 52-year-old accountant presents with a five hour history of confusion and agitation.

He is known to have an alcohol problem but has avoided all alcohol for the last three days.

On examination, he is sweating, is agitated and disorientated.

His temperature is 37.5°C, pulse 110 bpm regular and blood pressure is 152/74 mmHg. He claims to see things on the walls.

His investigations reveal:

FBC Normal

U&Es Normal

Plasma glucose 4.6 mmol/l (3.6-6)

Which of the following agents would be the most appropriate treatment for this man?

- 1- IV haloperidol
- 2- Oral lorazepam
- 3- IV phenobarbital
- 4- IV phenytoin
- 5- Oral diazepam

Answer & Comments

Answer: 2- Oral lorazepam

This is a typical history of delirium tremens (DTs).

In the UK it is estimated 24% of adults drink in a hazardous way, which is highest in the North East, North West and Yorkshire and Humber. Approximately 20% of patients admitted to hospital for illnesses unrelated to alcohol are drinking at potentially hazardous levels, and its therefore important to ask all patients about their alcohol use. An abrupt reduction in alcohol intake in a person who has been drinking excessively for a prolonged period of time, for example as occurs on admission to hospital, may result in the development of alcohol withdrawal.

Symptoms typically present about 8 hours after a significant fall in blood alcohol levels. The peak is on day two, and by day five the symptoms are significantly better. Minor withdrawal symptoms appear 6-12 hours after

cessation of alcohol and include: insomnia, fatigue, tremor, anxiety, nausea, vomiting, headache, sweating, palpitations, anorexia, depression and craving. Alcoholic hallucinosis can appear 12-24 hours after stopping alcohol and includes visual, auditory and tactile hallucinations. Withdrawal seizures can appear 24-28 hours after cessation and are generalised tonic-clonic seizures. Alcohol withdrawal delirium ('delirium tremens') can appear 48-72 hours after cessation.

This patient has delirium tremens, which should be treated as a medical emergency. The signs of altered mental status alert you to the fact that this is different from simple alcohol withdrawal. These signs can include hallucinations (auditory, visual, olfactory), confusion, delusions and severe agitation. Seizures can also occur. Delirium tremens is a hyperadrenergic state, and is often associated with tachycardia, hyperthermia, hypertension, tachypnoea, tremor and mydriasis. Patients at increased risk are those with a previous history of delirium tremens or alcohol withdrawal seizures, those with a co-existing infection or abnormal liver function, and older patients. It is a clinical diagnosis.

Delirium tremens should be treated with oral lorazepam as first-line treatment. If the symptoms persist, or the medication is refused, parenteral lorazepam, haloperidol or olanzapine should be given. Intensive care may be required.

If delirium tremens develops during treatment for acute withdrawal, the reducing regime should be reviewed.

The mortality rate can be up to 35% if untreated, which reduces to 5% with early recognition and treatment.

In patients with alcohol withdrawal seizures, a quick-acting benzodiazepine should be given (such as lorazepam). Phenytoin should not be given.

Patients who are at high-risk of alcohol withdrawal but have no or only mild symptoms are typically given a reducing dose of chlordiazepoxide (a long-acting benzodiazepine) over 5-7 days. Diazepam is an alternative. Chlormethiazole may also be offered as an alternative, but is rarely used as if used with alcohol there is a risk of fatal respiratory depression, especially in patients with liver cirrhosis.

In addition, you should not forget the importance of giving high-potency B vitamins, specifically thiamine (e.g. pabrinex) to all patients with a history of high alcohol intake to reduce the risk of Wernicke's encephalopathy.

[Q: 2887] OnExamination 2012 - Clinical pharmacology

You look up a drug in the BNF and note the following against it:

?????? missed sympol ??????

What does this signify?

- 1- Drug is not available on the NHS
- 2- Over the counter therapy
- 3- Prescription only drug
- 4- Report any potential adverse event
- 5- Report only potentially serious adverse events

Answer & Comments

Answer: 4- Report any potential adverse event

The Committee on the Safety of Medicines assigns the inverted black triangle to those relatively new drugs/vaccines or blood products to notify prescribers that the drug is under surveillance and that all suspected adverse reactions associated with the drug should be reported, typically with a yellow card.

[Q: 2888] OnExamination 2012 -
Clinical pharmacology

A 55-year-old man on treatment for hypertension, epilepsy and gastro-oesophageal reflux disease presented with an urticarial skin eruption. A drug reaction is suspected since he has recently started a new drug.

Which of the following medications is most likely to be responsible?

- 1- Aspirin
- 2- Atorvastatin
- 3- Omeprazole
- 4- Paracetamol
- 5- Sodium valproate

Answer & Comments

Answer: 1- Aspirin

Urticaria is one of the most common dermatologic problems seen by primary care physicians and often a source of frustration for patient and physician alike. Pinpointing the cause may be challenging--or impossible--because of the many and varied triggers.

Patients with aspirin sensitivity can present with either mucosal reactions (the aspirin triad of nasal polyposis, sinusitis, and asthma) or cutaneous reactions (urticaria or anaphylaxis).

More reading

[Q: 2889] OnExamination 2012 -
Clinical pharmacology

A 55-year-old male who is being treated with lithium for a bipolar disorder has a long history of hypertension for which he is receiving escalating doses of medication. On his most recent visit to clinic his blood pressure was noted to be 166/102 mmHg and a new antihypertensive was added to his current antihypertensive therapy.

Five days later he presents with features of lithium toxicity including tremor, nausea and weakness.

The addition of which of the following drugs was likely to have precipitated the lithium toxicity?

- 1- Doxazosin
- 2- Hydralazine
- 3- Irbesartan
- 4- Minoxidil
- 5- Moxonidine

Answer & Comments

Answer: 3- Irbesartan

The precipitation of lithium toxicity by diuretics is well appreciated. Yet ACE inhibitors [log-in required to read full text] and angiotensin antagonists are also capable of precipitating lithium toxicity through reduced lithium clearance.

Other drugs that may precipitate lithium toxicity include:

NSAIDs

Tetracycline

Phenytoin

Ciclosporin.

[Q: 2890] OnExamination 2012 -
Clinical pharmacology

A new drug is being studied to find the most appropriate dose in a dose response study.

Small doses of the drug lead to a linear increase in serum drug concentration.

At higher doses there is an exponential rise in serum drug concentration.

Which of the following best describes the pharmacokinetic properties of this new drug?

- 1- First order kinetics
- 2- First pass effect

- 3- Long plasma half life
- 4- Saturation kinetics
- 5- Zero order kinetics

Pupils tend to be dilated with TCA overdose. Paracetamol, cyanide, and paraquat should not affect pupils.

Answer & Comments

Answer: 4- Saturation kinetics

The description of the kinetics of this new drug show that with small doses there is a linear response (first order kinetics) to dosing but this becomes saturated and the serum concentration of the drug rises sharply (zero order kinetics).

This response is typical of drugs such as phenytoin (saturates liver metabolism).

[Q: 2891] OnExamination 2012 - Clinical pharmacology

A farmer on treatment for depression is admitted acutely one hour following an intentional overdose of an unidentified substance.

On examination he is bradycardic, hypotensive, disorientated, hypersalivating, and has small pupils.

Which of the following is he most likely to have ingested?

- 1- A tricyclic antidepressant (TCA)
- 2- An organophosphate insecticide
- 3- Cyanide
- 4- Paracetamol
- 5- Paraquat

Answer & Comments

Answer: 2- An organophosphate insecticide

Hypersalivation and miosis are the specific clues to acetylcholine overactivity.

The patient has occupational access to organophosphate insecticides.

[Q: 2892] OnExamination 2012 - Respiratory

A 21-year-old female presents with joint pains and rash. On examination her blood pressure was 140/100 mmHg.

Investigations reveal:

Creatinine 90 μ mol/l (60-110)

Anti dsDNA antibodies Strongly positive(0-73)

24 hour urinary protein excretion 1.7 g(<0.2)

Renal biopsy Membranous nephropathy

What is the most appropriate next treatment for her nephropathy?

- 1- ACE inhibitor for blood pressure control
- 2- Cyclophosphamide
- 3- NSAIDs for arthralgia
- 4- Prednisolone for immunosuppression
- 5- Warfarin anticoagulation

Answer & Comments

Answer: 1- ACE inhibitor for blood pressure control

This patient has systemic lupus erythematosus with the disease affecting her kidneys.

The renal manifestations of SLE are highly variable, ranging from mild asymptomatic proteinuria and/or haematuria to rapidly progressive uraemia. The various presentations are difficult to classify into clinical syndromes and histological classes. Although lupus nephritis affects a third of patients early in the disease it is frequently unrecognised until nephritic and/or nephrotic syndrome with renal failure occur.

Histologically, a number of different types of renal disease are recognised in SLE, with immune-complex mediated glomerular disease being the most common. The up to date International Society of Nephrology/Renal Pathology Society 2003 classification divides these into six different patterns:

- I - minimal mesangial
- II - mesangial proliferative
- III - focal
- IV - diffuse
- V - membranous
- VI - advanced sclerosis

Patients with membranous lupus nephritis tend to present with nephrotic syndrome. Microscopic haematuria and hypertension may also be seen. Biopsies show global or segmental subepithelial immune deposits or their morphologic sequelae, with or without mesangial alterations. It may occur in combination with class III or IV, in which case both are diagnosed. Progression is variable, and immunosuppression is not always needed. Cyclophosphamide, mycophenolate mofetil and azathioprine reduce mortality in proliferative forms of lupus glomerulonephritis, but the benefit is not clear in membranous forms.

More important to this patient's renal disease in this patient is aggressive blood pressure control. An angiotensin-converting enzyme (ACE) inhibitor would be first line, as it has been shown to reduce proteinuria independently of its effect on blood pressure.

Warfarin is not considered an appropriate treatment as this lady has not exhibited any prothrombotic tendencies.

Non-steroidal anti-inflammatory medication would treat her arthralgia but would have no effect on the prognosis of the disease.

Therefore the correct answer should be A, but immunosuppression may well be required to manage her extra-renal disease.

[Q: 2893] OnExamination 2012 - Respiratory

A 41-year-old woman comes to the clinic with increasing shortness of breath. She has a

history of systemic sclerosis, takes omeprazole for reflux symptoms and nifedipine slow release for Raynaud's disease.

On examination her BP is 155/85 mmHg, pulse is 82 and regular. There is peripheral calcinosis on examination of the hands and pinching of the corners of the mouth consistent with scleroderma. Auscultation of the chest reveals scattered inspiratory crackles across both lung fields.

Investigations show:

Haemoglobin 12.2 g/dl(11.5-16.0)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $199 \times 10^9/L$ (150-400)

ESR 62 mm/hr(<10)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 131 micromol/l (79-118)

CXR - Bilateral interstitial infiltrates.

Echocardiogram - Ejection fraction 53%.

Which of the following is the most likely diagnosis?

- 1- Bacterial pneumonia
- 2- Cryptogenic fibrosing alveolitis
- 3- Eosinophilic pneumonitis
- 4- Interstitial fibrosis
- 5- Pulmonary oedema

Answer & Comments

Answer: 4- Interstitial fibrosis

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. 90-95% of patients have positive antinuclear antibodies. There are two major subtypes: limited cutaneous and diffuse cutaneous. CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynauds' phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia).

Patients with systemic sclerosis can present with skin abnormalities, musculoskeletal changes, gastrointestinal complications, pulmonary disease, renal crisis and dry eyes and mouth.

A number of autoantibodies against extractable nuclear antigens can be detected in patients with systemic sclerosis. Anti-centromere antibodies and anti-topoisomerase I antibodies are the classic autoantibodies associated with the disease. Anti-centromere antibodies are linked with limited cutaneous involvement and isolated pulmonary hypertension, and a good prognosis, whereas anti-topoisomerase I and linked with diffuse skin disease and pulmonary fibrosis and a higher mortality.

Respiratory symptoms are common in patients with systemic sclerosis, but it is often difficult to distinguish between interstitial lung disease and pulmonary hypertension as the cause. Echocardiography, pulmonary hypertension and chest radiographs or CT are often required.

Inspiratory crackles heard here, coupled with bilateral interstitial infiltrates on chest radiograph, make interstitial lung disease the most likely diagnosis, but it is important to note they are not always present in the early stages of disease. The condition may be steroid responsive; as such a trial of prednisolone plus or minus an appropriate second line agent is indicated. Signs of pulmonary hypertension are jugular venous distension, right ventricular heave and an accentuated pulmonary second heart sound.

Given the chronic nature of her disease bacterial infection is unlikely.

Cryptogenic fibrosing alveolitis is by definition of unknown aetiology and this too therefore cannot be the correct answer.

Given the normal ejection fraction pulmonary oedema is also unlikely.

The absence of leukocytosis, and normal eosinophil count makes eosinophilic pneumonitis unlikely.

[Q: 2894] OnExamination 2012 - Respiratory

A 24-year-old man presents to the Emergency department and complains of shortness of breath.

Before his chest x ray is taken he tells the casualty officer that he is known to have an 'azygous lobe'.

In what region of the chest x ray would you expect to see an 'azygous lobe'?

- 1- Left lower zone
- 2- Left mid zone
- 3- Left upper zone
- 4- Right lower zone
- 5- Right upper zone

Answer & Comments

Answer: 5- Right upper zone

An azygous lobe is seen in about 0.5% of routine chest x rays and is a normal variant.

It is seen as a 'reverse comma sign' behind the medial end of the right clavicle on the upper zone of the right lung. It appears separated from the rest of the upper lobe by a deep groove (which contains the azygous vein). It has little clinical significance. It develops in utero when the apical bronchus grows medial to the arch of the azygous vein instead of lateral.

[Q: 2895] OnExamination 2012 - Respiratory

A 23-year-old man presents to the Emergency department with sudden onset left sided pleuritic chest pain. He has had a chronic cough over the past few days and says the pain came on after a coughing fit.

On examination his BP is 148/82 mmHg, pulse is 82 and regular, his saturations are 95% on air. Chest sounds appear normal.

Investigations show:

pH 7.42(7.35-7.45)

pCO₂ 4.8 kPa(4.8-6.1)

pO₂ 10.2 kPa(10-13.3)

CXR Small left sided pneumothorax (<5%)

Which of the following is the most appropriate way to manage him?

- 1- Admit for overnight oxygen therapy
- 2- Chest drain
- 3- Discharge and review in 24 hours
- 4- Discharge and review in the clinic in two to three weeks
- 5- Pleural aspiration

Answer & Comments

Answer: 4- Discharge and review in the clinic in two to three weeks

This gentleman has a spontaneous pneumothorax. It is primary (defined as age less than 50y, no significant smoking history, and no evidence of underlying lung disease). Management depends on the size, and the patient's symptoms. If it is small, as in this case, the patient can be discharged and reviewed in an outpatient clinic in 2-4 weeks. If the rim of air measures more than 2cm at the level of the hilum, and/or the patient is breathless the pneumothorax can be aspirated.

A chest drain is indicated if aspiration fails in a large or symptomatic primary pneumothorax. They can also be used in the management of secondary pneumothorax.

Supplemental oxygen accelerates reabsorption of air by a factor of four, but overnight treatment does not feature as part of the current UK guidelines in small primary pneumothoraces.

[Q: 2896] OnExamination 2012 - Respiratory

A 45-year-old man has been diagnosed with pulmonary tuberculosis.

Which of the following investigations is essential prior to starting antituberculous therapy?

- 1- Full blood count
- 2- Liver function test
- 3- Plasma glucose
- 4- Urine for acid-fast bacilli
- 5- Vitamin B6

Answer & Comments

Answer: 2- Liver function test

Hepatotoxicity is a feature of antituberculous treatment.

"Liver function should be checked before treatment for clinical cases."

[Q: 2897] OnExamination 2012 - Respiratory

You are asked to see a patient who attends the emergency department with shortness of breath.

The chest x ray shows right lower lobe consolidation.

Which of the following features should prompt admission to hospital?

- 1- Audible bronchial breathing
- 2- A paO_2 of 9.8 kPa (11-13)
- 3- A respiratory rate of 32/min
- 4- A SaO_2 of 95%
- 5- A white cell count of $16.8 \times 10^9/\text{L}$ (4-10)

Answer & Comments

Answer: 3- A respiratory rate of 32/min

The British Thoracic Society guidelines for community acquired pneumonia in adults recommend use of the CURB-65.

This is a 6-point score, one point for each of

Confusion

Urea more than 7 mmol/l

Respiratory rate 30/min or more

Systolic Blood pressure below 90 mmHg (or diastolic below 60 mmHg)

Age 65 years or older.

If the CURB score is 1-2 then risk of death is increased and hospital admission should be considered.

A CURB score of 3 or more puts the patient at high risk of death and hospital admission is warranted.

[Q: 2898] OnExamination 2012 - Respiratory

A 65-year-old man with known chronic obstructive pulmonary disease (COPD), treated with inhalers, was admitted with a six week history of gradually increasing shortness of breath.

He was afebrile, mildly confused with a respiratory rate of 26 breaths per minute and there were no changes on the chest x ray.

Investigations revealed:

paO_2 7.8kPa (9-12.6)

paCO_2 8.5kPa (4.7-6.0)

pH 7.3 (7.36-7.44)

What is the most appropriate immediate management?

- 1- High flow oxygen therapy
- 2- Intravenous aminophylline
- 3- Intravenous hydrocortisone
- 4- Intubation and mechanical ventilation.

- 5- Nebulised salbutamol and ipratropium bromide.

Answer & Comments

Answer: 5- Nebulised salbutamol and ipratropium bromide.

This patient has an exacerbation of COPD, defined as sustained worsening of the patient's symptoms which is acute in onset. This may include worsening breathlessness, cough, increased sputum and change in sputum colour. The diagnosis is usually made clinically. Supporting investigations include a chest radiograph, arterial blood gases, ECG, routine bloods and sputum and blood cultures.

Treatment is with bronchodilators, nebulised in the majority of patients. If a patient is hypercapnic or acidotic, as in this case, these should be driven by compressed air. If oxygen therapy is needed it should be administered simultaneously by nasal cannulae.

Oxygen should be given to maintain SaO₂ within the patient's individual target range, if available (COPD patients are being given cards with this information, so always ask). ABGs should be repeated at regular intervals to monitor response to treatment, and oxygen weaned when available. High-flow oxygen can potentially worsen hypercapnia and should be avoided.

Oral corticosteroids should also be given: 30mg prednisolone for 7-14 days. Prolonged courses offer no additional benefit. Intravenous can be used if the patient is unable to tolerate oral tablets. The effect is delayed, and nebuliser therapy should be initiated first.

Antibiotics should be used to treat exacerbations associated with more purulent sputum, consolidation on chest radiograph, or clinical signs of pneumonia. Empirical antibiotic choice should be guided by local

policy, and altered to take account of any subsequent culture results.

Non-invasive ventilation (NIV) is the treatment of choice for persistent hypercapnic ventilation failure despite optimal medical therapy. It has been shown in RCTs to reduce intubation rate and mortality in COPD patients with decompensated respiratory acidosis (pH <7.35 and pCO₂ >6kPa). NIV should therefore be considered within the first 60 minutes of hospital arrival in all patients with an acute exacerbation of COPD in whom a respiratory acidosis persists despite maximal medical therapy (controlled oxygen, nebulised salbutamol and ipratropium, prednisolone, antibiotic (where indicated)). Exceptions may be: life threatening hypoxaemia (when invasive ventilation may be more appropriate), severe co-morbidity, severe cognitive impairment (where NIV is not tolerated), facial burns/trauma/surgery, vomiting, fixed upper airway obstruction, undrained pneumothorax, upper GI surgery, unprotected airway, copious respiratory secretions, haemodynamic instability requiring inotropes.

Patients should be sitting or semi-recumbant, and a full-face mask used initially. An initial inspiratory positive airway pressure (IPAP) of 10cm H₂O and expiratory positive airway pressure (EPAP) of 4-5cm H₂O should be used. IPAP should be increased by 2-5cm increments every 10 minutes, with a usual target of 20cm H₂O or until a therapeutic response is achieved. Oxygen can be introduced into the circuit, usually with a target saturation of 88-92%. Bronchodilators are preferably administered off NIV. Patients should be closely monitored, including ABG, respiratory rate and heart rate. ABGs should be repeated after 1 hour of NIV therapy, and 1 hour after subsequent change in settings or 4 hours in stable patients.

All non-invasive ventilation services should have their own local protocol based on these

guidelines. There should be a clear plan of what to do in the event of deterioration.

Patients with a pH <7.26 should be managed with a low threshold for intubation, and this should be considered in this case. Functional status, BMI, requirement for oxygen when stable, comorbidities and previous admissions should be considered in addition to age and FEV₁ when assessing suitability. Whilst in clinical practice you would give NIV whilst awaiting consideration from intensive care, it is important to consider intubation in this patient who is failing to improve.

Intravenous aminophylline should be used only if there is an inadequate response to nebulised bronchodilators. Levels should be closely monitored.

[Q: 2899] OnExamination 2012 - Respiratory

Which of the following statements regarding the sweat test is true?

- 1- At least 25 mg of sweat is necessary for a reliable result.
- 2- False/positive results may be encountered in children with nephrotic syndrome.
- 3- More than 60 mmol/L of chloride in sweat is diagnostic of cystic fibrosis.
- 4- Sweating is enhanced by application of atropine.
- 5- The filter paper is left on for a total of about four hours.

Answer & Comments

Answer: 3- More than 60 mmol/L of chloride in sweat is diagnostic of cystic fibrosis.

The sweat test is conducted using pilocarpine iontophoresis.

A 3mA current carries pilocarpine into the skin of the forearm stimulating local sweating. The arm is washed with distilled water and sweat

collected on a filter paper or gauze. The duration of collection is usually 30-60 minutes.

The filter paper is removed, weighed and eluted in distilled water. At least 50 mg and preferably 100 mg of sweat should be collected for reliable results. It may not be possible to collect this amount in young infants.

More than 60mmol/L of chloride is diagnostic of cystic fibrosis (CF) when one or more other criteria are present. In healthy adults, the sweat chloride values increase slightly, but 60 mmol/L still differentiates CF from other conditions.

False/negative results may be encountered in nephrotic syndromes.

[Q: 2900] OnExamination 2012 - Respiratory

A 27-year-old woman is referred to the respiratory clinic with increasing shortness of breath and episodes of syncope. On further questioning it transpires that her mother suffered from a lung / circulatory condition and died a few years after a heart lung transplant, and her aunt died at a young age, from a condition which they were told was heart failure.

Her BP is 145/82 mmHg, her pulse is 85 and regular, and her BMI is 22. There is a murmur of tricuspid regurgitation, and bilateral pitting oedema of the ankles.

Investigations show:

Haemoglobin 12.6 g/dl(11.5-16.0)

White cell count $6.8 \times 10^9/L$ (4-11)

Platelets $205 \times 10^9/L$ (150-400)

Sodium 136 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 119 $\mu\text{mol/l}$ (79-118)

Echocardiogram Evidence of increased right sided pressures

Which of the following is the most likely mode of inheritance?

- 1- Autosomal dominant
- 2- Autosomal recessive
- 3- De-novo mutation
- 4- X linked dominant
- 5- X linked recessive

Answer & Comments

Answer: 1- Autosomal dominant

This woman has familial primary pulmonary hypertension (PPH). This is evidenced by her age, and particularly symptoms such as increased shortness of breath and recurrent syncope. The increased right sided pressures are also a give away with respect to the diagnosis.

The fact her aunt and mother suffered from a similar disease points to an inherited component.

The condition is recognised to account for 15-20% of cases of PPH and is due to an inherited mutation in the BMPR2 gene which codes for a receptor in the TGF beta family. Hereditary haemorrhagic telangiectasia, another cause of inherited pulmonary hypertension, also carries an autosomal dominant inheritance pattern.

The occurrence of pulmonary hypertension in a number of family members makes a de novo mutation highly unlikely.

Of the other modes of inheritance listed, only autosomal dominant is correct.

[Q: 2901] OnExamination 2012 - Respiratory

You review a 52-year-old gentleman with COPD in chest clinic three weeks after a recent admission for an exacerbation.

He has had repeated admissions to hospital with exacerbations of his COPD, but until now

has refused to quit smoking. He now reports that he is keen to quit smoking and is requesting help to achieve this.

Which of the following smoking cessation methods is most likely to be successful in this patient?

- 1- Acupuncture
- 2- Bupropion plus counselling
- 3- Counselling
- 4- Hypnosis
- 5- Nicotine replacement patches plus counselling

Answer & Comments

Answer: 5- Nicotine replacement patches plus counselling

Research has shown that medication to relieve nicotine cravings (such as nicotine patches or bupropion) coupled with counselling has the greatest potential of success, although rates of cessation are only 20%.

Bupropion is contraindicated in patients with eating disorders or a history of seizures.

It should also be avoided in patients also taking corticosteroids, antimalarials, tramadol and antidepressants, as these lower seizure threshold. Our patient is likely to be on corticosteroids at regular intervals.

Acupuncture success rates are between 5-15%, but the evidence for hypnosis is limited.

[Q: 2902] OnExamination 2012 - Respiratory

A 53-year-old dental secretary presents with a four month history of dry cough. She has never smoked.

She denies haemoptysis, weight loss and dyspnoea. There is no post nasal drip.

Her medical history consists only of hypertension for one year. She is on ramipril

2.5 mg, bendroflumethiazide 2.5 mg and amlodipine 10 mg.

On examination her JVP is not raised and her chest is clear. A CXR was requested.

What would be the most likely cause of her cough?

- 1- Allergic rhinitis
- 2- Bronchiectasis
- 3- Drug induced
- 4- Interstitial lung disease
- 5- Lung cancer

Answer & Comments

Answer: 3- Drug induced

ACE inhibitors can cause dry cough. They can then be replaced with an angiotensin receptor blocker. It is important to ask about the onset of cough and the start of a new drug.

There no history to suggest allergic rhinitis.

Bronchiectasis causes a productive cough.

Interstitial lung disease and lung cancer may be causes but they are not the most likely and in this scenario there is nothing to suggest either.

[Q: 2903] OnExamination 2012 - Respiratory

A 58-year-old man presents to the Emergency department with an acute episode of breathlessness and pleuritic-sounding chest pain.

He is currently receiving treatment for metastatic prostate cancer.

On examination he is dyspnoeic, tachycardic (heart rate of 121 bpm) and has saturations of 85% on air. His blood pressure is 107/67 mmHg.

Following assessment of his clinical probability, he is categorised as a high risk for a pulmonary embolism (PE) - Wells score 5.5.

The attending medical doctor requests a CTPA.

What treatment, if any, should this patient receive before the results of his imaging are known?

- 1- Low molecular weight heparin (LMWH)
- 2- No treatment until the result of the CTPA is known
- 3- Thrombolysis
- 4- Unfractionated heparin (UFH)
- 5- Warfarin

Answer & Comments

Answer: 1- Low molecular weight heparin (LMWH)

The latest British Thoracic Society (BTS) guidelines recommend that in the treatment of patients with a high or intermediate probability of a non-massive pulmonary embolism (PE), low molecular weight heparin should be given before imaging.

Thrombolysis should be reserved for those patients with a massive PE (with haemodynamic instability) and may be given in the absence of imaging if cardiac arrest is imminent.

Haemodynamic instability may be demonstrated by hypotension, right ventricular strain on an ECG or signs of right heart failure.

Unfractionated heparin should be considered in a massive PE, or if rapid reversal of anticoagulation may be necessary. It may also be given as a bolus dose. However LMWH is preferable to UFH due to ease of use and similar efficacy.

Warfarin therapy should only be started in a proven PE.

Management of suspected acute pulmonary embolism.

[Q: 2904] OnExamination 2012 - Respiratory

A stable hand is referred to the medical admission unit with increasing breathlessness over the last six months since starting work at a new yard.

He reports initially symptoms of dyspnoea in the evenings with a dry cough. He has also noted occasional fevers at night. His breathing has become steadily worse.

A chest x ray is performed which shows some fluffy nodular shadowing.

What is the most likely causative agent for his condition?

- 1- Avian proteins
- 2- *Epicoccum nigrum*
- 3- *Klebsiella*
- 4- *Penicillium* species
- 5- Thermophilic Actinomyces bacteria

Answer & Comments

Answer: 5- Thermophilic Actinomyces bacteria

The most common example of allergic alveolitis is farmer's lung.

This is caused by dust from mouldy hay contaminated with thermophilic Actinomyces bacteria, and as a stable hand this patient is likely to have been in close contact with this allergen. Typically symptoms tend to occur several hours after exposure. Chest x ray may demonstrate fluffy nodular shadowing or ground glass appearances.

Avian proteins are the allergen responsible for pigeon fancier's lung.

Penicillium species are responsible for respiratory disease in cheese and cork workers and are due to fungal contaminants of materials.

Klebsiella and *Epicoccum nigrum* are other bacterial causes of allergic alveolitis and are

found in contaminated water, wood shavings, etc.

[Q: 2905] OnExamination 2012 - Respiratory

A 47-year-old male presents with marked shortness of breath which has deteriorated over the last two weeks.

On examination he has a hard irregular thyroid mass and has some difficulty breathing. There appears to be no retrosternal extension and he appears clinically euthyroid.

What is the most likely diagnosis?

- 1- Anaplastic carcinoma of thyroid
- 2- Bleed into a thyroid nodule
- 3- Follicular thyroid carcinoma
- 4- Medullary thyroid carcinoma
- 5- Multinodular goitre

Answer & Comments

Answer: 1- Anaplastic carcinoma of thyroid

This patient is likely to have anaplastic carcinoma of the thyroid with compression/infiltration of the trachea causing the shortness of breath.

Bleeding into a thyroid nodule is usually associated with a rapid onset of pain.

Follicular thyroid carcinoma would be unlikely to produce such marked infiltrative features in such a short period of time. Typically patients with follicular disease would present with a nodule and/or LAP.

Medullary thyroid cancer is associated most often with multiple endocrine neoplasia (MEN) II and would be particularly unusual.

This is unlikely to be a multinodular goitre as this would be unlikely to compress the trachea unless retrosternal.

The description is more compatible with a thyroid malignancy as it has deteriorated rapidly

[Q: 2906] OnExamination 2012 - Respiratory

A 71-year-old man presents with a tender left calf and has a background history of headaches, tiredness and dizziness. He is a smoker of 20 cigarettes daily and drinks 45 units of alcohol weekly.

On examination he was plethoric, had a blood pressure of 186/102 mmHg and has a swollen, hot tender and erythematous left calf. Dopplers confirm the presence of a deep vein thrombosis.

Investigations reveal:

Haemoglobin 19 g/dl(13-18)

Haematocrit 0.58(0.40-0.52)

White cell count $12.5 \times 10^9/L$ (4-11)

Platelet count $500 \times 10^9/L$ (150-400)

Which one of the following is the most appropriate investigation to establish the diagnosis?

- 1- Abdominal ultrasound scan
- 2- Arterial blood gases
- 3- Bone marrow trephine
- 4- Leucocyte alkaline phosphatase score
- 5- Red blood cell mass

Answer & Comments

Answer: 5- Red blood cell mass

The most significant abnormality is the raised haemoglobin and haematocrit suggesting polycythaemia which in the presence of all the other features suggests secondary polycythaemia.

Therefore, the most useful and appropriate investigation will be red cell mass studies

which will distinguish between true and relative polycythaemia.

Further investigations will then be dictated by the the results of this initial test; an ultrasound scan (USS) bone marrow, etc, and blood gases may be needed after the initial red cell mass studies.

The leucocyte alkaline phosphatase score is rather outdated and seldom performed.

The raised WCC and platelet count would suggest that this is primary polycythaemia not apparent polycythaemia but red blood cell mass is still the best answer.

[Q: 2907] OnExamination 2012 - Respiratory

An 80-year-old man with a five year history of diet controlled type 2 diabetes mellitus presents with a one month history of cough and weight loss. He was a non-smoker and had difficulty expectorating.

Investigation revealed a HbA1c of 7% (3.8-6.4) but his chest x ray showed a cavitating left apical shadow.

Which of the following investigations would be most useful in establishing the cause of this lesion?

- 1- Bronchoscopy
- 2- CT scan of the chest
- 3- Gastric aspirate for acid-fast bacilli
- 4- Percutaneous lung biopsy
- 5- Sputum for acid-fast bacilli

Answer & Comments

Answer: 1- Bronchoscopy

The differential diagnosis of cavitating lung lesions is shown below.

The most likely diagnosis in this non-smoking man is post primary tuberculosis as a result of reactivation of quiescent disease. He has

several risk factors including increasing age and diabetes.

The patient is unable to produce sputum therefore undertaking a bronchoscopy with bronchial washings for microscopy staining and culture is the investigation of choice. Gastric lavage for AFB is unpleasant for the patient has a lower yield than bronchoscopy and is therefore rarely undertaken now.

Causes of cavitating masses on CXR:

Lung abscess

Tuberculosis

Fungal infection (for example, histoplasmosis, coccidioidomycosis)

Malignancy

Wegener's granulomatosis commonly

Rheumatoid arthritis (multiple)

Infarction.

Only untreated smear-positive pulmonary TB is likely to be infectious.

Active disease may be indicated by grade III/IV response to tuberculin. Eighty per cent of individuals with history of BCG vaccination have grade I/II response.

All forms of pulmonary TB may be treated equally except tuberculous pleural effusion which may require drainage (with large effusions causing breathlessness) and adjunct corticosteroids to delay reaccumulation.

Length of treatment for other forms are:

Bone TB nine months

Meningitis one year

Drug resistance two years.

Streptomycin has high activity against extracellular organisms whilst pyrazinamide has high activity against intracellular organisms.

[Q: 2908] OnExamination 2012 - Respiratory

Which of the following statements is true of infections with Mycobacterium tuberculosis?

- 1- A positive tuberculin test indicates active disease
- 2- In pregnant women treatment should not be given until after delivery
- 3- Lymph node positive disease requires longer treatment than pulmonary disease
- 4- Non-sputum producing patients are non-infectious
- 5- Pyrazinamide has high activity against active extracellular organisms

Answer & Comments

Answer: 4- Non-sputum producing patients are non-infectious

[Q: 2909] OnExamination 2012 - Respiratory

A 16-year-old boy with cystic fibrosis (CF) presents with abdominal pain.

Which of the following is most likely to be the cause?

- 1- Irritable bowel syndrome
- 2- Meconium ileus equivalent syndrome
- 3- Pyelonephritis
- 4- Renal calculi
- 5- Ulcerative colitis

Answer & Comments

Answer: 2- Meconium ileus equivalent syndrome

Meconium ileus equivalent or distal intestinal obstruction syndrome occurs in older children and adults with CF and presents with colicky

abdominal pain, distension, vomiting and failure to pass faeces.

The plain abdominal x ray confirms small bowel obstruction.

Initial management includes rehydration with intravenous fluids and oral N-acetyl cysteine.

Other gastrointestinal complications of / associations with CF include:

Liver cirrhosis

Gall bladder disease

Pancreatitis

Peptic ulceration

Hiatus hernia

Coeliac disease and

Crohn's disease.

[Q: 2910] OnExamination 2012 - Respiratory

A 41-year-old woman comes to the clinic with increasing shortness of breath. She has a history of systemic sclerosis, takes omeprazole for reflux symptoms and nifedipine slow release for Raynaud's disease.

On examination her BP is 155/85 mmHg, pulse is 82 and regular. There is peripheral calcinosis on examination of the hands and pinching of the corners of the mouth consistent with scleroderma. Auscultation of the chest reveals scattered inspiratory crackles across both lung fields.

Investigations show:

Haemoglobin 12.2 g/dl(11.5-16.0)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $199 \times 10^9/L$ (150-400)

ESR 62 mm/hr(<10)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 131 micromol/l (79-118)

CXR - Bilateral interstitial infiltrates.

Echocardiogram - Ejection fraction 53%.

Which of the following is the most likely diagnosis?

1- Bacterial pneumonia

2- Cryptogenic fibrosing alveolitis

3- Eosinophilic pneumonitis

4- Interstitial fibrosis

5- Pulmonary oedema

Answer & Comments

Answer: 4- Interstitial fibrosis

Interstitial fibrosis is recognised as the most common pulmonary manifestation of systemic sclerosis, and the scattered crackles on auscultation, coupled with bilateral interstitial infiltrates on chest radiograph fits best with the diagnosis.

The condition may be steroid responsive; as such a trial of prednisolone plus or minus an appropriate second line agent is indicated.

Given the chronic nature of her disease bacterial infection is unlikely.

Cryptogenic fibrosing alveolitis is by definition of unknown aetiology and this too therefore cannot be the correct answer.

Given the normal ejection fraction pulmonary oedema is also unlikely.

The absence of leukocytosis, and normal eosinophil count makes eosinophilic pneumonitis unlikely.

[Q: 2911] OnExamination 2012 - Respiratory

A 45-year-old female pigeon fancier comes to the emergency department with shortness of breath and flu-like symptoms.

She tells you that some of her birds have also been unwell.

There is no past medical history of note. On examination her BP is 110/60 mmHg, her pulse is 65 and regular, and temperature is 38.2°C. There are scattered crackles and wheeze on auscultation of the chest.

Investigations show:

Haemoglobin 11.8 g/dl (11.5-16.0)

White cell count $3.9 \times 10^9/L$ (4-11)

Platelets $193 \times 10^9/L$ (150-400)

ESR 72 mm/hr (<10)

Sodium 136 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 118 micromol/l (79-118)

Alanine aminotransferase 102 U/l (5-40)

Alkaline phosphatase 230 U/l (39-117)

CXR - Widespread hazy opacities affecting both lower lobes.

Which of the following is the most likely diagnosis?

- 1- Avian influenza
- 2- Legionnaire's disease
- 3- Psittacosis
- 4- Streptococcus pneumoniae
- 5- Q fever

Answer & Comments

Answer: 3- Psittacosis

There are a number of signs and investigations that support a diagnosis of psittacosis in this patient. Relative bradycardia with non-specific chest signs, coupled with diffuse chest x ray changes, a low white count and abnormal LFTs are consistent with the disease. Tetracyclines are the antibiotics of choice.

Avian influenza occurs in epidemics, and as yet H5N1, the strain thought most likely to lead to a human epidemic, has not acquired the ability to spread rapidly between individuals.

Q fever is mainly transmitted by ticks and legionnaire's disease by contaminated air conditioning systems.

Given the history of bird keeping and the diffuse consolidation seen, psittacosis is more likely than streptococcal pneumonia.

[Q: 2912] OnExamination 2012 - Respiratory

A 55-year-old gentleman has recently been diagnosed with idiopathic pulmonary fibrosis. He has been on the internet researching pulmonary fibrosis and wants to know if he is suitable for steroid therapy.

Which of the following is most likely to be associated with a response to steroid therapy?

- 1- Absence of pulmonary hypertension on an ECHO
- 2- Age at diagnosis
- 3- Bronchoalveolar lavage lymphocytosis
- 4- paO_2 of 8.6 kPa
- 5- Predominant reticular pattern on HRCT

Answer & Comments

Answer: 3- Bronchoalveolar lavage lymphocytosis

There are no satisfactory treatment options for idiopathic pulmonary fibrosis (usual interstitial pneumonia/UIP). It is necessary to distinguish UIP from non-specific interstitial pneumonia (NSIP) as this is more steroid-responsive.

Bronchoalveolar lavage (BAL) lymphocytosis predicts a better corticosteroid response than the typical BAL neutrophilia.

A predominant reticular pattern on HRCT is consistent with UIP and correlates with irreversible fibrosis. The ground glass appearance often associated with NSIP indicates inflammation, which may be responsive to steroids.

[Q: 2913] OnExamination 2012 - Respiratory

A 72-year-old patient with COPD would like to spend two weeks in Australia. He lives in Manchester.

His FEV₁ is 60%. He was last admitted to hospital a year ago because of an infective exacerbation of COPD. His O₂ sat is 96% on air.

He takes regular inhalers.

What advice would you give?

- 1- Advise him not to fly
- 2- Advise inflight oxygen 28%
- 3- Advise inflight oxygen 35%
- 4- Allow flight and no oxygen required
- 5- Perform a hypoxic challenge test

Answer & Comments

Answer: 4- Allow flight and no oxygen required

History, examination, assessment of severity of chronic obstructive pulmonary disease (COPD) and O₂ sat at sea level should be performed.

Air travel advice can be reviewed in BTS guidelines.

A summary is present in the table below: (additional risk factors: hypercapnia, FEV₁ <50% predicted, lung cancer, restrictive lung disease involving the parenchyma [fibrosis], chest wall [kyphoscoliosis] or respiratory muscles, ventilator support, cerebrovascular or cardiac disease, within six weeks of discharge for an exacerbation of chronic lung or cardiac disease).

Sea level SpO₂ > 95% - Oxygen not required

Sea level SpO₂ 92-95% and no risk factor - Oxygen not required

Sea level SpO₂ 92-95% and additional risk factor - Perform hypoxic challenge test with arterial or capillary measurements

Sea level SpO₂ < 92% - In-flight oxygen

Receiving supplemental oxygen at sea level - Increase the flow while at cruising altitude.

[Q: 2914] OnExamination 2012 - Respiratory

Which of the following is true of BCG vaccination?

- 1- Is a killed polysaccharide antigen vaccine
- 2- Is contraindicated in neonates
- 3- Is presently routinely offered in the UK at age 16 years
- 4- Provides protection against leprosy
- 5- Should be given to all children who have a strongly positive tuberculin test

Answer & Comments

Answer: 4- Provides protection against leprosy

A. The BCG vaccine is an attenuated strain; it provides approximately 70% protection.

B. BCG vaccine may given to newborns at high risk of exposure.

C. BCG is given at comprehensive school entry (age 11-13). 'to 'BCGs are no longer routine for the general population at school age, only for 'at risk' groups.'

D. It has also found a use in stimulating the immune system for the treatment of some cancers.

E. It should not be given to these children. A low reactivity Heaf test (grade 0-1) should be documented before administration.

[Q: 2915] OnExamination 2012 - Respiratory

A 48-year-old woman presents to her GP with Cushingoid facies and hyperpigmentation of the skin on her face and chest. She has smoked 20 cigarettes per day for 30 years.

Examination reveals no gross abnormalities. Her chest x ray reveals a 2 cm irregularly shaped mass in the right upper lobe, in proximity to the mediastinum. A CT guided needle biopsy of the lung lesion is performed.

Which would be the most likely cytologic finding?

- 1- Adenocarcinoma
- 2- Benign bronchial adenoma
- 3- Bronchoalveolar cell carcinoma (BAC)
- 4- Small cell (oat cell) carcinoma
- 5- Squamous cell carcinoma

Answer & Comments

Answer: 4- Small cell (oat cell) carcinoma

This patient has typical features of ectopic adrenocorticotrophic hormone (ACTH) secretion which is usually due to a small cell lung cancer.

Other less common causes of ectopic ACTH secretion include bronchial carcinoids.

[Q: 2916] OnExamination 2012 - Respiratory

A 53-year-old man presents to the respiratory clinic. He has been involved in nuclear power plant construction for much of his life and has increasing shortness of breath and chronic cough over the past 12 months.

On examination his BP is 138/82 mmHg, pulse is 72 and heart sounds are normal. There are occasional crackles on auscultation of the chest.

Investigations show:

Haemoglobin 12.4 g/dl(13.5-17.7)

White cell count $10.2 \times 10^9/L$ (4-11)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 122 micromol/l (79-118)

CXR - Bilateral hilar lymphadenopathy.

Which of the following is the most likely diagnosis?

- 1- Asthma
- 2- Berylliosis
- 3- COPD
- 4- Cryptogenic fibrosing alveolitis
- 5- Sarcoidosis

Answer & Comments

Answer: 2- Berylliosis

Exposure to beryllium is seen in the nuclear power, telecommunications, semi-conductor and electronics industries. It results in a similar clinical picture to that of sarcoidosis; in this case it is the patient's occupation that pushes us towards berylliosis as the most appropriate answer.

Sarcoidosis is the major differential here, but it is the possible exposure to beryllium because of occupation which points us away from this as the most likely diagnosis.

Cryptogenic fibrosing alveolitis would be associated with evidence of interstitial fibrosis on chest x ray.

We are not told of any smoking history consistent with chronic obstructive pulmonary disease (COPD) and there is no evidence of wheeze to suggest asthma.

[Q: 2917] OnExamination 2012 - Respiratory

A 43-year-old Caribbean female comprehensive school teacher complains of slowly increasing breathlessness. She has no smoking history.

Investigations reveal she has bilateral enlarged hilar lymph nodes, elevated serum calcium, interstitial lung disease, and enlarged liver and spleen.

What is the most likely diagnosis?

- 1- Coccidioidomycosis
- 2- Hyperparathyroidism
- 3- Hypervitaminosis D
- 4- Sarcoidosis
- 5- Tuberculosis

Answer & Comments

Answer: 4- Sarcoidosis

Sarcoid is common in subjects of Caribbean origin.

Subacute increasing breathlessness also suggests the diagnosis of sarcoid, and an elevated calcium narrows the differential diagnosis further.

Hyperparathyroidism would not cause symptoms of breathlessness.

Coccidioidomycosis is a non-infective fungal infection caused by inhalation of the spores of *Coccidioides immitis*. It usually presents with fever, cough, myalgia and rash. It is endemic mainly to the south-western USA and North Mexico.

TB is the major differential in this case.

Hypercalcaemia and bilateral hilar lymphadenomegaly (BHL) however are in favour of a diagnosis of sarcoid.

[Q: 2918] OnExamination 2012 - Respiratory

A 67-year-old man who has a long history of chronic bronchitis is admitted from home with an acute exacerbation.

Investigations show:

pCO₂ 11 kPa(4.7-6)

pO₂ 6.7 kPa(10-13.3)

Which of the following would be expected in this patient?

- 1- A metabolic acidosis with a low bicarbonate would be expected

- 2- Extensor plantar responses may be expected
- 3- Gentamicin would be a reasonable initial treatment until cultures are available
- 4- Oxygen therapy should aim to increase the pO₂ to above 8 kPa (60 mmHg)
- 5- Peripheral oedema indicates coexisting heart failure

Answer & Comments

Answer: 2- Extensor plantar responses may be expected

Together with emphysema, chronic bronchitis is part of the spectrum of respiratory disease described as chronic obstructive pulmonary disease (COPD). Chronic bronchitis itself is defined as chronic cough and sputum production for at least three months of two consecutive years in the absence of other disease which could explain these symptoms.

The ABG here demonstrates type 2 respiratory failure. The patient is likely to be acidotic, due to the raised pCO₂ - i.e. a respiratory acidosis. The bicarbonate is likely to be normal, or raised if the patient has chronic hypercapnia.

The signs and symptoms of respiratory acidosis are:

Central nervous system
Respiratory system
Cardiovascular system

Cerebral vasodilation
Breathlessness
Flushing, bounding pulse

Increased intracranial pressure
Cyanosis
Cor pulmonale

Headache, confusion, agitation
Pulmonary hypertension
Systemic hypotension

Hallucinations, transient psychosis
Arrhythmias

Myoclonic jerks, flapping tremor,

extensor plantars, depressed reflexes
Initially good cardiac output,

then decreases

Papilloedema, constricted pupils

Seizures, coma

BTS guidelines would recommend treatment of exacerbations with amoxicillin, co-amoxiclav or cephalosporin (depending on local sensitivities). Gentamicin is not usually indicated.

Oxygen should be given to maintain SaO₂ within the patient's individual target range, if available (COPD patients are being given cards with this information, so always ask). If the individual target is not known, saturations should be maintained at 88-92%. ABGs should be repeated at regular intervals to monitor response to treatment, and oxygen weaned when possible. The ABG is used to see the pH and pCO₂, and it is these values that guide treatment rather than the pO₂ alone.

Peripheral oedema may be present as a dependent oedema, as patients with COPD may have limited mobility due to dyspnoea, and therefore does not necessarily indicate heart failure.

[Q: 2919] OnExamination 2012 - Respiratory

A 24-year-old male presents after developing a bluish discolouration of the body, lips and nails. He denies any relevant past medical history.

Examination reveals a central cyanosis and a grey complexion.

Investigation revealed:

Haemoglobin 17.0 g/dl(13.0-18.0)

paO₂ 13.0 kPa(11.3-12.6)

SaO₂ (using an oximeter)85%(>95)

What is the most likely diagnosis?

- 1- Argyria
- 2- Cyanotic congenital heart disease
- 3- Haemochromatosis

4- Methaemoglobinaemia

5- Methylene blue poisoning

Answer & Comments

Answer: 4- Methaemoglobinaemia

This patient is otherwise well and has no specific features of congenital heart disease (clubbing, etc).

He appears desaturated with saturations of 85%, yet good pO₂. This is a typical description of methaemoglobinaemia, which is the accumulation of reversibly oxidised methaemoglobin causing reduced oxygen affinity of the Hb molecule with consequent cyanosis. It can occur due to an inherited condition or as a consequence of drugs such as nitrites.

Argyria is colloidal silver toxicity.

[Q: 2920] OnExamination 2012 - Respiratory

A 56-year-old woman is recently diagnosed with small cell carcinoma of the lung.

Which of the following non-metastatic manifestations is she most likely to develop?

- 1- Eaton-Lambert syndrome
- 2- Ectopic PTH-related peptide secretion
- 3- Erythema gyratum repens
- 4- Hypertrophic pulmonary osteoarthropathy (HPOA)
- 5- Myasthenia gravis

Answer & Comments

Answer: 1- Eaton-Lambert syndrome

Non-metastatic paramalignant manifestations for small cell carcinoma include:

Inappropriate ADH and ectopic ACTH secretion

Eaton-Lambert syndrome (70% occur in association with small cell carcinoma - autoimmune disorder affecting release of acetylcholine at neuromuscular junction causing proximal muscle weakness, fatiguability and muscle wasting. Often, power is increased initially by exercise - reversed myasthenia effect. Weakness and fatiguability can be improved with guanidine hydrochloride)

Polymyositis

Dementia

Cerebellar syndrome and

Peripheral neuropathy.

Cutaneous lesions (dermatomyositis, thrombophlebitis migrans, acanthosis nigricans and erythema gyratum repens) are rare.

HPOA and ectopic parathyroid hormone (PTH)-related peptide secretion relates particularly to squamous cell carcinoma.

[Q: 2921] OnExamination 2012 - Respiratory

A 24-year-old woman presents to the respiratory clinic some nine months after the birth of her first child.

She has suffered increasing shortness of breath over the past few weeks and months, so much so that she can barely walk up stairs or to the bus stop at the end of her street.

On examination she looks short of breath at rest. Her JVP is elevated and there is mild bilateral ankle swelling. Her lung fields are clear.

Investigations show:

Haemoglobin 13.2 g/dl(11.5-16.0)

White cell count $7.3 \times 10^9/L$ (4-11)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 116 micromol/l (79-118)

Echocardiogram - Evidence of pulmonary hypertension.

VQ scan - no evidence of pulmonary embolism.

Which of the following is the most appropriate initial management?

1- Beta blocker

2- Calcium antagonist

3- Endothelin receptor antagonist

4- PDE-5 inhibitor

5- Prostaglandin infusion

Answer & Comments

Answer: 3- Endothelin receptor antagonist

This woman has primary pulmonary hypertension, which often presents in women after the birth of the first child.

Calcium antagonists form the basis of initial therapy only for those patients without right sided heart failure, therefore an endothelin receptor antagonist would be initial therapy of choice. Examples of endothelin receptor antagonists include bosentan and ambrisentan. They significantly reduce pulmonary artery pressure, but adverse effects include peripheral oedema and liver function test monitoring is recommended.

Beta blockers are not recommended in the management of primary pulmonary hypertension as their major effect is on reducing peripheral blood pressure.

Calcium antagonists are effective in only 10-15% of patients and only recommended if there is no right sided heart failure.

PDE-5 inhibitors are used in mild disease, or in stage III or IV NYHA functional status in combination with endothelin receptor antagonists.

Nebulised or subcutaneous prostacyclin analogues are less convenient than oral options and tend to be reserved for combination with oral therapy.

[Q: 2922] OnExamination 2012 - Respiratory

A 29-year-old man is referred to the respiratory clinic with increasing shortness of breath. He smokes 5-10 cigarettes per day and drinks 30 units of alcohol per week. He reports wheeze and a chronic cough so his GP has been managing him for asthma.

On examination his BP is 132/72 mmHg, pulse is 80 and regular. There is scattered wheeze and coarse crackles on auscultation of the chest.

Investigations show:

Haemoglobin 13.5 g/dl (13.5-17.7)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $232 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 115 $\mu\text{mol/l}$ (79-118)

Alanine aminotransferase 110 U/l (5-40)

CXR Predominant lower lobe emphysema

Pulmonary function testing obstructive defect, FEV 42% of predicted

According to NICE, which of the following is the most appropriate treatment?

- 1- Alpha-1-antitrypsin
- 2- Home oxygen therapy
- 3- Inhaled corticosteroids and long acting beta agonist therapy
- 4- Ipratropium as required
- 5- Rotating antibiotics

Answer & Comments

Answer: 3- Inhaled corticosteroids and long acting beta agonist therapy

Alpha-1-antitrypsin is not recommended by NICE.

We are not told about any criteria which qualify this man for home O₂ therapy.

PRN ipratropium whilst symptom relieving does not impact on his prognosis.

Rotating antibiotics may only be of value for frequent infections.

[Q: 2923] OnExamination 2012 - Respiratory

A 39-year-old chef, who arrived in the United Kingdom from Pakistan eight months ago, presents to the chest clinic with a two month history of weight loss, dry cough and night sweats.

Investigations reveal he has multi-drug-resistant tuberculosis (MDR-TB).

What is the minimum overall duration of treatment for MDR-TB once the sputum is negative?

- 1- 3 months
- 2- 6 months
- 3- 9 months
- 4- 12 months
- 5- 24 months

Answer & Comments

Answer: 3- 9 months

This question requires an understanding of the definition of MDR-TB and the differences in treatment duration.

Multi-drug-resistant TB as the name suggests is Mycobacterium tuberculosis resistant to two or more first line agents, which most commonly are isoniazid and rifampicin. There can be monoresistance to each of the first line agents, but this is not MDR-TB.

Treatment of MDR-TB is complex and time consuming.

Risk factors for acquiring MDR-TB include previous TB treatment, HIV infection, contact with drug resistant disease and treatment failure.

Initial treatment includes the use of five agents until sputum is negative and then continuation of three to which the TB is sensitive to for a minimum of nine months but sometimes up to 24 months.

[Q: 2924] OnExamination 2012 - Respiratory

A 48-year-old woman presents to the Emergency department with a one week history of a non-productive cough and increasing breathlessness. She reports her breathing is much worse on exertion.

Her past medical history includes hypertension, migraines and a renal transplant for end stage hypertensive nephropathy.

Examination reveals mild pyrexia of 37.8°C and most notably she was profoundly hypoxic with oxygen saturations of 80% on air. An arterial blood gas confirmed her hypoxia. A CXR showed some patchy bilateral infiltrates, more pronounced on the left.

She is diagnosed with community-acquired pneumonia and treated empirically with recommended antibiotics. The next day she deteriorates and requires intubation and ventilation.

What is the most likely causative organism?

- 1- Chlamydia pneumoniae
- 2- Legionella pneumophila
- 3- Pneumocystis carinii
- 4- Pneumocystis jiroveci
- 5- Pseudomonas aeruginosa

Answer & Comments

Answer: 4- Pneumocystis jiroveci

Pneumocystis is yeast-like fungal organism that can cause opportunistic infection in those who are immunocompromised.

The organism was initially described as Pneumocystis carinii, but this is the variant that causes infection in animals and not humans. The human variant of the organism is Pneumocystis jiroveci.

Classically patients with Pneumocystis pneumonia (PCP) have a dry cough, profound hypoxia and bilateral infiltrates on chest x ray.

Pseudomonas is common in hospital-acquired pneumonia, and in patients with cystic fibrosis.

The other two are atypical pathogens. However given the history and findings, PCP should be excluded first.

[Q: 2925] OnExamination 2012 - Respiratory

According to the latest NICE guidance, which of the below combinations of results is now classed as severe airflow obstruction in chronic obstructive pulmonary disease (COPD)?

Note: all values are post bronchodilator.

- 1- FEV₁/FVC <0.7 & FEV₁ predicted <30%
- 2- FEV₁/FVC <0.7 & FEV₁ predicted 30-49%
- 3- FEV₁/FVC <0.7 & FEV₁ predicted 50-79%
- 4- FEV₁/FVC <0.75 & FEV₁ predicted <30%
- 5- FEV₁/FVC <0.75 & FEV₁ predicted 30-49%

Answer & Comments

Answer: 2- FEV₁/FVC <0.7 & FEV₁ predicted 30-49%

NICE have recently (2010) produced a clinical guideline as a tool to assess airflow obstruction.

There have been some alterations to the previous classification of airflow obstruction, based on the American Thoracic Society,

GOLD and European Respiratory Society standards.

Below are the new classifications:

Mild - FEV₁ predicted more than 80%

Moderate - FEV₁ predicted 50 - 79%

Severe - FEV₁ predicted 30-49%

Very severe - FEV₁ predicted less than 30%.

FEV₁/FVC ratio is less than 0.7 in COPD.

NICE guidelines on COPD.

[Q: 2926] OnExamination 2012 - Respiratory

Carcinoid tumours of the lung (bronchial adenomas) originate from which of the following cell types?

- 1- Ciliated cell
- 2- Clara cell
- 3- Kulchitsky (K) cell
- 4- Mucus (goblet) cell
- 5- Type 2 alveolar cell

Answer & Comments

Answer: 3- Kulchitsky (K) cell

Carcinoid tumours (so called argentaffinomas, as they take up silver) are neuroendocrine cells and are derived from the K cells in the lung.

[Q: 2927] OnExamination 2012 - Respiratory

A 62-year-old man, who has worked for a long period of his life as a boiler lagger, presents to the clinic for review.

He is worried as over the past year he has suffered increasingly severe shortness of breath with a dry cough. He also reports that his fingers have begun to change shape. His

GP has given him a salbutamol inhaler but it has had little effect on his symptoms.

Other history includes smoking of 10 cigarettes per day, and hypertension for which he takes indapamide.

On examination his BP is 142/72 mmHg, his pulse is 80 and regular, and he looks short of breath at rest. There are inspiratory basal crackles.

Investigations show:

Haemoglobin 13.1 g/dl(13.5-17.7)

White cell count 7.1 x 10⁹/L (4-11)

Platelets 152 x 10⁹/L (150-400)

Sodium 138 mmol/l (135-146)

Potassium 3.9 mmol/l (3.5-5)

Creatinine 110 micromol/l (79-118)

pH 7.42(7.35-7.45)

pCO₂ 4.2 kPa(4.8-6.1)

pO₂ 9.3 kPa(10-13.3)

CXR - Nodular opacification.

What is the diagnosis?

- 1- Asbestosis
- 2- Asthma
- 3- COPD
- 4- Cryptogenic fibrosing alveolitis
- 5- Tuberculosis

Answer & Comments

Answer: 1- Asbestosis

The likely exposure to asbestos from working in the boiler industry means that the changes seen here including signs of fibrosis on examination, hypoxia and chest x ray changes are most likely to be due to asbestosis. Progressive lung fibrosis occurs, eventually leading to respiratory failure, and the fibrotic changes are non-steroid responsive.

Whilst he has been given an inhaler by his GP, there is nothing on the examination to suggest

either chronic obstructive pulmonary disease (COPD) or asthma.

Cryptogenic fibrosing alveolitis by definition has no known cause so cannot be the correct answer, and there is no history to suggest exposure to tuberculosis.

[Q: 2928] OnExamination 2012 - Respiratory

A 58-year-old woman presents with early features of COPD.

She is a heavy smoker and asks about drugs that may help her to stop smoking. In particular, she has heard about a new drug that is now available called Champix (varenicline).

Varenicline is an agent used in the treatment of smokers to help them quit.

Which of the following best describes its mechanism of action?

- 1- A tricyclic antidepressant with mostly noradrenergic properties
- 2- An α_2 -noradrenergic agonist that suppresses sympathetic activity
- 3- Is a nicotine replacement therapy
- 4- Is a partial agonist of the $\alpha_4\beta_2$ nicotinic receptor
- 5- Reduces uptake of dopamine, serotonin and norepinephrine

Answer & Comments

Answer: 4- Is a partial agonist of the $\alpha_4\beta_2$ nicotinic receptor

There are now many therapies that have been investigated for use in smoking cessation. Newer drugs are becoming available that have been specifically developed for smoking cessation. Varenicline is one of them.

Nicotine is a stimulant and releases dopamine in the brain that leads to addictive effects of smoking. Its effects can be replaced in other

ways using nicotine replacement therapy and this reduces the addiction to cigarette smoking.

Bupropion (Zyban) reduces the neuronal uptake of dopamine, serotonin and norepinephrine.

Clonidine, a second line agent in smoking cessation because of its side effects, is an α_2 -noradrenergic agonist that suppresses sympathetic activity.

Nortriptyline is a tricyclic antidepressant with mostly noradrenergic properties and is an agent that appears to be effective.

Varenicline is a non-nicotine drug that is a partial agonist of the $\alpha_4\beta_2$ nicotinic receptor.

[Q: 2929] OnExamination 2012 - Respiratory

A 9-year-old boy presents with a history of headache and persistent green nasal discharge. At night he has a cough and snores loudly. The headache is exacerbated by leaning forwards.

On examination he is afebrile, but has a persistent nasal obstruction and nasal speech. He is tender over the maxillae and forehead.

What is the most likely diagnosis?

- 1- Allergic rhinitis
- 2- Asthma
- 3- Croup
- 4- Gastroesophageal reflux
- 5- Sinusitis

Answer & Comments

Answer: 5- Sinusitis

The picture is one of upper airways obstruction associated with nasal discharge, most likely due to sinusitis.

In this case the maxillary and frontal sinuses are most likely to be involved.

[Q: 2930] OnExamination 2012 - Respiratory

A 67-year-old man presents with a long history of cough, breathlessness on minimal exertion and ankle swelling. He smokes 30-40 cigarettes per day.

Investigations are as follows:

Haemoglobin 19g/dl

White blood count 7.3

paO₂ (air) 6.2kPa

paCO₂ (air) 8.9kPa

Serum [H⁺] 44 nmol/l

Serum [HCO₃] 36 mmol/l

What is the most likely explanation of these results?

- 1- Acute respiratory acidosis
- 2- Chronic respiratory acidosis
- 3- Chronic respiratory alkalosis
- 4- Metabolic acidosis
- 5- Metabolic alkalosis

Answer & Comments

Answer: 2- Chronic respiratory acidosis

Normal range [H] = 36-44 nM. Normal range [HCO₃] = 21 - 27.5 mM.

Even if you did not know the normal reference values for H and HCO₃ you should have been able to make an intelligent guess at compensated respiratory acidosis from the clinical history, type 2 respiratory failure and probable secondary polycythaemia.

[Q: 2931] OnExamination 2012 - Respiratory

A 22-year-old man presents with increased shortness of breath, a dry cough, right sided

pleuritic chest pain and extreme lethargy.

He has no significant medical history of note but says a few other people have been ill in his class at university over the past few weeks.

On examination he is pyrexial 38.2C, BP is 110/72 mmHg, pulse is 85 and regular. There is scattered wheeze, more marked on the right than the left, but the signs seem unremarkable compared to how ill he feels.

Investigations reveal:

Haemoglobin 11.4 g/dl(11.5-16.0)

White cell count 11.9 x 10⁹/L (4-11)

Platelets 163 x 10⁹/L (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 122 micromol/l (79-118)

ESR 83 mm/hr(<10)

CXR - Right lower lobe pneumonia.

Which of the following is the most appropriate antibiotic choice for him?

- 1- Amoxicillin
- 2- Benzyl penicillin
- 3- Ciprofloxacin
- 4- Clarithromycin
- 5- Doxycycline

Answer & Comments

Answer: 4- Clarithromycin

Epidemic pneumonia due to Mycoplasma infection is seen occasionally, and the fact that a number of his class mates have recently been ill points to this as a possible cause.

Although haemolytic anaemia and cold agglutinins are mentioned as associated phenomena, they are seen only infrequently.

Often signs on examination are less severe than would be expected once the x ray findings are reviewed, as is the case here.

Macrolides such as clarithromycin are first choice antibiotics in this case.

Amoxicillin is a reasonable oral option for community acquired pneumonia related to *S pneumoniae*, with benzyl penicillin the IV alternative.

Ciprofloxacin and doxycycline may be considered for exacerbation of chronic obstructive pulmonary disease (COPD), but neither is first line in the treatment of pneumonia.

[Q: 2932] OnExamination 2012 - Respiratory

A 62-year-old man comes to the clinic with increasing shortness of breath and a dry cough. He is known to have worked previously in the ship building industry.

On examination he is mildly short of breath at rest. There is finger clubbing and bilateral inspiratory crackles on auscultation of the chest.

It is noted on his pulmonary function testing that the DLCO is reduced.

Which of the following is likely most to affect interpretation of the test?

- 1- Consumption of two units of alcohol the night before the test
- 2- Mild kyphosis
- 3- Mild scoliosis
- 4- Smoking on the morning of the test
- 5- Use of salbutamol

Answer & Comments

Answer: 4- Smoking on the morning of the test

Although the conventional single breath diffusing capacity (DLCO) has been accepted as a standard non-invasive test to assess the integrity of pulmonary function, there are numerous pitfalls in its use.

One such pitfall is the effect of carbon monoxide in cigarette smoke, which raises carboxyhaemoglobin (COHb) to as high as 10-15% (normal value 1-2%). Most regression values for DLCO are derived from the study of lifetime non-smokers, so that the use of these in smokers underestimates the percent of predicted DLCO values, unless additional adjustments are made. Increasing COHb reduces DLCO because carbon monoxide (CO) is substantially increased, leading to a reduced driving pressure for CO across the air-blood barrier. In addition, some of the patient's haemoglobin (Hb) will already be tightly bound by CO and therefore the overall amount of Hb available for binding by the test CO is decreased.

Whilst alcohol vapours can interfere with interpretation of the test it is highly unlikely that two units of alcohol consumed the night before will have any impact at all.

Severe kyphosis and scoliosis can affect interpretation of the test, therefore DLCO should be adjusted according to the calculated alveolar volume. However, mild thoracic cage abnormalities are unlikely to have significant effects.

Salbutamol should not affect the results.

[Q: 2933] OnExamination 2012 - Respiratory

A 71-year-old man presents with severe emphysema. He is on maximal therapy including high dose Seretide and tiotropium. He tells you that he is so unwell that he can barely manage the walk of 200 metres to the corner shop.

On examination he looks short of breath at rest. His BP is 155/72 mmHg, pulse is 75 and regular. There are quiet breath sounds, occasional coarse crackles and wheeze on auscultation of the chest.

Investigations show:

Haemoglobin 14.1 g/dl(13.5-17.7)

White cell count $8.1 \times 10^9/L$ (4-11)
 Platelets $292 \times 10^9/L$ (150-400)
 Sodium 136 mmol/l (135-146)
 Potassium 4.0 mmol/l (3.5-5)
 Creatinine 123 micromol/l (79-118)
 pH 7.42(7.35-7.45)
 pCO_2 7.4 kPa(4.8-6.1)
 pO_2 9.8 kPa(10-13.3)
 CXR - Predominant upper lobe emphysema.
 FEV₁ - 30% of predicted.

Which of the features of his history, examination or investigations would preclude referral for lung reduction surgery?

- 1- pCO_2 7.4
- 2- pO_2 9.8
- 3- FEV₁ 30% predicted
- 4- Predominant upper lobe emphysema
- 5- Severe limitation of exercise capacity

Answer & Comments

Answer: 1- pCO_2 7.4

Very mild hypoxia (pO_2 is just below the lower limit of normal) need not necessarily preclude referral for lung reduction surgery, but CO_2 retention does. The upper cut off for referral for lung reduction surgery for pCO_2 is 7.3; as such he is unsuitable for referral.

Severe limitation of exercise capacity despite maximal therapy is an indication for referral for lung reduction surgery. Other factors include predominant upper lobe emphysema, FEV₁ greater than 20% predicted, and TLCO greater than 20% predicted.

Patients should of course also have undergone a period of pulmonary rehabilitation prior to considering surgery.

[Q: 2934] OnExamination 2012 - Respiratory

A patient is admitted to the intensive care unit for ventilatory support several hours after being admitted to the emergency department following a near drowning incident.

He is extremely hypoxic and a chest x ray shows bilateral infiltrates. He is diagnosed with acute respiratory distress syndrome (ARDS).

Which of the following is a direct pulmonary cause of ARDS?

- 1- Anaphylaxis
- 2- Burns
- 3- Post arrest
- 4- Sepsis
- 5- Tuberculosis

Answer & Comments

Answer: 5- Tuberculosis

This question addresses the phenomena of ARDS and its causes both direct and indirect.

Direct pulmonary causes include:

Inhalation of gastric contents (pH <2)

Infective (pneumonia, tuberculosis)

Pulmonary trauma

Near drowning

Toxic gas inhalation and

Oxygen toxicity.

Indirect causes include:

Sepsis

Non-thoracic trauma

Uraemia

Bowel infraction

Anaphylaxis and

Burns.

ARDS mortality is generally high (40%), but is determined by the cause with aspiration pneumonia having a mortality rate of almost 80% when associated with ARDS.

[Q: 2935] OnExamination 2012 - Respiratory

Which one of the following is true regarding acute pulmonary embolism?

- 1- A normal ECG excludes the diagnosis
- 2- Embolectomy is more effective than thrombolysis in improving survival
- 3- Heparin is as effective as thrombolytic therapy
- 4- The presence of hypoxaemia is an indication for thrombolysis
- 5- Thrombolysis administered through a peripheral vein is as effective as through a pulmonary artery catheter

Answer & Comments

Answer: 5- Thrombolysis administered through a peripheral vein is as effective as through a pulmonary artery catheter

Embolectomies are rarely done nowadays due to the excellent results with thrombolysis.

Thrombolytic therapy is reserved for those with severely compromised circulation (equally effective through peripheral vein or via catheter in pulmonary artery).

Heparin reduces the risk of further embolism (anticoagulant) and reduces pulmonary vasoconstriction.

[Q: 2936] OnExamination 2012 - Respiratory

A 56-year-old man presents with night time sweats, nocturia, poor concentration and daytime somnolence.

To which of the following conditions does this diagnosis predispose?

- 1- Hypoglycaemia
- 2- Hypotension
- 3- Insulin sensitivity
- 4- Osteoporosis
- 5- Stroke

Answer & Comments

Answer: 5- Stroke

This history is typical of sleep apnoea.

Sleep apnoea is an independent risk factor for stroke (and death from all causes), and is associated with hypertension, impaired glucose tolerance (IGT) and insulin resistance.

Severe Sleep Apnea and Risk of Ischemic Stroke in the Elderly.

Stroke 2006. 37. 2317-2321

[Q: 2937] OnExamination 2012 - Respiratory

A 68-year-old gentleman with a 45 year pack history is referred to the respiratory clinic by his GP with increasing breathlessness over the last 12 months.

He has a cough productive of clear sputum, which appears to be present most days. He has no weight loss and no history of haemoptysis.

His spirometry results are as follows;

FEV₁/FVC 0.65%

FEV₁ (% predicted) 71%

Based on the latest NICE guidelines, what (if any) is the severity of this gentleman's airflow obstruction?

- 1- Mild
- 2- Moderate
- 3- No airflow obstruction
- 4- Severe

5- Very severe

Answer & Comments

Answer: 2- Moderate

In 2010 NICE produced a clinical guideline as a tool to assess airflow obstruction. There have been some alterations to the previous classification of airflow obstruction, based on the American Thoracic Society, GOLD and European Respiratory Society standards.

Below are the new classifications:

Mild - FEV₁ predicted >80%

Moderate - FEV₁ predicted 50 - 79%

Severe - FEV₁ predicted 30-49%

Very severe - FEV₁ predicted <30%.

These guidelines can be found at:

<http://www.nice.org.uk/nicemedia/live/13029/49399/49399.pdf>

[Q: 2938] OnExamination 2012 - Respiratory

A 40-year-old man is undergoing investigation for acromegaly.

MRI of the pituitary fossa is normal, but a routine chest x ray reveals a large centrally based mass. The patient is a non-smoker.

What is the most likely type of this lung tumour?

- 1- Adenocarcinoma
- 2- Carcinoid
- 3- Large cell
- 4- Small cell
- 5- Squamous cell

Answer & Comments

Answer: 2- Carcinoid

A centrally based mass in a non-smoker showing clinical evidence of neuroendocrine

cell origin is consistent with a carcinoid and surgery offers a very high chance of cure.

[Q: 2939] OnExamination 2012 - Respiratory

A 75-year-old woman presents with an acute infective exacerbation of her longstanding chronic obstructive airways disease.

Blood gas analysis whilst she was receiving oxygen shows:

pH 7.14 (7.36-7.44)

pO₂ 18 kPa (11.3-12.6)

pCO₂ 10.5 kPa (4.7-6.0)

What is the most appropriate immediate management for this patient?

- 1- CPAP
- 2- Doxapram infusion
- 3- Invasive ventilation
- 4- Nebulised salbutamol with ipratropium
- 5- Reduce inspired oxygen concentration

Answer & Comments

Answer: 5- Reduce inspired oxygen concentration

This patient's blood gases show she is receiving too high a concentration of oxygen which is likely to have precipitated her hypercapnic acidosis.

Patients with chronic obstructive airways disease (COPD) should not in general receive more than 24-28% oxygen without arterial blood gas monitoring. Reduction of FiO₂ may be sufficient to improve this lady's acidosis.

Once this is done she should be treated with nebulised bronchodilators driven on air and if she fails to improve despite controlled oxygen and bronchodilators non-invasive ventilation (NIV) is indicated.

[Q: 2940] OnExamination 2012 -

Respiratory

In restrictive lung disease due to respiratory muscle weakness, which of the following statements is true?

- 1- Low FEV₁/FVC, high RV/TLC
- 2- Low FEV₁/FVC, normal TLC
- 3- Low VC, low FEV₁, normal TLC, low RV/TLC
- 4- Low VC, low RV, low TLC
- 5- Low VC, low TLC, high RV/TLC

Answer & Comments

Answer: 5- Low VC, low TLC, high RV/TLC

The lung is itself can function normally yet muscle weakness will result in grossly low lung volumes including forced expiratory volume in one second (FEV₁), forced vital capacity (FVC) and total lung capacity (TLC).

However residual volume (RV) will be relatively high as a consequence of this weakness.

Consequently, RV/TLC will be elevated.

However the transfer of carbon monoxide (TCO) will be unaffected.

[Q: 2941] OnExamination 2012 - Respiratory

An 18-year-old attending the emergency department is noted to have central cyanosis.

She is perfectly well but was told to go to the emergency department by her friends who said she looked blue.

What is the most likely cause?

- 1- Anorexia nervosa
- 2- Carbon monoxide poisoning
- 3- Drinking water contaminated with nitrates
- 4- Lead poisoning
- 5- Severe anaemia

Answer & Comments

Answer: 3- Drinking water contaminated with nitrates

This is typical of methaemoglobinaemia which may be caused by nitrates.

[Q: 2942] OnExamination 2012 - Respiratory

A 35-year-old homeless gentleman is admitted to the acute medical unit with a four month history of cough, weight loss and night sweats.

A chest x ray is highly suggestive of miliary tuberculosis (TB).

Which of the following statements is true regarding this condition?

- 1- A negative tuberculin test excludes diagnosis
- 2- A normal chest x ray excludes this diagnosis
- 3- Anti-TB drugs should not be given unless patient is sputum positive (for acid fast bacilli)
- 4- Nodules are typically 4-6 mm
- 5- Tuberculous meningitis is also seen in 15-20% of patients with miliary TB

Answer & Comments

Answer: 5- Tuberculous meningitis is also seen in 15-20% of patients with miliary TB

Fifteen per cent to 20% of patients who have miliary TB also have TB meningitis at the time of presentation. Conversely 33% of patient with TB meningitis have concomitant miliary TB.

The tuberculin test is often negative.

A chest x ray may be normal in up to one third of patients.

The classic millet seed nodules are small measuring about 1-2 mm.

Not all patients will be sputum positive and with evidence supporting a diagnosis of tuberculosis treatment should be commenced swiftly.

[Q: 2943] OnExamination 2012 - Respiratory

A 74-year-old gentleman with known metastatic carcinoma of the pancreas presents with an acute episode of dyspnoea and pleuritic-sounding chest pain.

He is tachycardic with a rate of 118 bpm and his oxygen saturations on pulse oximetry are 84% on 2L of oxygen.

He is investigated for a presumed pulmonary embolism and a CTPA confirms a clot in the right middle lobe.

Which of the following forms part of the Wells scoring criteria for pulmonary embolism?

- 1- Chest pain
- 2- Classical ECG changes (S1Q3T3)
- 3- Haemoptysis
- 4- Signs of right ventricular failure
- 5- Widened A-a gradient on arterial blood gas sampling

Answer & Comments

Answer: 3- Haemoptysis

Although all the above answers are features associated with pulmonary embolism, only haemoptysis forms part of the Wells score.

The Wells scoring system was devised in 1995 by Wells et al, and is a prediction tool based on clinical criteria.

The Wells score:

Clinically suspected DVT - 3.0 points

Alternative diagnosis less likely than a PE - 3.0 points

Tachycardia - 1.5 points

Immobilisation or surgery in the previous four weeks - 1.5 points

History of DVT or PE - 1.5 points

Haemoptysis - 1.0 point

Malignancy (treatment for within six months, palliative) - 1.0 point.

Traditional interpretation:

Score >6.0 - High

Score 2.0 to 6.0 - Moderate

Score <2.0 - Low.

Alternate interpretation:

Score > 4 - PE likely. Consider diagnostic imaging.

Score 4 or less - PE unlikely. Consider D-dimer to rule out PE.

[Q: 2944] OnExamination 2012 - Respiratory

A 40-year-old gentleman is referred to the chest clinic with worsening asthma symptoms. He had been diagnosed with late onset asthma aged 35 years.

On questioning the patient reports a short history of malaise, fever and tender subcutaneous nodules on his legs. He has had no haemoptysis.

A full blood count is performed and the results are as follows:

Hb 14.5 g/dl(11.5-16g/dl)

PLT $240 \times 10^9/L$ ($4-11 \times 10^9/L$)

WBC $12.5 \times 10^9/L$ (neut 7.8, lymph 2.5, monocytes 0.1, eosinophils 2.0, basophils 0.09) ($4-11 \times 10^9/L$)

A full blood count from three years earlier was reviewed and its results were as follows:

Hb 12.5 g/dl (11.5-16g/dl)

PLT $162 \times 10^9/L$ ($4-11 \times 10^9/L$)

WBC $9.5 \times 10^9/L$ (neut 5.5, lymph 3.5, monocytes 0.5, eosinophils 0.9, basophils 0.1) ($4-11 \times 10^9/L$)

A chest x ray is performed which shows patchy pulmonary infiltrates.

Given the patient's history and the results of initial investigations, which is the most likely diagnosis?

- 1- Acute respiratory distress syndrome
- 2- Churg-Strauss syndrome
- 3- Intrinsic asthma
- 4- Microscopic polyangiitis
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Churg-Strauss syndrome

This patient has

Asthma

Eosinophilia

Pulmonary infiltrates and

Neuropathy

which is diagnostic of Churg-Strauss syndrome.

Churg-Strauss is a medium/small vessel vasculitis. Most patients have a history of asthma and eosinophilia that may predate vasculitis by up to a decade.

Wegener's granulomatosis (WG) predominately involves the upper and lower respiratory system and renal glomeruli. It usually presents with upper airway symptoms.

Microscopic polyangiitis is microscopically similar to WG, but does not tend to involve the nasopharynx. It has an association with hepatitis B and C.

Acute respiratory distress syndrome describes an acute diffuse inflammatory lung injury, often in previously healthy lungs.

The presence of systemic symptoms makes a diagnosis of asthma alone unlikely.

[Q: 2945] OnExamination 2012 - Respiratory

A 38-year-old man presents with a two week history of recurrent haemoptysis which he has noted over the last 18 months.

He is unaware of any chest pain and is a smoker of five cigarettes daily.

A chest x ray reveals collapse of the left lower lobe.

What is the most likely diagnosis?

- 1- Bronchial carcinoid
- 2- Bronchial carcinoma
- 3- Bronchiectasis
- 4- Inhaled foreign body
- 5- Pulmonary embolism

Answer & Comments

Answer: 1- Bronchial carcinoid

The most likely diagnosis is of a carcinoid tumour.

These are slow growing tumours of the lung that occur in younger patients than do bronchial carcinoma, the peak incidence is when patients are in their 40s. They account for between 1-5% of all lung tumours.

They are not linked with smoking. The incidence is equal between men and women.

They usually present with recurrent haemoptysis or infections. Chest pain, breathlessness, wheeze and cough are less common.

They usually occur in the major bronchi, 85% can be seen bronchoscopically.

A carcinoid tumour in the left lower lobe bronchus could cause distal collapse of the left lower lobe.

[Q: 2946] OnExamination 2012 - Respiratory

A 45-year-old male with type 2 diabetes presented to the clinic as his wife complained that he snored excessively.

Which of the following would suggest a diagnosis of obstructive sleep apnoea?

- 1- Daytime sleepiness
- 2- Nasal polyps
- 3- Nocturnal cough
- 4- Poor memory
- 5- Stridor

Answer & Comments

Answer: 1- Daytime sleepiness

The typical problem associated with sleep apnoea syndrome is excessive daytime somnolence, associated with:

Obesity
Acromegaly
Hypothyroidism
Cushing's syndrome.

It is thought that the somnolence is due to the interruption of rapid eye movement (REM) sleep by frequent episodes of waking due to apnoeic episodes.

[Q: 2947] OnExamination 2012 - Respiratory

Progressive massive fibrosis (PMF) is most likely to be found in which of the following?

- 1- Complicated silicosis
- 2- Extrinsic allergic alveolitis
- 3- Lobar pneumonia
- 4- Sarcoidosis
- 5- Simple coal worker's pneumoconiosis

Answer & Comments

Answer: 1- Complicated silicosis

Progressive massive fibrosis is diagnosed by chest x ray as round masses, several centimetres in diameter usually in the upper lobes. They may have necrotic centres.

In silicosis a more accurate term is 'conglomerate nodules'. It is due to exposure to dust of high silicon content and hence PMF is more likely with higher silicon exposure than in simple coal worker's lung.

[Q: 2948] OnExamination 2012 - Respiratory

A 38-year-old gentleman with known emphysema secondary to alpha 1-antitrypsin (A1AT) deficiency attends the local chest clinic for follow up. He is also known to have liver cirrhosis.

Which of the following conditions is associated with A1AT deficiency?

- 1- Bladder carcinoma
- 2- Churg-Strauss vasculitis
- 3- Polyarteritis nodosa
- 4- Primary biliary cirrhosis
- 5- Pulmonary fibrosis

Answer & Comments

Answer: 1- Bladder carcinoma

A1AT deficiency is has associations with a number of varied conditions.

A1AT deficiency is associated with a number of malignancies including hepatocellular cancer, lung cancer, bladder cancer and lymphoma.

Other associated conditions include

Cirrhosis
Pancreatitis
Gall stones

COPD

Bronchiectasis

Primary sclerosing cholangitis

Wegener's granulomatosis and

Pelvic prolapse.

[Q: 2949] OnExamination 2012 - Respiratory

Which of the following is true regarding primary pulmonary tuberculosis?

- 1- Commonly leads to miliary TB
- 2- Is highly infective
- 3- Leads to pleural effusion
- 4- May be totally asymptomatic
- 5- Usually produces cavitation

Answer & Comments

Answer: 4- May be totally asymptomatic

Primary pulmonary tuberculosis is often asymptomatic consisting of primary complex.

Cavitation and pleural effusions are manifestations of post primary TB.

[Q: 2950] OnExamination 2012 - Respiratory

A 55-year-old man who has a 25 year pack history of smoking presents with productive cough with mucoid sputum of two year duration.

On examination he has scattered rhonchi and wheezing.

The likeliest diagnosis is:

- 1- Bronchial asthma
- 2- Bronchiectasis
- 3- Chronic bronchitis
- 4- Fibrosing alveolitis
- 5- Pneumonitis

Answer & Comments

Answer: 3- Chronic bronchitis

Chronic bronchitis is one of the most common respiratory diseases due to cigarette smoking.

The smoking history and productive cough for at least two years is indicative of chronic bronchitis.

[Q: 2951] OnExamination 2012 - Respiratory

Which of the following statements is not true of primary pulmonary tuberculosis?

- 1- A positive tuberculin skin test develops within two weeks of infection
- 2- It is characteristically asymptomatic
- 3- Miliary spread is commoner in a younger age group
- 4- Pleural effusion occurs before tuberculin skin testing is positive
- 5- The initial immunological response causes hilar lymphadenopathy

Answer & Comments

Answer: 1- A positive tuberculin skin test develops within two weeks of infection

Primary TB is usually asymptomatic with miliary TB most likely to occur in young children.

The Ghon focus is the area of consolidation from cellular infiltration and response to uptake of organisms by macrophages which transform into epithelioid cells and group into granulomata. Bacilli are transported via lymphatics early in the disease process to regional lymph nodes to cause marked lymphadenopathy.

Pleural and pericardial infections (which can result in effusions) occur at or shortly after primary infection.

Positive tuberculin test occurs between three weeks and three months after primary infection.

[Q: 2952] OnExamination 2012 - Respiratory

A 58-year-old man presents with weight loss and haemoptysis. He has smoked most of his life.

On examination he is clubbed and has clinical evidence of right pleural effusion. His serum calcium is 3.2 mM (2.2-2.6 mmol/l). A bone scan is normal.

From which of the following histological type of lung cancer is he most likely to suffer?

- 1- Adenocarcinoma
- 2- Large cell carcinoma
- 3- Mesothelioma
- 4- Small cell carcinoma
- 5- Squamous cell carcinoma

Answer & Comments

Answer: 5- Squamous cell carcinoma

Hypercalcaemia in absence of bony metastases occurs in about 15% of squamous cell lung carcinoma from parathyroid hormone related protein (PTHrP) production. This is a feature of non-metastatic manifestation of malignancy.

Inappropriate antidiuretic hormone (ADH) secretion (hyponatraemia) and ectopic adrenocorticotrophic hormone (ACTH) production (Cushing's syndrome) occur with small cell lung cancer.

Clubbing is predominantly associated with squamous cell cancers and occasionally adenocarcinoma.

[Q: 2953] OnExamination 2012 - Respiratory

A 72-year-old man with severe COPD presents

to the clinic for review.

He is on maximal Seretide and tiotropium inhalers yet is suffering from significant shortness of breath and is able to walk only 50-100 m before having to stop.

On examination his BP is 148/88 mmHg, pulse is 82 (atrial fibrillation), there are coarse crackles and wheeze on auscultation of the chest.

Investigations show:

Haemoglobin 18.5 g/dl(13.5-17.7)

White cell count $9.1 \times 10^9/L$ (4-11)

Platelets $280 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 120 micromol/l (79-118)

pH 7.40 (7.35-7.45)

pCO₂ 6.1 kPa(4.8-6.1)

pO₂ 7.8 kPa(10-13.3)

Which of the above features is an indication for LTOT?

- 1- pCO₂ 6.1
- 2- pO₂ 7.8
- 3- Hb 18.5 with current ABG results
- 4- Presence of atrial fibrillation
- 5- Significant exercise limitation

Answer & Comments

Answer: 3- Hb 18.5 with current ABG results

Ordinarily pO₂ above 7.3 would not be an indication for long term oxygen therapy (LTOT), however if the pO₂ is between 7.3 and 8.0, then O₂ may be prescribed if secondary polycythaemia (as here), or pulmonary hypertension are present.

pO₂ 7.8 is an indication for LTOT only if there is coexistent polycythaemia or pulmonary hypertension.

Hypercarbia, significant exercise limitation or atrial fibrillation are not in their own right indications for LTOT.

[Q: 2954] OnExamination 2012 - Respiratory

A 30-year-old man is referred to the chest clinic with an eight month history of progressive shortness of breath. He has smoked 20/day for 15 years.

Investigations reveal a diagnosis of severe panacinar emphysema. On questioning he informs the consultant that his father died from COPD in his early 40s. Following a diagnosis of alpha-1 antitrypsin (A1AT) deficiency, he undergoes genetic testing.

Given his history what is most likely to be his genotype?

- 1- PiMM
- 2- PiMS
- 3- PiSZ
- 4- PiZZ
- 5- PiSS

Answer & Comments

Answer: 4- PiZZ

The genotype PiZZ is associated with the most severe form of alpha 1-antitrypsin deficiency as the circulating levels of A1AT are 10-15% of normal.

The serum levels of some of the other common genotypes are:

PiMM: 100% (normal)

PiMS: 80% of normal serum level of A1AT

PiSS: 60% of normal serum level of A1AT

PiMZ: 60% of normal serum level of A1AT

PiSZ: 40% of normal serum level of A1AT.

Cigarette smoking is especially harmful to those with A1AT deficiency and can accelerate the progression of emphysema by 10 years.

[Q: 2955] OnExamination 2012 - Respiratory

A 39-year-old gentleman is referred to the chest clinic with an eight month history of progressive shortness of breath. He has smoked 20/day for 20 years.

Investigations reveal a diagnosis of moderate emphysema. On questioning he informs the consultant that his father died from COPD in his early 50s. Following a diagnosis of alpha-1 antitrypsin (A1AT) deficiency, he undergoes genetic testing and is found to have the PiSZ genotype.

What levels of alpha1 antitrypsin would be expected if they were to be measured?

- 1- 10% of normal
- 2- 20% of normal
- 3- 40% of normal
- 4- 60% of normal
- 5- 80% of normal

Answer & Comments

Answer: 3- 40% of normal

The serum levels of some of the common genotypes are:

PiMM: 100% (normal)

PiMS: 80% of normal serum level of A1AT

PiSS: 60% of normal serum level of A1AT

PiMZ: 60% of normal serum level of A1AT

PiSZ: 40% of normal serum level of A1AT

PiZZ: 10-15% (severe alpha 1-antitrypsin deficiency).

Cigarette smoking is especially harmful to those with A1AT deficiency and can accelerate the progression of emphysema by 10 years.

[Q: 2956] OnExamination 2012 - Respiratory

A 19-year-old smoker presents to the Emergency department with right sided pleuritic chest pain and dyspnoea. He has no previous medical history.

His BP is 120/75 mmHg. A CXR is done and confirms a right sided pneumothorax with a rim of 2.5 cm.

Aspiration was done and was successful. He is about to go on holiday abroad in three days time.

Which of the following advice would you give?

- 1- Advise not to drive
- 2- Advise not to swim
- 3- Allow flight but advise not to do any diving
- 4- Do not advise any flight for at least one week
- 5- Repeat CXR before the flight and allow if no residual pneumothorax

Answer & Comments

Answer: 4- Do not advise any flight for at least one week

Atmospheric air drops during flights and increases in deep sea diving can cause recurrence of pneumothorax. This is due to expansion and rupture of pulmonary blebs. Many commercial airlines previously advised a 6-week interval between pneumothorax and air travel, but this has now been amended to 1 week following full resolution. However, the British Thoracic Society emphasises that the recurrence risk only significantly falls after 1 year, and therefore in the absence of a definitive surgical procedure patients might wish to defer travel until then.

[Q: 2957] OnExamination 2012 - Respiratory

A 19-year-old smoker presents to the Emergency department with right sided

pleuritic chest pain and dyspnoea. He has no previous medical history.

His BP is 120/75 mmHg. A CXR is done and confirms a right sided pneumothorax with a rim of 2.5 cm.

Which of the following is the best course of action?

- 1- Advise to stop smoking and discharge
- 2- Aspirate
- 3- Check arterial blood gases and only if hypoxic aspirate
- 4- Insert a chest drain
- 5- Repeat the CXR in two hours

Answer & Comments

Answer: 2- Aspirate

Aspiration is indicated in spontaneous primary pneumothorax if breathless and/or there is a rim of air greater than 2 cm on chest x ray.

Blood gases will not affect the decision making in the above scenario.

Chest drain is not indicated at this stage.

It is important to read the pneumothorax guidelines for the British Thoracic Society.

[Q: 2958] OnExamination 2012 - Respiratory

A 47-year-old male presents with shortness of breath.

He has cirrhosis secondary to hepatitis C infection.

He gives a chronic history of progressive shortness of breath on exertion, and now gets short of breath walking up steps. He gives a history of being more short of breath whilst sitting up, preferring to sleep with no pillows.

The blood pressure is 110/70 mmHg, heart rate 85 beats per minute, and pulse oximetry, breathing room air, shows saturations of 95% lying flat and 87% sitting up.

Which of the following tests is the most appropriate to confirm the diagnosis?

- 1- Contrast echocardiography
- 2- High resolution CT chest
- 3- MRI chest
- 4- Pulmonary angiography
- 5- V:Q scan

Answer & Comments

Answer: 1- Contrast echocardiography

This patient has hepatopulmonary syndrome. Platypnoea and orthodeoxia are typical of this syndrome.

A greater than 5% desaturation on sitting up is very suggestive of this condition which complicates liver cirrhosis and is characterised by pulmonary arteriovenous malformations.

Contrast echo is the diagnostic tool of choice.

Visualisation of late-appearing bubbles in the left atrium following the injection of agitated saline is strongly suggestive of a pulmonary arteriovenous shunt.

[Q: 2959] OnExamination 2012 - Respiratory

A 34-year-old woman with severe asthma comes to the clinic for review. She is currently taking 800 mcg per day of inhaled beclomethasone, yet still feels significantly short of breath and is coughing at night nearly every night.

On examination her PEFR is 340, compared to 500 predicted. She has extensive wheeze on auscultation of both lung fields.

Which of the following is the most appropriate next intervention?

- 1- Add salmeterol 50 mg/day
- 2- Change to fluticasone 400 mcg/day
- 3- Increase beclomethasone to 1600 mcg/day
- 4- Start montelukast 10 mg/day

- 5- Start prednisolone 5 mg/day

Answer & Comments

Answer: 1- Add salmeterol 50 mg/day

BTS guidelines suggest that adding in a long-acting beta 2 agonist (LABA) is more appropriate than further increasing inhaled corticosteroids.

A change to fluticasone 400 mcg/day is essentially maintaining the status quo, as fluticasone is roughly twice as potent as beclomethasone.

If control was not reached after addition of the LABA, then montelukast would be a reasonable next step.

[Q: 2960] OnExamination 2012 - Respiratory

A 25-year-old man presents to the Emergency department with shortness of breath.

One week ago he developed influenza and has become more short of breath and fatigued in the last 24 hours.

His temperature is 38.5°C, his SaO₂ is 90% on 2L of oxygen, a blood pressure 100/60 mmHg and heart rate 120/min.

The CXR shows patchy consolidation.

Which antibiotic therapy should you select for this man?

- 1- Amoxicillin
- 2- Amoxicillin and flucloxacillin
- 3- Co-amoxiclav and clarithromycin
- 4- Co-amoxiclav
- 5- Flucloxacillin

Answer & Comments

Answer: 3- Co-amoxiclav and clarithromycin

This gentleman has community acquired pneumonia (CAP). The recent history of

influenza may lead you to consider staphylococcus aureus as the possible underlying organism, although this is an uncommon cause of CAP in the UK. It is more common in the winter months, and coincident influenza-type symptoms in approximately 40%. Pneumonia complications approximately 3% of cases of influenza, 10% of those admitted have been confirmed to be due to Staphylococcus aureus.

In the majority of patients CAP should be confirmed by chest radiography before the commencement of antibiotics. However, if patients are critically unwell they should be treated for the presumptive diagnosis. Antibiotic treatment should always be initiated within 4 hours of presentation.

CAP caused by Staphylococcus aureus is more likely to present with multilobar shadowing, cavitation, pneumatoceles and spontaneous pneumothorax than other organisms. However, there are no characteristic features of chest radiographs that allow a confident prediction of the likely pathogen. Therefore, the general guidelines for treatment of CAP should be followed until an organism is identified. Staphylococcus aureus carries a high mortality, and therefore if suspected treatment should initially be for a severe CAP (see below for details).

Low severity CAP (CURB 0-1) can be treated with amoxicillin 500mg TDS PO. CURB 2 CAP should be treated with amoxicillin 500mg-1g TDS and clarithromycin 500mg TDS. Alternatives are available if patients are allergic to any of the above combinations. High severity CAP (CURB 3-5) should be treated as soon as possible with co-amoxiclav 1.2g TDS and clarithromycin 500mg BD.

The oral route is recommended in those with low and moderate severity CAP. Patients treated with parenteral antibiotics initially should be switched to an oral regimen once clinical improvement is seen and the patients has been afebrile for at least 24 hours. For

most patients with uncomplicated CAP 7 days of antibiotic treatment is recommended. For those with high severity pneumonia where an organism has not been identified, 7-10 days treatment is indicated and extended to 14-21 days where clinically needed.

If Staphylococcus aureus is identified, treatment should be altered. Non-MRSA organisms should be treated with flucloxacillin and/or rifampicin; an alternative for penicillin-allergic patients is teicoplanin and rifampicin. MRSA should be treated with vancomycin. A prolonged antibiotic course is indicated.

[Q: 2961] OnExamination 2012 - Respiratory

A 42-year-old woman presents with an acute attack of asthma. She is able to speak in short sentences.

Her respiratory rate is 28 breaths per minute and the peak expiratory flow rate 120 L/min (predicted 480 L/min).

What is the most appropriate treatment for this patient?

- 1- Intravenous aminophylline
- 2- Intravenous salbutamol
- 3- Nebulised salbutamol
- 4- Oral salbutamol
- 5- Oral theophylline

Answer & Comments

Answer: 3- Nebulised salbutamol

This patient has features of acute severe asthma, and should be given oxygen, steroids and nebulised salbutamol as immediate treatment.

Although the PFR is less than 33% of predicted normal (feature of life-threatening attack), we do not know what her previous best is. It could be low, for example, 240 L/min.

If it had been a life-threatening attack, nebulised ipratropium and intravenous aminophylline, salbutamol or terbutaline should be given. The guidelines do not specify a preference.

This is another clue that the answer should be nebulised salbutamol.

[Q: 2962] OnExamination 2012 - Respiratory

The pulmonary vascular system is different from the systemic circulation in that the pulmonary system demonstrates which of the following?

- 1- High pressures, high flow rates, highly compliant vessels
- 2- High pressures, high flow rates, low compliance vessels
- 3- Low pressures, high flow rates, high compliance vessels
- 4- Low pressures, low flow rates, high compliance vessels
- 5- Low pressures, low flow rates, low compliance vessels

Answer & Comments

Answer: 4- Low pressures, low flow rates, high compliance vessels

The normal pulmonary circulation is characterised by low pressures, low flow rates, high compliance vessels.

[Q: 2963] OnExamination 2012 - Respiratory

Which of the following statements is true regarding smoking in pregnancy?

- 1- Dysmorphic facies is a recognised complication.
- 2- Maternal smoking may adversely affect testicular function in male children.

- 3- Smoking assists in maturation of the fetal lung.
- 4- The newborn baby may require adjustments in drug dosages because of it.
- 5- The reduction in birth weight is related to the number of cigarettes smoked per day.

Answer & Comments

Answer: 5- The reduction in birth weight is related to the number of cigarettes smoked per day.

Smoking reduces birth weight which may be of critical importance if the baby is born pre-term.

On average, the babies of smokers weigh 170 g less than non-smokers, but the reduction in birth weight is related to the number of cigarettes smoked per day.

Smoking is also associated with an increased risk of miscarriage and still birth. The infant has a greater risk of sudden infant death syndrome.

There is some evidence that maternal smoking may adversely affect ovarian function in female children.

No dysmorphic syndrome has yet been described.

[Q: 2964] OnExamination 2012 - Respiratory

A 45-year-old woman is referred to the respiratory clinic with shortness of breath. She has been unable to work due to a long term back injury and is therefore on long term sickness benefit.

On examination her BP is 155/85 mmHg, pulse is 85 and regular. Her BMI is 32, there is bilateral lower limb pitting oedema with varicose vein formation. Heart sounds are normal, auscultation of the chest is clear.

Investigations show:

pH 7.43 (7.35-7.45)

pCO₂ 5.8 kPa (4.8-6.1)

pO₂ 9.9 kPa (10-13.3)

Which of the following is likely to be the most effective therapy?

- 1- Furosemide
- 2- Salbutamol
- 3- Seretide
- 4- Tiotropium
- 5- Warfarin

Answer & Comments

Answer: 5- Warfarin

Given this woman's obesity, slowly progressive shortness of breath, absence of chest signs, and presence of peripheral oedema and varicose veins, chronic pulmonary emboli are the most likely possibility. As such warfarinisation is the optimal long term strategy to reduce the risk of further clots. She should also be encouraged to lose a significant amount of weight.

Salbutamol and Seretide are treatments for asthma and chronic obstructive pulmonary disease (COPD), and tiotropium is a treatment for COPD alone, therefore none of the three are appropriate here.

We are given no history of wheeze or cough which fits with either COPD or asthma as the underlying diagnosis.

Whilst furosemide may relieve peripheral oedema, it will not have a positive effect on the underlying cause of right heart failure.

[Q: 2965] OnExamination 2012 - Respiratory

A 43-year-old woman presents to the respiratory clinic with increasing shortness of breath and a dry cough. She also has fever and night sweats which have worsened over the

past six to nine months and has lost a few kg in weight.

On examination her BMI is 23, BP is 135/72 mmHg, pulse is 73, and there are scattered crackles on auscultation of the chest. She also has erythema nodosum on examination of both lower limbs.

Investigations show:

Haemoglobin 12.1 g/dl(11.5-16.0)

White cell count 9.1 x 10⁹/L (4-11)

Platelets 192 x 10⁹/L (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 108 µmol/l (79-118)

pH 7.41(7.35-7.45)

pCO₂ 4.7 kPa(4.8-6.1)

pO₂ 9.8 kPa(10-13.3)

CXR - Bilateral hilar lymphadenopathy.

Which of the following is the most appropriate initial treatment?

- 1- Azathioprine
- 2- Hydroxychloroquine
- 3- Infliximab
- 4- Methotrexate
- 5- Prednisolone

Answer & Comments

Answer: 5- Prednisolone

This patient has sarcoidosis as evidenced by the hilar lymphadenopathy, erythema nodosum and mild hypoxia on blood gas analysis. Prednisolone is the mainstay of initial treatment for sarcoid, continued for 12 months or more in those patients who respond, but tapered to the minimal effective dose.

All of the other agents have been used in the management of sarcoidosis, although they are all subsidiary to use of corticosteroids.

Systematic reviews have not so far however supported the use of any particular second line agent.

[Q: 2966] OnExamination 2012 - Respiratory

A 21-year-old woman presents to the Emergency department with an hour history of chest tightness, dyspnoea, tingling in her hands and light-headedness. She has neither past medical history nor family history of note.

Examination is unremarkable aside from an elevated respiratory rate. Her pulse oximetry shows saturations of 96% on air, which do fall when she walks across the room. A chest x ray is also normal. An arterial blood gas sample (on air and at rest) is obtained and the results are as follows:

pH 7.52(7.36 - 7.44)

pCO₂ 2.2kPa(4.7 - 6.0)

pO₂ 9.1kPa(11.3 - 12.6)

HCO₃ 25 mmol/L(20 - 28)

What is the most likely diagnosis?

- 1- Acute asthma attack
- 2- Hyperventilation (psychogenic)
- 3- Pulmonary embolism
- 4- Respiratory muscle disease
- 5- Volume depletion

Answer & Comments

Answer: 3- Pulmonary embolism

This patient's blood gas sample shows respiratory alkalosis, as demonstrated by the raised pH, low pCO₂ and normal bicarbonate. Her pO₂ is over 8kPa, and she is therefore not technically in type 1 respiratory failure, but it is important to realise she is working hard to maintain this oxygenation. The most likely cause is an acute pulmonary embolism given the relative hypoxia, and saturation dropping on exertion. Given her age she may be taking

the oral contraceptive pill, which would be a risk factor.

In acute asthma the pCO₂ may be low, as the patient has an elevated respiratory rate, however in this instance there should be a history of the condition, clinical signs or a reduced pO₂.

Hyperventilation often demonstrates a respiratory alkalosis picture on analysis, however she should have a normal pO₂ and her saturations should not fall on exertion.

Respiratory muscle disease typically results in a respiratory acidosis.

Volume depletion (from a number of causes) would typically cause a metabolic alkalosis.

[Q: 2967] OnExamination 2012 - Respiratory

A 25-year-old man presented to the Emergency department with cough, shortness of breath and headache.

He had been treated by his GP with amoxicillin but did not improve. He had recently been on holiday in Spain.

On examination he had bilateral crackles. His liver enzymes were deranged.

Which antibiotic should be used?

- 1- Co-amoxiclav
- 2- Clarithromycin
- 3- Intravenous cefuroxime
- 4- Metronidazole
- 5- Oseltamivir (Tamiflu)

Answer & Comments

Answer: 2- Clarithromycin

Legionella pneumophila will respond to macrolides, quinolones and tetracyclines.

One should be careful to cover atypical pneumonia when choosing antibiotics.

Mortality can be high especially in the immunocompromised.

One should not wait for the results of culture or urinary antigens.

[Q: 2968] OnExamination 2012 - Respiratory

A patient's arterial blood gas analysis gives the following results:

pO₂ 10 kPa/75mmHg(11.3-12.6 kPa)

pCO₂ 7 kPa/52 mmHg(4.7-6.0 kPa)

pH 7.47(7.36-7.44)

Bicarbonate 37 mmol/L(20-28)

Which of the following is the most likely cause?

- 1- Acute exacerbation of chronic obstructive pulmonary disease
- 2- Chronic hyperventilation syndrome
- 3- Diabetic coma
- 4- Pulmonary embolism
- 5- Pyloric obstruction

Answer & Comments

Answer: 5- Pyloric obstruction

These results demonstrate a metabolic alkalosis and there is respiratory compensation with an elevation of pCO₂.

Consequently, pO₂ is slightly low.

The most probable cause is pyloric stenosis.

[Q: 2969] OnExamination 2012 - Respiratory

An 18-year-old woman presents with an acute pulmonary embolism in the ninth week of pregnancy.

What is the most appropriate treatment for this patient throughout her pregnancy?

- 1- Aspirin

- 2- Intravenous unfractionated heparin
- 3- Subcutaneous low molecular weight heparin (LMWH)
- 4- Subcutaneous unfractionated heparin
- 5- Warfarin

Answer & Comments

Answer: 3- Subcutaneous low molecular weight heparin (LMWH)

Anticoagulation with subcutaneous heparin is recommended in most guidelines with LMWH being a suitable alternative. The latter has the advantage of requiring no monitoring but is a less well established therapy in pregnancy.

She cannot be treated with intravenous (IV) heparin throughout her pregnancy and warfarin is also contra-indicated due to teratogenicity.

Aspirin provides no demonstrable prophylactic value for venous thromboembolism.

For further information please see the following link:

<http://www.rcog.org.uk/files/rcog-corp/GTG37aReducingRiskThrombosis.pdf>

[Q: 2970] OnExamination 2012 - Respiratory

A 27-year-old female with adult respiratory distress syndrome (ARDS) is ventilated on intensive care.

Her inspired oxygen is 100%, positive end expiratory pressure is 15 cmH₂O and peak airway pressure is 40 cmH₂O.

Her arterial blood gas shows:

paO₂ 6 kPa(11.3-12.6)

paCO₂ 6.9 kPa(4.7-6.0)

SpO₂ 88%(>92%)

What treatment has been shown to decrease mortality in this patient group?

- 1- High frequency oscillatory ventilation (HFOV)
- 2- Increasing tidal volume and respiratory rate on the ventilator
- 3- Inhaled nitric oxide therapy
- 4- Prone position
- 5- None

Answer & Comments

Answer: 5- None

This lady is on maximal ventilatory therapy but is still hypoxic.

Her high CO₂ is a reflection of permissive hypercapnia to prevent overdistension of the lungs with high tidal volumes.

None of the therapies above are proven to improve mortality. However proning a patient in this situation will improve ventilation/perfusion mismatch and temporarily improve oxygenation.

Some clinicians would move immediately to HFOV without proning as placing a patient face down is obviously fraught with difficulty.

Nitric oxide therapy to improve hypoxic pulmonary vasoconstriction is used infrequently.

[Q: 2971] OnExamination 2012 - Respiratory

A 26-year-old man with a history of alcohol and drug abuse was admitted with a 14 day history of fever, cough and fatigue.

He was emaciated. His temperature was 39.4 C. Cervical and axillary lymphadenopathy were present. Chest x ray revealed bilateral areas of pulmonary shadowing.

Which of the following is the most likely diagnosis?

- 1- Alcoholic cardiomyopathy
- 2- Pneumococcal pneumonia

- 3- Pneumocystis pneumonia
- 4- Pulmonary tuberculosis
- 5- Tricuspid endocarditis

Answer & Comments

Answer: 3- Pneumocystis pneumonia

This is a tricky question. It is leading you to consider a diagnosis of HIV in this gentleman, and subsequent opportunistic infections. His clinical presentation fits best with a diagnosis of *Pneumocystis jirovecii*.

Pneumocystis jirovecii is a eukaryotic microorganism. In immunosuppressed patients it can cause a pneumonia, which is most recognised in patients with AIDS but can also be seen in those with organ transplants or when undergoing chemotherapy. A CD4 count of less than 200 is associated with significant risk. In Europe, the USA and Australia *P. jirovecii* pneumonia in HIV-positive patients is seen largely in those unaware of their HIV status. Unfortunately it is a major cause of death in Africa, especially in children. Previously it was thought that disease was caused by reactivation of latent infection acquired in childhood, but *de novo* infection is increasingly recognised.

The pneumonia caused by *P. jirovecii* is potentially severe and fatal in immunosuppressed patients. Clinically it presents with several weeks' history of dry cough, fever and dyspnoea. Examination findings are often subtle, but include tachypnoea, tachycardia, cyanosis and fine respiratory crackles. Typically, patients desaturate markedly on exertion. There may be reduced transfer factor, vital capacity and total lung capacity on spirometry. Bronchoalveolar lavage or induced sputum can be used to demonstrate the organism (open lung biopsy is gold standard, but rarely performed in clinical practice). Giemsa, Papanicolaou and Grocott's stains are used.

There are a variety of different chest radiograph findings. Typically it causes bilateral symmetrical perihilar reticular or granular interstitial shadowing. Less often there can be asymmetric shadowing, or progression to a reticular-alveolar pattern. Occasionally lobar consolidation, nodular lesions, prominent pulmonary arteries, pneumothorax, pneumomediastinum, cysts or pneumatoceles can be seen. In patients who have been on prophylactic inhaled pentamidine the infiltrates may predominantly affect the upper lobes. A normal chest x-ray does not exclude the diagnosis. Pleural effusions and lymphadenopathy are not typical, but be aware of the possibility of multiple disease processes in an immunosuppressed patient.

If allowed to progress, *P. jiroveci* can disseminate via the lymphatic and haematogenous routes to affect the thyroid, liver, bone marrow, lymph nodes and spleen.

If PCP is suspected, treatment with full dose co-trimoxazole should be started as soon as possible. It should be given for 21 days in HIV-positive cases, but shorter doses can be used in other causes of immunosuppression. In patients who are intolerant or co-trimoxazole, intravenous pentamidine can be used. Some studies have shown that that corticosteroids can reduce the risk of respiratory failure, and they are therefore used in some cases.

Prophylaxis should be used in immunosuppressed patients who are at risk of developing PCP: all those with a CD4 count of <200, patients started on high dose steroids, and those on chemotherapeutic regimens associated with significant immunosuppression. Co-trimoxazole is also the first line prophylactic agent.

Tuberculosis is another possible diagnosis, but would likely be miliary given the lymphadenopathy and respiratory symptoms. This usually presents with a more insidious onset, and the radiographic findings generally

take a few weeks to develop. The incidence is dependent on the patient's exposure to TB, and it is therefore more common in patients who originate from areas of high prevalence.

Tricuspid endocarditis is definitely a possibility in an intravenous drug user presenting with these symptoms. Bilateral areas of pulmonary shadowing are possible due to septic emboli, but you may expect the question to report a murmur heart on auscultation.

Pneumococcal pneumonia typically has a shorter history than this, and bilateral disease is unusual.

Alcoholic cardiomyopathy presents with signs and symptoms of congestive cardiac failure, not those described here.

[Q: 2972] OnExamination 2012 - Respiratory

Which of the following is found in subjects acclimatised to life at high altitudes?

- 1- Increased mean corpuscular haemoglobin concentration
- 2- Increased pulmonary artery pressure
- 3- Periodic respiration
- 4- Increased airway resistance
- 5- Reduced cardiac output

Answer & Comments

Answer: 2- Increased pulmonary artery pressure

This is a discriminating question.

Acclimatisation results in increased Hb with erythrocytosis.

Periodic respiration is a feature of non-acclimatisation.

Respiration is normal when subjects are acclimatised to altitude as is cardiac output.

Pulmonary artery pressure increases in an effort to oxygenate more blood.

2,3-DPG increases.

Here's a good read from Adaptation to Altitude.

[Q: 2973] OnExamination 2012 - Respiratory

Sleep apnoea syndrome is best diagnosed by which the following?

- 1- Blood gases during apnoeic episodes
- 2- EEG
- 3- Polygraphic sleep studies
- 4- Presence of HLA-DR2 and DQw1
- 5- Therapeutic trial of amphetamines

Answer & Comments

Answer: 3- Polygraphic sleep studies

Sleep apnoea is characterised by cessation of breathing during sleep.

This causes extreme restlessness with frequent respiratory pauses during night sleep. Consequently, patients report daytime drowsiness and irritability.

It is associated with snoring.

The diagnosis is established by polygraphic recording of sleep which shows periods (at least 30 of 10 or more seconds duration in seven hours of sleep) of apnoea, associated with a fall in arterial oxygen saturation.

[Q: 2974] OnExamination 2012 - Respiratory

A 55-year-old man presents with ataxia and bilateral gynaecomastia.

Which of the following is the most likely diagnosis?

- 1- Bronchial carcinoma
- 2- Hypereosinophilic syndrome
- 3- Klinefelter's syndrome

4- Long term treatment with cyclophosphamide for Wegener's granulomatosis

5- Long term treatment with oral steroids for chronic asthma

Answer & Comments

Answer: 1- Bronchial carcinoma

Klinefelter's and lung cancer are causes of gynaecomastia but the combination of ataxia and gynaecomastia makes it far more likely to be lung cancer.

Gynaecomastia is a non-metastatic paraneoplastic syndrome usually due to non-small cell lung cancer.

It can be painful and may be associated with testicular atrophy.

Ataxia can occur as a result of a paraneoplastic cerebellar degeneration associated with the malignancy.

[Q: 2975] OnExamination 2012 - Respiratory

A 27-year-old woman with a known history of asthma who lives in the countryside comes to the clinic for review.

She has progressively worsening disease and is currently taking high dose Seretide and montelukast. Apparently she coughs every night, occasionally with frank haemoptysis and is finding it impossible to do any regular exercise at all.

On examination her BP is 128/82 mmHg, pulse is 74 and regular. There is extensive wheeze and scattered coarse crackles on auscultation of the chest. Her peak flow is 320 (580 predicted).

Investigations show:

Haemoglobin 12.7 g/dl(11.5-16.0)

White cell count $7.9 \times 10^9/L$ (4-11)

Eosinophil count $1.2 \times 10^9/L$ (0.04-0.4)

Platelets $173 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 98 micromol/l (79-118)

Which of the following is the best investigation?

- 1- Aspergillus precipitins
- 2- CT thorax
- 3- CXR
- 4- IgE
- 5- Sputum culture

Answer & Comments

Answer: 1- Aspergillus precipitins

The most likely diagnosis here is allergic bronchopulmonary aspergillosis (ABPA); as such aspergillus precipitins can contribute significantly to confirming the diagnosis.

Oral steroids are the mainstay of initial treatment and anti-fungals such as itraconazole may also improve resolution of symptoms in some cases.

Whilst both chest x ray and CT thorax may show evidence of infiltrates this is relatively non-specific and therefore would not be optimal investigations; they may, however, prove useful in assessing severity of disease.

IgE is elevated in ABPA but is not as specific an investigation as aspergillus precipitins.

Sputum culture may be positive but negative culture would not exclude the disease.

[Q: 2976] OnExamination 2012 - Respiratory

A patient presents to chest clinic with an eight month history of cough and progressive breathlessness.

Simple spirometry is performed and the results are below:

FEV 11.2L (54% predicted)

FVC 2.3L (61% predicted)

FEV₁/ FVC 0.79

Which of the below conditions are associated with this lung function picture?

- 1- Bronchiectasis
- 2- Emphysema
- 3- Obesity
- 4- Obliterative bronchiolitis
- 5- Simple coal worker's pneumoconiosis

Answer & Comments

Answer: 3- Obesity

This patient has a restrictive lung defect (FEV₁/FVC >0.7). Obesity is a well recognised cause of restrictive lung defects. It is associated with hypoventilation and as a result can cause hypercapnia.

Patient's with simple coal worker's pneumoconiosis do not show significant abnormalities on pulmonary function tests. The other conditions listed all cause an obstructive result (FEV₁/FVC <0.7).

[Q: 2977] OnExamination 2012 - Respiratory

A 22-year-old woman comes to the clinic with tiredness and shortness of breath. She is 30 weeks pregnant. The pregnancy has been uneventful so far.

On examination her BP is 122/72 mmHg, pulse is 75 and regular, saturations are 95% on air.

Respiratory, cardiovascular and abdominal examinations are unremarkable, her BMI is 24.

Investigations show:

Haemoglobin 9.5 g/dl(11.5-16.0)

White cell count $8.0 \times 10^9/L$ (4-11)

Platelets $200 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 90 µmol/l (79-118)

Which of the following is the next most appropriate investigation?

- 1- B12
- 2- Faecal occult bloods
- 3- Ferritin
- 4- Folate
- 5- Upper GI endoscopy

Answer & Comments

Answer: 3- Ferritin

Ferritin is the most important first investigation, so is the only correct answer.

The most likely explanation is pregnancy related iron deficiency, so with respect to further investigations, faecal occult bloods and upper GI endoscopy are unnecessary.

The need for folate supplements should of course also be reinforced during the consultation.

[Q: 2978] OnExamination 2012 - Respiratory

You are an SHO working in the Emergency department when a 67-year-old gentleman with known COPD attends via ambulance.

He has a short history of increasing breathlessness. He denies a productive cough. On arrival he is dyspnoeic with a respiratory rate of 33. Other observations are as follows saturations 88% on 28% O₂, HR 105 bpm, BP 118/86 mmHg, temperature 36.9C.

On examination he has a widespread polyphonic wheeze. A blood gas 45 minutes after arrival and following initial treatment is performed, results are as below.

pH 7.24 (7.36 - 7.44)

pCO₂ 8.8 (4.7 - 6.0 kPa)

pO₂ 8.4 (11.3 - 12.6 kPa)

What should your management be?

- 1- Call ITU for consideration on invasive ventilation
- 2- Continue controlled oxygen and repeated nebuliser therapy - repeat gas in 45 minutes
- 3- Continue controlled oxygen, nebulised therapy and IV antibiotics (repeat gas in 45 minutes)
- 4- Start non-invasive ventilation (NIV) on settings 10 IPAP and 4 EPAP
- 5- Start non-invasive ventilation (NIV) on settings 14 IPAP and 4 EPAP

Answer & Comments

Answer: 1- Call ITU for consideration on invasive ventilation

This patient has an exacerbation of COPD, defined as sustained worsening of the patient's symptoms which is acute in onset. This may include worsening breathlessness, cough, increased sputum and change in sputum colour. The diagnosis is usually made clinically. Supporting investigations include a chest radiograph, arterial blood gases, ECG, routine bloods and sputum and blood cultures.

Treatment is with bronchodilators, nebulised in the majority of patients. If a patient is hypercapnic or acidotic, as in this case, these should be driven by compressed air. If oxygen therapy is needed it should be administered simultaneously by nasal cannulae.

Oxygen should be given to maintain SaO₂ within the patient's individual target range, if available (COPD patients are being given cards with this information, so always ask). ABGs should be repeated at regular intervals to monitor response to treatment, and oxygen weaned when available.

Oral corticosteroids should also be given: 30mg prednisolone for 7-14 days. Prolonged courses offer no additional benefit.

Antibiotics should be used to treat exacerbations associated with more purulent sputum, consolidation on chest radiograph, or clinical signs of pneumonia. Empirical antibiotic choice should be guided by local policy, and altered to take account of any subsequent culture results.

Non-invasive ventilation (NIV) is the treatment of choice for persistent hypercapnic ventilation failure despite optimal medical therapy. It has been shown in RCTs to reduce intubation rate and mortality in COPD patients with decompensated respiratory acidosis (pH <7.35 and pCO₂ >6kPa). NIV should therefore be considered within the first 60 minutes of hospital arrival in all patients with an acute exacerbation of COPD in whom a respiratory acidosis persists despite maximal medical therapy (controlled oxygen, nebulised salbutamol and ipratropium, prednisolone, antibiotic (where indicated)). Exceptions may be: life threatening hypoxaemia (when invasive ventilation may be more appropriate), severe co-morbidity, severe cognitive impairment (where NIV is not tolerated), facial burns/trauma/surgery, vomiting, fixed upper airway obstruction, undrained pneumothorax, upper GI surgery, unprotected airway, copious respiratory secretions, haemodynamic instability requiring inotropes.

Patients should be sitting or semi-recumbant, and a full-face mask used initially. An initial inspiratory positive airway pressure (IPAP) of 10cm H₂O and expiratory positive airway pressure (EPAP) of 4-5cm H₂O should be used. IPAP should be increased by 2-5cm increments every 10 minutes, with a usual target of 20cm H₂O or until a therapeutic response is achieved. Oxygen can be introduced into the circuit, usually with a target saturation of 88-92%. Bronchodilators are preferably administered off NIV. Patients should be closely monitored, including ABG, respiratory rate and heart rate. ABGs should be repeated after 1 hour of NIV therapy, and 1 hour after

subsequent change in settings or 4 hours in stable patients.

All non-invasive ventilation services should have their own local protocol based on these guidelines. There should be a clear plan of what to do in the event of deterioration.

Patients with a pH <7.26 should be managed with a low threshold for intubation, and this should be considered in this case. Functional status, BMI, requirement for oxygen when stable, comorbidities and previous admissions should be considered in addition to age and FEV₁ when assessing suitability. Whilst in clinical practice you would give NIV whilst awaiting consideration from intensive care, it is important to consider intubation in this patient who is failing to improve and remains persistently severely acidotic.

Intravenous theophylline should be used only if there is an inadequate response to nebulised bronchodilators. Levels should be closely monitored.

Respiratory stimulants are only indicated when NIV is inappropriate, and their use supervised by a specialist physician.

There is no indication from the information provided that this is an infective exacerbation so the use of antibiotics at this time is not indicated.

[Q: 2979] OnExamination 2012 - Respiratory

A 25-year-old man presented to the Emergency Department with cough, shortness of breath and headache.

He had been treated by his GP with amoxicillin but did not improve. He had recently been on holiday in Spain.

On examination he had bilateral crackles. His liver enzymes were deranged.

What would be the most useful diagnostic test?

- 1- Chest x ray
- 2- O₂ saturation at rest and on exertion
- 3- Viral serology
- 4- White cell count
- 5- Urinary antigen

Answer & Comments

Answer: 5- Urinary antigen

Legionella pneumonia is spread via aerosols.

It occurs in 2-15% of community acquired pneumonia. It should be suspected in case of foreign travel or stay in hotels, failure to respond to penicillins, diarrhoea accompanying respiratory symptoms, deranged liver function tests and low sodium.

The diagnostic test is urinary antigen. One should not wait for the result. Sputum cultures (if productive) are also diagnostic.

O₂ saturation at rest and desaturation after exertion will help in Pneumocystis carinii pneumonia (PCP).

Chest x ray may show unilateral or bilateral lobar pneumonia and there may be small pleural effusions but this is not diagnostic.

WCC may be high or low.

[Q: 2980] OnExamination 2012 - Respiratory

A 60-year-old man is admitted with a productive cough with flecks of blood in his sputum.

Chest x ray reveals a mass lesion in the right mid zone.

Investigations reveal:

Sodium 110 mmol/L(137-144)

Potassium 4.0 mmol/L(3.5-4.9)

Bicarbonate 24 mmol/L(20-28)

Urea 3.0 mmol/L(2.5-7.5)

Creatinine 80 µmol/L(60-110)

Which of the following findings suggest a diagnosis of the syndrome of inappropriate ADH (SIADH) secretion?

- 1- Plasma osmolality 236 mosmol/kg (278-305)
- 2- Presence of ascites
- 3- Urine flow rate 20 mL/hour
- 4- Urine osmolality 250 mosmol/kg (350-1000)
- 5- Urine sodium 110 mmol/L

Answer & Comments

Answer: 5- Urine sodium 110 mmol/L

The serum osmolality associated with hyponatraemia is generally low and so would not in itself suggest SIADH.

However, in the context of the low plasma osmolality a high urine osmolality (2x that of the plasma osmolality) with an elevated urine sodium (above 20 mmol/L) is suggestive of this diagnosis.

[Q: 2981] OnExamination 2012 - Respiratory

A 62-year-old woman presents with stridor associated with a retrosternal goitre.

What is the most appropriate investigation of her airways obstruction?

- 1- FEV₁/FVC ratio
- 2- Flow volume loop
- 3- Peak expiratory flow rate
- 4- Spirometry
- 5- Transfer factor

Answer & Comments

Answer: 2- Flow volume loop

The flow volume loop is the best method of detecting an obstruction associated with a retrosternal mass.

See an example of a flow volume loop of large airway obstruction.

[Q: 2982] OnExamination 2012 - Respiratory

A 60-year-old man presents with inspiratory stridor with a chest x ray revealing compression of the trachea by a retrosternal goitre.

Which of the following investigations is the most useful to assess the severity of his airways obstruction?

- 1- Flow/volume loop
- 2- Forced expiratory volume
- 3- Forced vital capacity
- 4- Peak expiratory flow rate
- 5- Residual volume

Answer & Comments

Answer: 1- Flow/volume loop

A flow volume loop is the most appropriate investigation to assess severity of the obstruction.

[Q: 2983] OnExamination 2012 - Respiratory

A 65-year-old woman, a heavy smoker for many years, has had worsening dyspnoea for the past five years, without a significant cough.

A chest x ray shows increased lung size along with flattening of the diaphragm, consistent with emphysema. Over the next several years she develops worsening peripheral oedema. Her BP is 115/70 mmHg.

Which of the following cardiac findings is most likely to be present?

- 1- Constrictive pericarditis
- 2- Left ventricular aneurysm
- 3- Mitral valve stenosis

- 4- Non-bacterial thrombotic endocarditis
- 5- Right ventricular hypertrophy

Answer & Comments

Answer: 5- Right ventricular hypertrophy

This lady has chronic obstructive airways disease and subsequent cor pulmonale leading to right heart failure.

Non-bacterial thrombotic endocarditis is a condition seen in frail ill individuals.

[Q: 2984] OnExamination 2012 - Respiratory

A 47-year-old woman presenting with breathlessness has arterial blood gases taken which give the following results:

pO₂ 8.7 kPa/65mmHg (11.3-12.6)

pCO₂ 4.4 kPa/33mmHg (4.7-6.0)

pH 7.46 (7.36-7.44)

HCO₃ 24 mmol/L (20-28)

Which of the following is the most likely diagnosis?

- 1- Acute severe asthma
- 2- Emphysema
- 3- Hyperventilation syndrome
- 4- Kyphoscoliosis
- 5- Opiate overdose

Answer & Comments

Answer: 1- Acute severe asthma

The patient has an acute respiratory alkalosis with associated hypoxia. This is consistent with an acute asthmatic attack.

A normal or rising CO₂ is an ominous sign indicative of a life-threatening attack and the need to consider ventilatory support.

Patients with hyperventilation syndrome do show a respiratory alkalosis but this is not associated with hypoxia.

[Q: 2985] OnExamination 2012 - Respiratory

Which of the following is not true with regard to the radiological appearance of a chest x ray?

- 1- Consolidation of the left lower lobe will elevate the left hemidiaphragm
- 2- Consolidation of the lingular lobe will obliterate the aortic knuckle and pulmonary trunk in the PA view
- 3- Consolidation of the right anterior segment of the right middle lobe will extend to the right transverse fissure and the right hilum in PA view
- 4- Consolidation of the right apical segment will extend to the horizontal fissure in the PA view
- 5- Consolidation of the right middle lobe will obliterate the right atrial shadow in the PA view

Answer & Comments

Answer: 1- Consolidation of the left lower lobe will elevate the left hemidiaphragm

Consolidation in the left lower lobe obliterates the diaphragm whilst lingular consolidation will obliterate the left heart border.

The oblique fissure runs obliquely at 45 degrees from T4 or 5 vertebrae to the anterior costophrenic angle on lateral chest film.

The horizontal fissure runs from the hilum anteriorly to anterior chest wall.

The area above the horizontal fissure is the upper lobe, below the horizontal fissure is the middle lobe and below the oblique fissure is the lower lobe.

[Q: 2986] OnExamination 2012 - Respiratory

A 65-year-old man presents to the clinic with progressively increasing shortness of breath over the past three years. He is a non-smoker and worked until retirement in a bank office. There is no past medical history of note.

On examination he is clubbed, his BP is 142/72 mmHg, pulse is 73 and regular. There are widespread bilateral inspiratory crackles on auscultation. Chest x ray reveals a honeycomb appearance.

You suspect cryptogenic fibrosing alveolitis.

What is the chance of this being responsive to corticosteroids?

- 1- 1 in 50
- 2- 1 in 20
- 3- 1 in 10
- 4- 1 in 5
- 5- 1 in 2

Answer & Comments

Answer: 4- 1 in 5

Unfortunately responsiveness to corticosteroids in cryptogenic fibrosing alveolitis although up to 20% may show some objective response with respect to stabilisation of lung function.

Whilst only 20% of patients may be steroid responsive, other treatments for alveolitis include azathioprine and cyclophosphamide.

Other options under clinical trials include interferon-gamma 1beta and bosentan.

[Q: 2987] OnExamination 2012 - Respiratory

A 67-year-old man with known COPD attends the emergency department via ambulance with a severe exacerbation.

On arrival the ambulance crew hand over the oxygen alert card provided to him by his local chest clinic.

Which of the following pieces of information is listed on the standardised oxygen alert cards?

- 1- His previous oxygen saturations (when well)
- 2- His previous pCO₂ reading (when well)
- 3- His previous pO₂ reading (when well)
- 4- The oxygen concentration via venturi mask to be used
- 5- Underlying respiratory condition

Answer & Comments

Answer: 4- The oxygen concentration via venturi mask to be used

The British Thoracic Society in conjunction with the Intensive Care Society has produced oxygen alert cards that can be downloaded and printed to give to patients.

The details provided include the patient's name, that they are at risk of type II respiratory failure (with raised CO₂ levels), the concentration of oxygen to be delivered via venturi mask and their target oxygen saturations.

It also contains advice regarding the use of air and oxygen driven nebuliser machines in such patients.

The early identification of at risk patients is essential in avoiding over-oxygenation and precipitating CO₂ retention.

[Q: 2988] OnExamination 2012 - Respiratory

A 65-year-old man is admitted from home with a community-acquired pneumonia (CAP).

He has a history of skin rash to penicillin documented in his medical notes. He has adverse prognostic features and a CURB score of 4.

What would be an appropriate empirical antibiotic choice?

- 1- Augmentin
- 2- Augmentin and gentamycin
- 3- Cefotaxime and erythromycin
- 4- Cefuroxime and metronidazole
- 5- Ciprofloxacin and clarithromycin

Answer & Comments

Answer: 3- Cefotaxime and erythromycin

Community-acquired pneumonia is most commonly caused by Strep. pneumoniae, hence the use of a beta-lactam antibiotic because of the increased incidence of atypical organisms such as Mycoplasma. A macrolide such as erythromycin is also recommended.

Augmentin is contraindicated as it is penicillin-based.

Ciprofloxacin has poor cover against Strep. pneumoniae and metronidazole is used for anaerobic infections.

In this case a credible alternative for beta-lactam sensitivity is not mentioned and the best choice, because of clinical necessity since severe pneumonia can be fatal if treated with antibiotics that are not effective, is to go with the only cephalosporin and macrolide combination that is offered.

The chance of cross reactivity of penicillin allergy with beta-lactams is only 10%. A rash is not a contraindication for this.

If the patient has a documented anaphylactic reaction specifically to penicillin then this case would need to be discussed between the medical and microbiology consultants before the prescription was given. Different trusts have different policies regarding this and consequently it is highly unlikely you will be tested on this.

[Q: 2989] OnExamination 2012 -

Respiratory

65-year-old man came to the hospital for worsening breathlessness. He was a chronic smoker and previously diagnosed with lung cancer.

Chest x ray revealed elevation of left hemidiaphragm and left phrenic nerve palsy was suspected.

Which of the following findings on fluoroscopy of diaphragm will confirm the diagnosis?

- 1- No movement of the left hemidiaphragm
- 2- No movement of the right hemidiaphragm
- 3- Normal movement of both hemidiaphragms
- 4- Paradoxical movement of the left hemidiaphragm
- 5- Paradoxical movement of the right hemidiaphragm

Answer & Comments

Answer: 4- Paradoxical movement of the left hemidiaphragm

The diagnosis of phrenic nerve palsy is suspected when on the chest radiograph the diaphragmatic leaflet is elevated and is confirmed fluoroscopically by observing paradoxical diaphragmatic motion on sniff and cough.

In patients with normal lungs unilateral paralysis is usually asymptomatic and rarely requires treatment.

[Q: 2990] OnExamination 2012 - Respiratory

A 64-year-old man presented with shortness of breath. On examination he had the signs of a large right-sided pleural effusion.

Investigations revealed:

Pleural fluid analysis: protein 48 g/L

What is the most likely cause?

- 1- Cardiac failure

- 2- Constrictive pericarditis

- 3- Hepatic cirrhosis

- 4- Mesothelioma

- 5- Nephrotic syndrome

Answer & Comments

Answer: 4- Mesothelioma

The high protein content of the effusion suggests that it is an exudate.

Mesothelioma is the only cause of an exudate in this list.

The remaining choices cause a transudative effusion.

[Q: 2991] OnExamination 2012 - Respiratory

A 19-year-old intravenous drug user presents to the emergency department with a fever of 38.5°C, dyspnoea, and right sided pleuritic chest pain.

Bilateral cavitating lesions are seen in both lungs on his chest x ray.

What is the most likely diagnosis?

- 1- Aspiration pneumonia
- 2- Endocarditis of the tricuspid valve
- 3- Pneumocystis carinii pneumonia (PCP)
- 4- Pulmonary embolic disease
- 5- Pulmonary tuberculosis

Answer & Comments

Answer: 2- Endocarditis of the tricuspid valve

PCP can be excluded as it does not present in this manner.

Aspiration pneumonia is more likely to show a single abscess cavity rather than multiple bilateral lesions.

The patient is certainly at higher risk of TB and this is difficult to exclude without additional

information regarding constitutional symptoms (weight loss, night sweats, etc).

The remaining two choices are somewhat unfair since pulmonary emboli could clearly arise from tricuspid endocarditis due to dislodged vegetations. However, an argument might be made that PEs arising from venous thromboemboli do not typically cavitate.

The best answer, therefore, is that these cavities are due to septic emboli arising from infection on the tricuspid valve. Systemic embolisation occurs in 20-50% of cases of infective endocarditis, and can involve the lungs, central nervous system, coronary arteries, spleen, bowel and extremities. This highest incidence of emboli is seen with aortic and mitral valve infections, due to *S. aureus*, *Candida*, *HACEK* and *Abiotrophia*. Most occur within the first 2-4 weeks of therapy.

[Q: 2992] OnExamination 2012 - Respiratory

A 68-year-old male is admitted with a two month history of difficulty raising his arms, ascending stairs, and is also aware of a dry mouth. He smokes 15 cigarettes daily and admits to heavy alcohol consumption.

On examination he has proximal weakness affecting all four limbs with absent tendon reflexes. His chest x ray shows a right pleural effusion.

What is the most likely diagnosis?

- 1- Alcohol induced myopathy
- 2- Eaton-Lambert syndrome
- 3- Myasthenia gravis
- 4- Polymyalgia rheumatica
- 5- Polymyositis

Answer & Comments

Answer: 2- Eaton-Lambert syndrome

Eaton-Lambert syndrome is characterised by

Proximal muscle weakness (the cranial nerves and respiratory muscles are usually spared)

Depressed or absent tendon reflexes and

Autonomic features (for example, dry mouth, impotence, etc).

Seventy percent of cases are due to small cell lung cancer.

Unlike myasthenia gravis exercise is associated with increasing muscle strength and there is a negative response to Tensilon. Electromyography is useful in confirming the diagnosis where repeated nerve stimulations cause a progressive increase in the size of the muscle action potential.

Eaton (1905-1958) U.S. neurologist at Mayo Clinic. Lambert (1915-2003) U.S neuro-physiologist at Mayo Clinic and Prof. of physiology at University of Minnesota.

[Q: 2993] OnExamination 2012 - Respiratory

In the normal lung which of the following is correct?

- 1- Cartilage is present in all respiratory bronchioles.
- 2- The majority of airway resistance is generated by small airways.
- 3- There is an intrapleural pressure of 30 cmH₂O (3kPa) at the end of normal expiration.
- 4- There is a resting pulmonary blood flow of 10L/min.
- 5- The V:Q ratio is greater in apical than basal segments of the lung when upright and at rest.

Answer & Comments

Answer: 5- The V:Q ratio is greater in apical than basal segments of the lung when upright and at rest.

Because of surfactant, the pressure difference across the pleura required to inflate the lungs, is usually no more than about 4cmH₂O.

Resting pulmonary blood flow in an adult is around 5L/min.

Gas rises, so the V:Q ratio is higher in the apical than the basal segments.

While a single small airway provides more resistance than a single large airway, resistance to air flow depends on the number of parallel pathways present. For this reason, the large and particularly the medium-sized airways actually provide greater resistance to flow than do the more numerous small airways.

Cartilage disappears in the terminal bronchioles.

[Q: 2994] OnExamination 2012 - Respiratory

In asbestos related disorders which of the following statements is correct?

- 1- Basal fibrotic shadowing on CXR suggests coincidental idiopathic fibrosing alveolitis
- 2- Increased incidence of primary lung cancer
- 3- Pleural effusion develops more than 20 years after causative asbestos exposure
- 4- Pleural plaques are recognised precursors of mesothelioma
- 5- The risk of malignant mesothelioma is greatly increased in smokers compared with non-smokers

Answer & Comments

Answer: 2- Increased incidence of primary lung cancer

The risk of mesothelioma is not affected by smoking but smoking and asbestos exposure greatly increase the risk of lung cancer.

It is pleural plaques which do not become apparent until 20 years or more after exposure.

Pleural effusions may result from acute asbestosis pleurisy.

Pleural plaques are not precursors of malignant change, but they reflect previous asbestos exposure.

Basal fibrotic changes suggest the presence of asbestosis as the fibres are fibrogenic.

[Q: 2995] OnExamination 2012 - Respiratory

A 17-year-old female presents with acute breathlessness. She has had asthma for approximately three years and recently commenced new therapy.

Which agent may be responsible for this exacerbation?

- 1- Beclomethasone
- 2- Ipratropium bromide
- 3- Montelukast
- 4- Salmeterol
- 5- Theophylline

Answer & Comments

Answer: 4- Salmeterol

Salmeterol has been reported to produce an acute exacerbation of asthma, possibly through an acute hypersensitivity reaction.

[Q: 2996] OnExamination 2012 - Respiratory

A 65-year-old man, with a history of smoking presents with chronic cough, haemoptysis and weight loss. His chest x ray shows a cavitating lesion.

What is the likely diagnosis?

- 1- Adenocarcinoma
- 2- Alveolar cell carcinoma

- 3- Undifferentiated large cell carcinoma
- 4- Small cell carcinoma
- 5- Squamous cell carcinoma

Answer & Comments

Answer: 5- Squamous cell carcinoma

The combination of cough, haemoptysis and weight loss in a smoker should lead you to consider lung carcinoma as a possible diagnosis. A lifelong smoker has a 20 to 30 times increased risk of smoking compared to a non-smoker. Haemoptysis in particular is one of the common presenting symptoms of carcinoma.

The two major forms of lung carcinoma are non-small cell lung carcinoma (85%) and small cell lung carcinoma (15%). Non-small cell lung carcinomas are further divided into squamous cell (35%), adenocarcinoma (30%), undifferentiated large cell (10%) and bronchial-alveolar cell (5%). Squamous cell carcinomas usually arise from a central airway, and cavitate. Small cell carcinomas arise in the central airways and grow rapidly. Adenocarcinomas may be peripheral and slow-growing; they are the commonest lung carcinomas in non-smokers. Smoking is associated with all forms but is most strongly linked with small-cell and squamous cell carcinoma.

Other causes of cavitating lung lesions include:

Infection (Staphylococcus aureus, tuberculosis, Klebsiella, Pneumocystis jiroveci)

Pulmonary infarcts

Wegener's granulomatosis

Rheumatoid nodules.

[Q: 2997] OnExamination 2012 - Respiratory

A 23-year-old woman attends the clinic for asthma review.

She remains significantly short of breath and has wheeze and coughing in the early hours of the morning. At her last appointment you instigated treatment with salmeterol as she was already on a stable dose of 400 mcg per day inhaled beclomethasone.

On examination in the clinic her BP is 100/70 mmHg, her pulse is 70 and regular. She has scattered wheeze on auscultation of the chest and her PEF is 380 (predicted 550). This is similar to prior to starting the salmeterol from which she perceives she has gained no benefit.

According to asthma guidelines which of the following is the most appropriate next step?

- 1- Add low dose oral steroids
- 2- Add montelukast
- 3- Add theophylline
- 4- Increase inhaled corticosteroid to 800 mcg/day
- 5- Stop salmeterol and increase inhaled corticosteroid to 800 mcg/day

Answer & Comments

Answer: 5- Stop salmeterol and increase inhaled corticosteroid to 800 mcg/day

2011 BTS guidelines suggest that if the patient has not, as in this case, derived benefit from the LABA then it should be stopped and inhaled corticosteroid increased. Only in the circumstance that there has been some benefit derived should it be continued with increase in the corticosteroids.

Montelukast and theophylline are considered after the dose of inhaled corticosteroids has been maximised according to the asthma guidelines.

Given asthma is a chronic condition low dose oral steroids are considered a treatment of last resort at step 5.

[Q: 2998] OnExamination 2012 - Respiratory

A 45-year-old man presents with a three month history of wheezing and dyspnoea whilst at work. His symptoms improve significantly when at home and at weekends.

What is the likely causative agent?

- 1- Asbestos
- 2- Cotton dust
- 3- Isocyanates
- 4- Silica
- 5- Simple coal worker's lung

Answer & Comments

Answer: 3- Isocyanates

This patient presents with typical symptoms of occupational asthma and the most likely causative substance is isocyanate which is used in the manufacture of foams/plastics.

There are an estimated 1500 to 3000 cases of occupational asthma reported each year.

Other implicated substances include flour dust, wood dust, latex, solder and glues.

[Q: 2999] OnExamination 2012 - Respiratory

A 44-year-old man with advanced HIV/AIDS presents with a two week history of fever, weight loss (8 kg) and sweats. His latest CD4 T-lymphocyte count (taken four weeks previously) was 20 cells/mm³. He had failed multiple regimens of antiretroviral therapy and was not currently taking any prescribed medications other than co-trimoxazole as prophylaxis against *Pneumocystis carinii* pneumonia.

Investigations:

Hb 8.2 g/dL (13.0-18.0)

Total WBC $2.1 \times 10^9/L$ (4-11)

Platelets $75 \times 10^9/L$ (150-400)

A bone marrow aspirate showed acid/alcohol fast bacilli on light microscopy.

Which one of the following mycobacteria is the most likely cause of his presenting illness?

- 1- *Mycobacterium avium*
- 2- *Mycobacterium bovis*
- 3- *Mycobacterium chelonae*
- 4- *Mycobacterium fortuitum*
- 5- *Mycobacterium marinum*

Answer & Comments

Answer: 1- *Mycobacterium avium*

Mycobacterium bovis and *Mycobacterium tuberculosis* are classified as 'typical' mycobacteria that cause a similar spectrum of disease.

As its name suggests, *M. bovis* also causes disease in cattle and the usual source of human infection was from drinking contaminated milk; this is now rare.

BCG is a live attenuated vaccine derived from a strain of *M. bovis*. BCG is currently used as a form of immunotherapy for treating bladder cancer; several cases of disseminated *M. bovis* infection (systemic 'BCG-it is') have been described as a result of systemic infection following this treatment.

The other organisms listed are non-tuberculous mycobacteria (NTM); sometimes referred to as 'atypical' mycobacteria. They differ from *M. tuberculosis* in that they are ubiquitous organisms and have no person-to-person spread.

Mycobacterium avium (also known as *Mycobacterium avium* complex [MAC], or *Mycobacterium avium* intracellulare [MAI]) causes disseminated infection in patients with advanced HIV, typically when the CD4 count is less than 50 cells/mm³.

This is a disseminated infection that usually causes symptoms of fatigue, weight loss and

fevers. Bone marrow infiltration is typical and patients are often anaemic and/or pancytopenic. The diagnosis is best made from bone marrow aspiration and culture. It may also be detected in blood cultures.

M. fortuitum, and *M. chelonae* typically present as painful papular, nodular or ulcerating skin lesions. Both are classified as a rapidly growing mycobacteria and infect immunocompetent individuals. It is a natural environmental organism that has been found in water sources, sewage and dirt.

Other manifestations include osteomyelitis, lymphadenitis, and ocular disease (keratitis and corneal ulceration), usually a result of wound contamination after trauma.

Disseminated disease may be seen in immunosuppressed patients.

Mycobacterium marinum infection occurs when contaminated water is exposed to skin that has experienced open trauma. It is an uncommon infection that is usually seen in patients who handle fish or swim in freshwater or saltwater. The skin is the most common site of infection, where it usually produces a solitary indolent granulomatous lesion - the 'fish tank granuloma'.

[Q: 3000] OnExamination 2012 - Respiratory

A 17-year-old man presented with a strongly positive Mantoux test.

Which one of the following statements regarding his immune reaction is correct?

- 1- If a skin biopsy were taken, immunohistochemistry would show immune complex deposition
- 2- It is a cell mediated immune response
- 3- The area of induration will be less than 10 mm in diameter
- 4- The reaction typically develops within 24 hours

5- The response is mediated by B lymphocytes

Answer & Comments

Answer: 2- It is a cell mediated immune response

The Mantoux test replaced the Heaf test in 2005 in the UK. One of its uses is for patients who have had close contact with a person known to have tuberculosis. It measures the T cell-mediated immune response to TB antigen. Immune complexes are not involved (these result from antibody mediated immune responses).

The injection site should be reviewed 48-72 hours following intradermal inoculation of tuberculin. The left forearm is typically used. Only the induration, not surrounding erythema, is used in the measurement and the longest diameter is measured in millimetres:

- Less than 6mm: negative test, previously unvaccinated individuals can be given the BCG (within three months) provided there are no contraindications
- More than 6mm but less than 15mm: hypersensitive to tuberculin protein (may be due to previous TB infection, BCG, or atypical mycobacteria). Patients are not given the BCG if part of an immunisation programme. However, in other contexts (e.g. immigrant screening and contact tracing), further investigation should and follow-up may be indicated.
- More than 15mm: strongly hypertensive to tuberculin, suggestive of TB infection. Patients should be referred for further investigation and treatment

The reaction to tuberculin protein may be suppressed by viral infections, live viral vaccines, sarcoidosis, corticosteroids, immunosuppression, severe tuberculous disease and poor nutrition.

[Q: 3001] OnExamination 2012 - Respiratory

A 16-year-old male presents to his GP with exertional breathlessness.

The chest x ray reveals a lesion in the anterior mediastinum.

Which one of the following is the most likely cause for such an appearance?

- 1- Ascending aorta
- 2- Hilar lymph nodes
- 3- Left atrium
- 4- Oesophagus
- 5- Thymus gland

Answer & Comments

Answer: 5- Thymus gland

Abnormalities of the anterior/superior mediastinum may relate to the thymus, thyroid.

Inferior or middle mediastinal masses relate to the aorta, lungs, hilar lymph nodes, oesophagus and heart.

Posterior mediastinal masses may relate to the nerves and vertebrae.

[Q: 3002] OnExamination 2012 - Respiratory

In a study of a new drug for asthma, a researcher wishes to compare average serum drug concentrations in volunteers four hours after taking the drug:

- A. In the fasting state then
- B. After a meal.

Which of the following would be the most appropriate statistical test to use?

- 1- Chi-squared test
- 2- Pearson's correlation coefficient
- 3- Student's paired t test
- 4- Student's unpaired t test

5- Wilcoxon test

Answer & Comments

Answer: 3- Student's paired t test

In this scenario we are dealing with use of the drug in the same volunteers with the intervention being the effect of feeding on drug concentrations.

Thus you will be comparing means in the same subjects and the paired t test would be the most appropriate test.

[Q: 3003] OnExamination 2012 - Respiratory

A 63-year-old man presents with recurrent gradually increasing shortness of breath over the last few weeks.

His chest x ray is shown:

On examination his hands showed the following:

What is the diagnosis?

- 1- Chronic mucocutaneous candidiasis
- 2- Iron deficiency
- 3- Ochronosis
- 4- Polychondritis
- 5- Yellow nail syndrome

Answer & Comments

Answer: 5- Yellow nail syndrome

This is yellow nail syndrome where the nails are yellow, thickened, curved, stop growing and may become detached from the nail bed.

Associated findings include lymphoedema, bronchiectasis and pleural effusions.

[Q: 3004] OnExamination 2012 - Respiratory

A 32-year-old woman presents to the clinic with symptoms of pneumonia and you suspect

she has an underlying Mycoplasma infection.

On examination she is pyrexial, 38.2°C, her BP is 110/70 mmHg and her pulse is 90. She looks pale and has signs of a right sided pneumonia.

You suspect that she may have haemolytic anaemia.

Which of the following would you expect to find on laboratory testing?

- 1- Decreased LDH
- 2- Decreased reticulocyte count
- 3- Increase in bilirubin (predominantly conjugated)
- 4- Increased haptoglobin
- 5- Presence of spherocytes on the blood film

Answer & Comments

Answer: 5- Presence of spherocytes on the blood film

Reticulocyte counts are of course increased in haemolytic anaemia due to increased circulating immature red blood cells.

The increase in bilirubin is predominantly unconjugated. Lactate dehydrogenase (LDH) is increased and haptoglobins are reduced.

Urinary urobilinogen is increased and haemosiderinuria may be seen.

[Q: 3005] OnExamination 2012 - Respiratory

A 58-year-old man presents with a month history of breathlessness. He is a non-smoker.

On examination, his temperature was 36.7°C, with a respiratory rate of 20 breaths per minute and normal breath sounds to auscultation and a pulse of 92 bpm.

Arterial blood gases on air showed:

pH 7.51 (7.36 - 7.44)

pO₂ 8.4 kPa (11.3 - 12.6)

pCO₂ 4.0 kPa (4.7 - 6.0)

What is the most likely diagnosis?

- 1- Atypical pneumonia
- 2- Fibrosing alveolitis
- 3- Hysterical hyperventilation
- 4- Inhaled foreign body
- 5- Pulmonary thromboembolism

Answer & Comments

Answer: 5- Pulmonary thromboembolism

This patient has a respiratory alkalosis with type 1 respiratory failure as evidenced by low pO₂ and low pCO₂.

Chronic venous thromboembolism would be the most likely explanation for this man's presentation.

Hyperventilation would be excluded by the type 1 respiratory failure, an inhaled foreign body would not produce such a picture and an atypical pneumonia would be associated with pyrexia and some clinical signs.

The differential diagnosis here is pulmonary fibrosis but basal crackles may be expected and the history is somewhat short.

[Q: 3006] OnExamination 2012 - Respiratory

Which one of the following is correct regarding long acting beta-2 agonists?

- 1- Are beneficial in acute viral croup.
- 2- Become less effective over time (tolerance).
- 3- Can be used to prevent activity-induced symptoms without anti-inflammatory therapy.
- 4- Protect against allergen challenge for up to 48 hours.
- 5- Should not be used in association with erythromycin.

Answer & Comments

Answer: 3- Can be used to prevent activity-induced symptoms without anti-inflammatory therapy.

Long acting beta-2 agonists, for example salmeterol, can be used twice daily to assist in prophylaxis in chronic asthma as step 3 of the British Thoracic Society Asthma Guidelines.

There is no evidence that the bronchodilator effect wanes with time, though there is debate that it may become less effective in protecting against exercise or methacholine induced bronchospasm. Its duration of action is around 12 hours, and has gone completely by 36 hours.

Aminophylline interacts with erythromycin, giving an increased risk of toxicity.

There is no evidence that salmeterol works in viral croup, though oral steroids are highly effective.

[Q: 3007] OnExamination 2012 - Respiratory

A 40-year-old female is admitted with a suspected pulmonary embolism. A ventilation perfusion scan is requested.

Which of the following is true of lung ventilation perfusion scanning in suspected pulmonary embolism (PE)?

- 1- A normal perfusion scan virtually excludes pulmonary embolism (PE)
- 2- It is contraindicated if the patient is pregnant
- 3- It is contraindicated in those with iodine hypersensitivity
- 4- There is reduced perfusion in the upper lobes in mitral stenosis
- 5- The appearances of the scan is very different in those with pulmonary embolism and those with emphysema

Answer & Comments

Answer: 1- A normal perfusion scan virtually excludes pulmonary embolism (PE)

Increased pulmonary venous pressure, especially secondary to mitral valve disease, causes increased flow to the upper lobes.

Chronic obstructive pulmonary disease (COPD) usually gives rise to matched defects.

Radiation to the fetus is small.

Ventilation quotient (VQ) scan is not contraindicated in pregnant women, although the perfusion only scan is adequate.

Xenon is used for imaging ventilation, whilst technetium labelled macroaggregated human serum albumin (MAA) is used to image perfusion. A normal perfusion scan has a sensitivity of 98% but a specificity of only 40%.

[Q: 3008] OnExamination 2012 - Respiratory

Which of the following statements concerning industrial lung disorders is correct?

- 1- Occupational asthma occurs more frequently in atopic persons
- 2- Pneumoconiosis can be diagnosed in the absence of chest x ray abnormalities
- 3- Silo filler's disease is caused by allergy to grain
- 4- Widespread crepitations are typically heard in extrinsic allergic alveolitis (EAA)
- 5- Symptoms occur within minutes of exposure to mouldy hay in farmer's lung

Answer & Comments

Answer: 1- Occupational asthma occurs more frequently in atopic persons

Occupational asthma also occurs more frequently in smokers.

Pneumoconiosis is an x ray diagnosis. It is due to deposition of coal dust in parenchyma and

reaction to its presence. The types - simple/complicated - are diagnosed on x ray appearance.

Silo filler's disease is pulmonary oedema caused by inhalation of oxides of nitrogen generated by fresh silage.

Symptoms of farmer's lung usually occur within hours.

Examination in EAA usually reveals inspiratory crepitations which tend to be basal rather than widespread, sometimes squeaks, but wheeze is not typical.

[Q: 3009] OnExamination 2012 - Respiratory

A 54-year-old woman with multiple medical problems attends the respiratory clinic with increasing shortness of breath.

Medication of note includes dosulepin, omeprazole, amlodipine, ramipril and atorvastatin.

On examination her BP is 132/78 mmHg, pulse is 72 and regular. There are scattered inspiratory crackles throughout both lung fields. Pulmonary function testing reveals a restrictive defect.

Which of the following agents is most likely to be responsible?

- 1- Amlodipine
- 2- Atorvastatin
- 3- Dosulepin
- 4- Omeprazole
- 5- Ramipril

Answer & Comments

Answer: 3- Dosulepin

Dosulepin is recognised as a very rare cause of pulmonary fibrosis. Both subacute interstitial pneumonia and acute alveolitis have been reported in association with dosulepin therapy.

1. McEwan S R, Clark R A, Guthrie W. Dosulepin and fatal fibrosing alveolitis. Lancet 1986; i: 970

2. Veale D, Gilmartin J J. Acute alveolitis associated with dosulepin treatment. Br Med J 1985; 290: 606

None of the other agents listed are recognised as causes of pulmonary fibrosis.

More commonly recognised drug causes of pulmonary fibrosis include

Amiodarone

Bleomycin

Methotrexate

Busulphan

Gold

Nitrofurantoin and

Penicillamine.

[Q: 3010] OnExamination 2012 - Respiratory

A 62-year-old man presents to the respiratory clinic with increasing shortness of breath and reduced exercise tolerance over the past few months.

He has recently commenced a course of immunosuppressive therapy for mixed connective tissue disease.

On examination his BP is 125/72 mmHg, pulse is 80 and regular, saturations are 94% on air. There are fine inspiratory crackles on auscultation of the chest, and a CXR reveals evidence of diffuse interstitial shadowing.

Which of the following is the most likely causative agent?

- 1- Cyclophosphamide
- 2- Methotrexate
- 3- Penicillamine
- 4- Prednisolone

5- Sulphasalazine

Answer & Comments

Answer: 2- Methotrexate

Methotrexate is recognised to be associated with pulmonary fibrosis, it is however extremely effective in control of rheumatoid and psoriatic arthritis. Baseline pulmonary function tests are recommended prior to starting therapy, and physicians are warned to be alert to increased shortness of breath.

Cyclophosphamide is rarely associated with non-cardiogenic pulmonary oedema, rather than pulmonary fibrosis.

Penicillamine may rarely be associated with pulmonary haemorrhage.

The main concern of sulphasalazine therapy is its association with blood dyscrasias.

[Q: 3011] OnExamination 2012 - Respiratory

You are called to see a 67-year-old lady on the ward because of severe dyspnoea. She was admitted three days ago with an exacerbation of COPD.

Her respiratory rate is 36 /min, temp 37.2°C and BP 136/80 mmHg with a pulse of 102 /min. O₂ sat is 88% on 35 % O₂ (venturi mask). Her chest shows scattered wheezes with decreased air entry.

She is on IV antibiotics, nebulised B2 agonists, ipratropium and oral prednisolone 30 mg.

You check her blood gases and the results are as follows:

ph 7.28(7.35-7.45)

pCO₂ 9.4(4.7-6.0)

PO₂ 6.8(11.3-12.6)

Bicarbonate 29mmol/L(21-29)

Which is the best option for her next treatment?

- 1- BIPAP (bilevel positive airway pressure)
- 2- CPAP (continuous positive airway pressure)
- 3- Decrease O₂ to 28%
- 4- Intravenous corticosteroids
- 5- Mechanical ventilation

Answer & Comments

Answer: 1- BIPAP (bilevel positive airway pressure)

BiPAP is indicated in type 2 respiratory failure.

CPAP is used in type 1 respiratory failure.

Steroids will not help as the patient is already on a good dose.

Decreasing O₂ is not a good idea as the patient is hypoxic.

Mechanical ventilation may be considered if the patient does not improve on BiPAP.

Before considering BiPAP, optimisation of medical treatment should be done.

[Q: 3012] OnExamination 2012 - Respiratory

A 72-year-old man is referred to the chest clinic with a progressive history of dyspnoea, and a dry cough over the last eight months. He currently smokes 20/day and has done for 53 years.

He has had several episodes of acute shortness of breath for which he has received antibiotics from his GP.

On examination he is clubbed, and basal inspiratory crepitations are heard on auscultation. His oxygen saturations are 87% on air.

He undergoes a high-resolution computed tomography (HRCT) which demonstrates bilateral basal and subpleural reticular changes with honeycombing evident.

What is the most likely diagnosis?

- 1- Cryptogenic organising pneumonia (COP)
- 2- Desquamative interstitial pneumonia (DIP)
- 3- Non-specific interstitial pneumonia (NSIP)
- 4- Respiratory bronchiolitis - interstitial lung disease (RB-ILD)
- 5- Usual interstitial pneumonia (UIP)

Answer & Comments

Answer: 5- Usual interstitial pneumonia (UIP)

This patient most likely has idiopathic interstitial pneumonitis (IIP).

IIP is further subdivided into

Usual interstitial pneumonia (previously known as idiopathic pulmonary fibrosis, or cryptogenic fibrosing alveolitis) and

Non-usual interstitial pneumonitis.

UIP causes 70% of IIP. It is typically found in an older population and is characterised by a gradual onset with acute exacerbations. It is worse in smokers.

Reticular abnormalities, honeycombing and traction bronchiectasis are typical HRCT findings. Unfortunately patients with UIP have a poor response to steroids and immunosuppressants and the median survival is two to three years post-diagnosis.

The remaining answers are members of the non-usual interstitial pneumonitis (non-UIP). Of this group non-specific interstitial pneumonia (NSIP) is the most common. On CT there is typically ground glass appearance and there is better steroid responsiveness when compared to UIP, with an improved survival.

COP is subacute and tends to cause patchy consolidation and/or nodules on CT scan.

RB-ILD usually occurs in heavy smokers. CT findings include bronchial wall thickening and patchy ground glass appearance.

DIP is a form of severe RB-ILD.

[Q: 3013] OnExamination 2012 - Respiratory

Listed below are the five causes of hypoxia.

Which one of the five inevitably causes an increased $paCO_2$?

- 1- Diffusion impairment
- 2- Hypoventilation
- 3- Low inspired pO_2
- 4- Right-to-left shunt
- 5- Ventilation-perfusion mismatch

Answer & Comments

Answer: 2- Hypoventilation

Hypoventilation, where inadequate alveolar ventilation results in low alveolar PO_2 , is the only cause of hypoxia that inevitably causes raised $PaCO_2$.

If the hypoxia is out of proportion to the hypercapnia and the A-a PO_2 gradient increased then another mechanism (diffusion impairment, right-to-left shunt or ventilation-perfusion mismatch) must also be present.

The primary effects of right-to-left shunts and ventilation-perfusion mismatching are to raise arterial CO_2 content, however this is usually corrected (and sometimes over-corrected) by a reflex increase in ventilation.

[Q: 3014] OnExamination 2012 - Respiratory

A 32-year-old man who is a lifelong non-smoker presents to the respiratory clinic with shortness of breath, wheeze and a chronic cough. He works as a stone mason carving grave stones and has a property on a farm.

At the same time, his father maintains that he only ever used to smoke between five and ten cigarettes per day, yet he is 59-years-old with severe COPD on home oxygen.

On examination the patient has bilateral wheeze and coarse crackles consistent with obstructive lung disease.

Investigations show

Haemoglobin 12.1 g/dl(13.5-17.7)

White cell count $6.2 \times 10^9/L$ (4-11)

Platelets $172 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 88 $\mu\text{mol/l}$ (79-118)

Alanine amino transferase 86 U/l (5-40)

PEFR 280 l/min(Predicted 550)

Chest x ray Evidence of lower lobe emphysema

Which of the following is the most likely diagnosis?

- 1- Alpha-1 antitrypsin deficiency
- 2- Asthma
- 3- Chronic bronchitis
- 4- Extrinsic allergic alveolitis
- 5- Silicosis

Answer & Comments

Answer: 1- Alpha-1 antitrypsin deficiency

The clues are the very early development of obstructive lung disease, with lower lobe emphysema seen on CXR, and the fact that despite a relatively low pack year history of smoking, his father has developed severe chronic obstructive pulmonary disease (COPD).

Many patients with alpha-1 antitrypsin deficiency develop significant liver disease, including cirrhosis, and the raised alanine aminotransferase (ALT) seen here is suggestive of that.

Management of alpha-1 antitrypsin deficiency is similar to that for smoking-related COPD, with high dose inhaled steroids and

bronchodilators. Additionally, patients should be advised to avoid consumption of alcohol.

Alpha-1-antitrypsin replacement is available, but currently it is not recommended by NICE.

[Q: 3015] OnExamination 2012 - Respiratory

Which of the following statements is true of psittacosis (ornithosis)?

- 1- Infection responds rapidly to penicillin therapy
- 2- It does spread from person to person
- 3- It is more of a risk to children than to adults who are exposed to birds
- 4- It is only a risk from contact with psittacines (parrots), not other birds
- 5- It usually causes many polymorphs to be present in the sputum

Answer & Comments

Answer: 2- It does spread from person to person

Chlamydia psittaci is endemic in birds including psittacine birds, canaries, finches, pigeons and poultry.

Pet owners, vets and zoo keepers are most at risk. It is rare in children.

Person to person transmission occurs especially in a hospital environment.

Sputum Gram stain reveals a few leucocytes and no predominant bacteria. There are few signs and few laboratory/x ray findings.

Positive serology is with complement-fixing antibodies.

It is treated with tetracycline.

[Q: 3016] OnExamination 2012 - Respiratory

A 29-year-old man is diagnosed with

pulmonary tuberculosis.

A blood sample is sent to determine his acetylator status prior to starting therapy. This showed that he was a fast acetylator. He was subsequently started on antituberculous therapy that included isoniazid.

Which of the following statements is correct?

- 1- There is an increased risk of convulsions
- 2- There is a higher plasma drug concentration
- 3- There is an increased risk of hepatitis
- 4- There is an increased risk of megaloblastic anaemia
- 5- There is an increased risk of peripheral neuropathy

Answer & Comments

Answer: 3- There is an increased risk of hepatitis

This is a tricky question, especially as there is a lot of debate in the literature about this issue. It is important, however, not to get too bogged down in detail and appreciate the key points for the MRCP exam.

Isoniazid is metabolised primarily by acetylation and dehydrazination.

The rate of acetylation is genetically determined. Approximately 50% of black and Caucasian people are 'slow acetylators' and the rest are 'rapid acetylators'. The majority of Eskimos and Orientals are 'rapid acetylators'.

Fast acetylation leads to higher blood levels of the toxic metabolite acetylisoniazid and thus to an increase in toxic hepatitis which is 250 times more common than in slow acetylators.

Slow acetylators, on the other hand, may be associated adverse effects secondary to higher drug concentrations, which can lead to peripheral neuropathy.

[Q: 3017] OnExamination 2012 - Respiratory

A 7-month-old boy is presented to a doctor by his parents with symptoms of recurrent upper respiratory tract infections. No other members of the family suffer from any similar infections.

Physical examination showed mild facial hypoplasia.

Biochemistry investigations revealed hypocalcaemia.

Microbiological investigations were normal and immunoglobulins were within normal limits.

The infant's immune function would show which of the following deficiencies?

- 1- B cell number and function
- 2- Complement deficiency
- 3- Macrophage number and function
- 4- Plasma cell
- 5- T cell number and function

Answer & Comments

Answer: 5- T cell number and function

This child suffers from DiGeorge's syndrome.

Patients with DiGeorge's syndrome often have near normal levels of immunoglobulins but with significant decreases in T cell numbers and relative increase in the percentage of B cells.

[Q: 3018] OnExamination 2012 - Respiratory

A lifelong non-smoker is diagnosed with emphysema.

Which of the following would be the most likely aetiological agent?

- 1- Asbestos
- 2- Cadmium exposure
- 3- Isocyanates

4- Steel

5- Zinc

Answer & Comments

Answer: 2- Cadmium exposure

Cadmium fume inhalation is a recognised cause of emphysema.

Other industrial associations with chronic obstructive pulmonary disease (COPD) include

Coal

Cotton

Grain and

Cement.

[Q: 3019] OnExamination 2012 - Respiratory

A 45-year-old man develops facial swelling and breathlessness.

His chest x ray reveals paratracheal lymphadenopathy.

Which of the following statements is most accurate regarding the superior vena caval obstruction (SVCO)?

- 1- The most common cause is squamous cell carcinoma
- 2- Treatment of choice is radiotherapy
- 3- It may be associated with voice hoarseness
- 4- It is associated with Kussmaul's sign
- 5- The commonest symptom is stridor

Answer & Comments

Answer: 3- It may be associated with voice hoarseness

A. SVCO is most likely caused by bronchogenic carcinoma, especially small cell carcinoma (10% of small cell cancers present with SVCO) due to mediastinal lymphadenopathy. Other causes include:

Lymphoma

Aortic aneurysm

Mediastinal fibrosis and

Mediastinal goitre.

B. Chemotherapy ± radiotherapy is the treatment of choice in small cell carcinoma. Radiotherapy may be the treatment of choice for non-small cell carcinoma. Median survival of lung cancer presenting with SVCO, even with treatment is five months. Lymphoma has a better prognosis and will require specific chemotherapy ± radiotherapy.

C. Recurrent laryngeal nerve palsy usually occurs with malignant tumour but can occur with aneurysm of aortic arch. There may also be Horner's syndrome due to involvement of sympathetic chain. Compression of vital structures can result in stridor and dysphagia.

D. SVCO is associated with elevated non-pulsatile jugular venous pressure (JVP). Kussmaul's sign is the paradoxical rise in JVP on inspiration due to constrictive pericarditis or significant pericardial effusion.

E. The commonest symptoms are usually cough and chest pain, due to the distortion of mediastinal anatomy. Physical signs are often absent or minimal, but classically there are facial and periorbital oedema, chemosis and distended veins.

[Q: 3020] OnExamination 2012 - Respiratory

A 67-year-old retired plumber presents to the clinic with increasing shortness of breath and dull left sided chest pain.

You understand that this has been a problem for some six months or more. There is no past medical history of note apart from essential hypertension for which he takes ramipril 10 mg / day.

Investigations show:

Haemoglobin 13.6 g/dl(13.5-17.7)

White cell count $9.1 \times 10^9/L$ (4-11)

Platelets $252 \times 10^9/L$ (150-400)

Sodium 137 mmol/l (135-146)

Potassium 3.7 mmol/l (3.5-5)

Creatinine 119 $\mu\text{mol/l}$ (79-118)

pH 7.41(7.35-7.45)

pCO₂ 6.2 kPa(4.8-6.1)

pO₂ 9.6 kPa (10-13.3)

CXR Large left pleural effusion

Which of the following is the optimal investigation to deliver the diagnosis?

- 1- Blind pleural biopsy
- 2- CT thorax
- 3- Sputum cytology
- 4- Thoracocentesis
- 5- Thoracoscopy with drainage and biopsy

Answer & Comments

Answer: 5- Thoracoscopy with drainage and biopsy

Blind pleural biopsy may result in tissue being obtained from an area not affected by mesothelioma. As such this is not correct.

Whilst thoracocentesis is likely to obtain malignant cells, the histopathologist may not be able to type them adequately.

CT scanning may reveal structural abnormalities but will not give a histological diagnosis and sputum cytology would be unlikely to reveal malignant cells.

[Q: 3021] OnExamination 2012 - Respiratory

A 32-year-old man is admitted by ambulance after being caught up in a house fire and gas explosion whilst trying to rescue a neighbour.

He has been resuscitated at the scene, but on arrival in the Emergency department is extremely unwell. His saturations are 91% on

a non-rebreather; his BP is 142/82 mmHg with a pulse of 84. There is audible stridor and bibasal crackles on auscultation of the chest. Portable chest is suggestive of pulmonary oedema.

Which of the following is the most appropriate management?

- 1- BIPAP
- 2- Intubation and ventilation
- 3- IV furosemide
- 4- IV nitrate
- 5- IV noradrenaline

Answer & Comments

Answer: 2- Intubation and ventilation

The suspicion here is that this patient has non-cardiogenic pulmonary oedema as a result of smoke inhalation. There is also stridor, a sign of laryngeal oedema and this patient is at significant risk of airway obstruction. As such the optimal management is intubation and ventilation.

BIPAP is inappropriate because of the risk of airway obstruction.

The other treatments are conventional ones for cardiogenic pulmonary oedema.

[Q: 3022] OnExamination 2012 - Respiratory

A 31-year-old woman is brought to the Emergency department by ambulance. She has just got off a long-haul flight and collapsed at the baggage carousel.

On examination in the department she is hypotensive with a BP of 80/50 mmHg, her pulse is 95 and regular. Her chest is clear and her abdomen is soft and non-tender. You notice that her left leg appears swollen.

Investigations show:

pH 7.38 (7.35-7.45)

pO₂ 9kPa (10-13.3) on non-rebreather

pCO₂ 3.6kPa (4.8-6.1)

ECG - Right heart strain

Which of the following would be an indication for thrombolysis in this patient?

- 1- BP 80/50
- 2- ECG showing right heart strain
- 3- pCO₂ 3.6
- 4- pH 7.38
- 5- pO₂ 9

Answer & Comments

Answer: 1- BP 80/50

Hypotension and cardiogenic shock are the most significant factors associated with increased mortality in massive pulmonary embolus (PE). As such it is the BP here which drives progression to thrombolysis rather than anti-coagulation.

The pH is in the normal range, as such it would not be a driver of more aggressive intervention here.

All of the other factors are indications of a large PE, but without hypotension they would not necessarily drive thrombolysis or surgical embolectomy. This is because the evidence for thrombolysis in sub-massive PE is much less strong than that for a massive event.

[Q: 3023] OnExamination 2012 - Respiratory

A 76-year-old lady with COPD wants to visit a friend in Japan.

Her FEV₁ is 40 %. Her last hospital admission was four months ago. She is known to have significant kyphoscoliosis. Her O₂ sat on air is 93 %. You perform a hypoxic challenge and her pO₂ is 7.8.

What would you advise?

- 1- Advise inflight oxygen 28%
- 2- Advise inflight oxygen 35%

- 3- Advise not to fly
- 4- Allow flight and no oxygen required
- 5- Perform a walking test

Answer & Comments

Answer: 4- Allow flight and no oxygen required

An hypoxic challenge test gives the patient FiO₂ 15% for 15 minutes and measures PO₂.

PaO₂ > 7.4 kPa (> 55 mmHg) - Oxygen not required.

PaO₂ 6.6-7.4 kPa (50-55 mmHg) - Borderline. A walk test may be helpful.

PaO₂ < 6.6 kPa (< 50 mmHg) - In-flight oxygen (2L/min).

[Q: 3024] OnExamination 2012 - Respiratory

A 73-year-old woman is referred to the emergency medical take with a lower respiratory tract infection. She has seen the GP because of an increasingly problematic cough, productive of rusty coloured sputum and severe shortness of breath.

On examination in the Emergency department her blood pressure is 135/82 mmHg. Her temperature is 38.5°C and her pulse is 80 and regular. Her respiratory rate is 22. Auscultation of the chest reveals right lower lobe consolidation.

Investigations show:

Haemoglobin 12.1 g/dl(11.5-16.0)

White cell count 12.2 x 10⁹/L (4-11)

Platelets 209 x 10⁹/L (150-400)

Serum Sodium 135 mmol/l (135-146)

Serum Potassium 4.4 mmol/l (3.5-5)

Creatinine 125 µmol/l (79-118)

Urea 10.2 mmol/l (2.5-6.7)

Glucose 5.4 mmol/l (4.5-5.6)

Chest x ray Right lower lobe pneumonia

Which of the following features is consistent with scoring a point on the CURB criteria?

- 1- BP 135/82
- 2- Creatinine 125
- 3- Respiratory rate 22
- 4- Urea 10.2
- 5- White cell count 12.2

Answer & Comments

Answer: 4- Urea 10.2

The CURB criteria are based on the presence of

Confusion

Urea >7

Respiratory rate >30/min

BP <90/60 mmHg.

The utility of CURB scoring is in determining possible patients who may be discharged from hospital and those who are at greatest risk with respect to mortality.

High scores can be used to determine which patients should be managed on the respiratory HDU or who needs ITU support.

[Q: 3025] OnExamination 2012 - Respiratory

A 19-year-old student has been brought to the emergency department by his housemates.

He was diagnosed with chicken pox a few days earlier by a GP, told to go home, rest, stay well hydrated and take regular paracetamol. He now presents with a dry cough and increasing shortness of breath.

On examination he looks unwell and is pyrexial 37.8°C. He has a widespread rash consistent with chicken pox. His BP is 132/72 mmHg and his respiratory rate is 29. There is

wheeze on auscultation of the chest. Saturation is 92% on air.

Investigations show:

Haemoglobin 13.8 g/dl(13.5-18)

White cell count $8.1 \times 10^9/L$ (4-10)

Platelets $191 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 4.0 mmol/l (3.5-5)

Creatinine 100 $\mu\text{mol/l}$ (60-120)

CXR Bilateral pneumonitis

Which of the following is the most appropriate management?

- 1- IV aciclovir
- 2- IV penicillin
- 3- Oral aciclovir
- 4- Supportive care with fluids and paracetamol
- 5- Varicella zoster immunoglobulin

Answer & Comments

Answer: 1- IV aciclovir

This man has chicken pox pneumonitis which has a high level of morbidity and mortality, occurring more commonly in older children and young adults where it may occur in 20% of individuals.

Treatment of choice is initial IV aciclovir.

Varicella zoster immunoglobulin is only recommended as post exposure prophylaxis in patients at significant risk from varicella infection.

Secondary bacterial infection may occur.

[Q: 3026] OnExamination 2012 - Respiratory

A 42-year-old lady re-attends the chest clinic following investigations that have confirmed a diagnosis of sarcoidosis.

Which of the following would be a poor prognostic sign?

- 1- Caucasian race
- 2- Current smoker
- 3- Erythema nodosum
- 4- Lupus pernio
- 5- Markedly elevated serum ACE level

Answer & Comments

Answer: 4- Lupus pernio

The American Thoracic Society has produced a statement on the prognostic indicators associated with sarcoidosis.

Lupus pernio is a chronic raised indurated (hardened) lesion of the skin, often purplish in color, and is associated with sarcoid. It is noted to be an adverse prognostic factor.

Other adverse prognostic factors include;

Age of onset >40 years

Afro-Caribbean or Afro-American race

Cardiac involvement

Chronic hypercalcaemia

Nasal mucosal involvement

Neurosarcoidosis

Progressive pulmonary sarcoidosis.

[Q: 3027] OnExamination 2012 - Respiratory

A 58-year-old man is admitted with bacterial pneumonia following influenza. He initially improved but subsequently developed a cough productive of purulent blood-stained sputum and swinging fevers.

On examination he is pyrexial 38.4°C, has a BP of 110/70 mmHg and a pulse of 105. You can hear coarse crackles throughout both lung fields, decreased air entry and a stony dull percussion note at the right base.

Investigations reveal

Haemoglobin 12.8 g/dl(13.5-18)

White cell count 13.1 x 10⁹/L (4-10)

Platelets 192 x 10⁹/L (150-400)

Sodium 141 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 145 µmol/l (60-120)

CXR Bilateral basal consolidation, right-sided pleural effusion

Which of the following is the next appropriate investigation?

- 1- Blood cultures
- 2- CT thorax
- 3- Diagnostic pleural fluid sampling
- 4- MRI thorax
- 5- Ultrasound thorax

Answer & Comments

Answer: 3- Diagnostic pleural fluid sampling

The BTS guidelines on pleural infection contain a clear flow chart which recommends diagnostic pleural fluid sampling as the next most appropriate investigation.

If it is not possible to obtain fluid, then drainage under ultrasound should be attempted.

If pus is obtained then the pH should be recorded and the sample sent for culture.

If pus is not obtained then the respiratory team should be involved prior to the insertion of a chest drain.

[Q: 3028] OnExamination 2012 - Respiratory

A 50-year-old lady presented to the Emergency department with cough and dyspnoea for the past two days.

She was previously well. She smokes 20 cigarettes per day.

She has a temperature of 38.3°C and is agitated and confused. Her pulse is 110/min and her blood pressure is 88/60 mmHg. Her oxygen saturation is 89% on air and she has a respiratory rate of 40/min.

Chest x ray shows left basal consolidation.

Results show:

Sodium 143 mmol/L(137-144)

Potassium 3.8 mmol/L(3.5-4.9)

Urea 9.2 mmol/L(2.5-7.5)

Creatinine 85 µmol/L(60-110)

Her CURB score is documented and she is admitted to hospital with severe pneumonia.

Which of the following would count towards her CURB score?

- 1- Consolidation on chest x ray
- 2- Oxygen saturation
- 3- Peak expiratory flow rate
- 4- Raised blood urea
- 5- Temperature

Answer & Comments

Answer: 4- Raised blood urea

The CURB score is calculated by assessment of core adverse prognostic features which are used in assessment of severity of pneumonia.

Two from four features indicate a severe pneumonia and hospital admission is advised.

The CURB score is calculated using:

1. Confusion abbreviated mental test score less than 8.
2. Urea more than 7 mmol/l.
3. Respiratory rate more than 30/min.
4. Blood pressure; systolic BP less than 90 or diastolic BP less than 60 mmHg.

[Q: 3029] OnExamination 2012 - Respiratory

Which of the following is not employed in the laboratory diagnosis of respiratory viral infections?

- 1- ELISA
- 2- Haemagglutination
- 3- Immunofluorescence
- 4- Single radial haemolysis (SRH)
- 5- Tissue culture

Answer & Comments

Answer: 4- Single radial haemolysis (SRH)

Rapid antigen detection kits utilising direct immunofluorescence are used to demonstrate:

Respiratory syncytial virus (RSV)

Influenza

Parainfluenza and

Adenovirus

in respiratory secretions.

Respiratory viruses can be grown in various cell lines, for example, HeLa cells or fibroblasts.

Influenza is a haemagglutinating virus as red cells stick to the infected cells after addition to the culture.

Enzyme-linked immunosorbent assay (ELISA) is used to look for antibodies in acute and convalescent sera.

The SRH test is used to screen for rubella antibodies in pregnant women.

[Q: 3030] OnExamination 2012 - Respiratory

An 18-year-old woman presents with red, tender lumps on her shins and arthralgia.

Chest x ray shows bilateral hilar lymphadenopathy and clear lung fields. A clinical diagnosis of sarcoidosis is made.

Which one of the following is the most appropriate management plan?

- 1- 24 hour urinary calcium measurement
- 2- Follow up appointment with chest x ray in three months
- 3- Mediastinoscopy and lymph node biopsy
- 4- Skin biopsy
- 5- Thoracic CT scan

Answer & Comments

Answer: 2- Follow up appointment with chest x ray in three months

This is also known as Löfgren's syndrome (a benign form of sarcoidosis).

The presentation of erythema nodosum-arthropathy-bilateral hilar lymphadenopathy syndrome is so characteristic that histological diagnosis is not necessary.

The prognosis is excellent with less than 10% having persistent disease.

With less characteristic presentations, positive biopsies are needed.

Mediastinoscopy is the method of choice for anterior mediastinal nodes.

[Q: 3031] OnExamination 2012 - Respiratory

A 58-year-old man is admitted to the Emergency department some five days after becoming unwell with influenza.

Over the past 48 hours he has become progressively more short of breath with a cough productive of purulent and bloody sputum.

On examination he is pyrexial 38.6, his BP is 95/60 mmHg, pulse is 95 and regular. His

saturations are 93% on air. There are signs of extensive right sided consolidation.

Investigations show:

Haemoglobin 13.4 g/dl(13.5-17.7)

White cell count $14.9 \times 10^9/L$ (4-11)

Platelets $191 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 132 micromol/l (79-118)

CXR - Right sided consolidation with evidence of cavitation.

Which of the following is the most appropriate therapy?

- 1- Benzylpenicillin
- 2- Ciprofloxacin
- 3- Clarithromycin
- 4- Doxycycline
- 5- Flucloxacillin

Answer & Comments

Answer: 5- Flucloxacillin

The history of pneumonia with cavitation post-influenza raises the possibility of staphylococcal pneumonia; as such flucloxacillin is the most appropriate answer. In patients with a history of alcoholism, Klebsiella in particular may be an alternative diagnosis.

Benzylpenicillin would be a consideration if Pneumococcus is the most likely diagnosis, with clarithromycin an alternative in those who are penicillin allergic.

Doxycycline may be considered in Chlamydia pneumoniae.

[Q: 3032] OnExamination 2012 - Respiratory

A 21-year-old student presents to the Emergency department with fever, cough and

significant wheeze; he has returned a few days ago from a long trip working with an aid organisation in East Asia.

On examination he is pyrexial 37.8°C, his pulse is 88 and regular and his BP is 110/72 mmHg. He has marked wheeze on auscultation of his chest. There is an urticarial rash on his buttocks and he has some abdominal discomfort.

Investigations show:

Haemoglobin 12.3 g/dl(11.5-16.0)

White cell count $7.1 \times 10^9/L$ (4-11)

Eosinophils $0.8 \times 10^9/L$ (0.04 - 0.4)

Platelets $182 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 102 $\mu\text{mol/l}$ (79-118)

Which of the following is the most likely cause?

- 1- Enterobius
- 2- Diphyllbothrium
- 3- Schistosomiasis
- 4- Strongyloides
- 5- Taenia

Answer & Comments

Answer: 4- Strongyloides

Strongyloides is associated with a larval stage, the pulmonary migration of which can lead to symptoms of bronchospasm with severe wheeze and shortness of breath. This is also known as Loeffler's syndrome.

Tapeworms, of which Diphyllbothrium and Taenia are species, result in predominantly gastrointestinal symptoms such as abdominal pain and intermittent obstruction.

Schistosomiasis can manifest as a cough, but symptoms are not usually as severe as those seen here.

Enterobius is a species of threadworm which does not have a larval stage which affects the lungs.

[Q: 3033] OnExamination 2012 - Respiratory

A 69-year-old lady is seen in chest clinic for her increasing breathlessness. She has a significant smoking history having smoked 40/day for 50 years.

When questioned she reports that she notices that she has to walk slower than her husband and friends due to her breathlessness. When walking at her own pace she often stops every 300 m, again due to breathlessness.

What grade of dyspnoea does she have according to the MRC dyspnoea scale?

- 1- Grade I
- 2- Grade II
- 3- Grade III
- 4- Grade IV
- 5- Grade V

Answer & Comments

Answer: 3- Grade III

One of the main symptoms of chronic obstructive pulmonary disease (COPD) is breathlessness and the MRC dyspnoea scale should be used to quantify this.

GradeDegree of breathlessness related to activities

1Not troubled by breathlessness except on strenuous exercise

2Short of breath when hurrying or walking up a slight hill

3 Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath when walking at own pace

4Stops for breath after walking about 100 metres or after a few minutes on level ground

5 Too breathless to leave the house, or breathless when dressing or undressing

Adapted from Fletcher CM, Elmes PC, Fairbairn MB et al. (1959) The significance of respiratory symptoms and the diagnosis of chronic bronchitis in a working population. British Medical Journal 2: 257-66.

[Q: 3034] OnExamination 2012 - Respiratory

Which of the following conditions may result in pulmonary hypertension (PH) by causing pulmonary venous hypertension?

- 1- Acute respiratory distress syndrome (ARDS)
- 2- Chronic obstructive airways disease (COAD)
- 3- Chronic thromboembolism
- 4- Interstitial lung disease (ILD)
- 5- Veno-occlusive disease

Answer & Comments

Answer: 5- Veno-occlusive disease

Pulmonary venous hypertension with increased left atrial pressure is most commonly caused by left ventricular dysfunction as in congestive cardiac failure, which causes an elevation in PA pressure by increased back-pressure through the lungs.

Other causes of pulmonary venous hypertension include mitral stenosis or insufficient, fibrosing mediastinitis and veno-occlusive disease.

Acute or chronic thromboembolism causes PH by mechanical obstruction of the pulmonary arteries.

Respiratory disease including ILD, COAD and ARDS causing hypoxia leads to constriction of the pulmonary arteries. Any disorder resulting in hypoxia may cause PH.

[Q: 3035] OnExamination 2012 - Respiratory

A 48-year-old gentleman with moderate chronic obstructive pulmonary disease (COPD), and multiple previous presentations to the Emergency department presents with a two hour history of mild pleuritic chest pain.

He is minimally breathless, with oxygen saturations of 96% on air (he usually has saturations of 95-97%).

A chest x ray is performed and an observant CT1 recognises a 1.8 cm (18 mm) apical pneumothorax on a background of chronic changes consistent with emphysema/emphysematous changes.

Accordingly to current guidelines, what intervention should be undertaken?

- 1- Admit and treat with high flow oxygen and repeat CXR in 24 hours
- 2- Aspirate and admit for 24 hours observation
- 3- Aspirate and discharge home after 12 hours if well
- 4- Discharge with advice to return if symptoms worsen
- 5- Intercostal chest drain insertion (Seldinger technique)

Answer & Comments

Answer: 2- Aspirate and admit for 24 hours observation

This patient has a small apical pneumothorax most likely as a result of his underlying lung disease and as such can be classed as a secondary pneumothorax.

According to current BTS guidelines, if the patient is under 50, minimally breathless and the rim of air is less than 2 cm the initial intervention should be simple aspiration. Even if successful the patient should be admitted and observed for at least 24 hours.

Unlike a primary pneumothorax, a secondary pneumothorax always requires intervention.

Aspiration is less likely to be effective in a secondary pneumothorax and so if it fails or does not meet the above criteria, a chest drain needs to be inserted. The Seldinger technique using a 16G is the preferred method for this.

Blunt dissection is usually reserved for trauma cases.

Management of spontaneous pneumothorax

[Q: 3036] OnExamination 2012 - Respiratory

A 26-year-old man who works in a car body shop spray painting vehicles comes to the respiratory clinic complaining of increasing shortness of breath and wheeze. He says that he is fine at the end of a weekend off, and particularly well when he goes on holiday, but steadily gets worsening symptoms from Monday to Friday.

He is a non-smoker who has no significant past medical history. On examination his BP is 125/75 mmHg, his pulse is 75 and regular. He has significant bilateral wheeze and a non-productive cough.

Investigations show

Haemoglobin 14.9 g/dl (13.5-17.7)

White cell count $5.6 \times 10^9/L$ (4-11)

Platelets $192 \times 10^9/L$ (150-400)

Serum Sodium 140 mmol/l (135-146)

Serum Potassium 4.0 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

PEFR 245 l/min

Which of the following is the best initial way to elucidate any link between the workplace and possible asthma?

- 1- Bronchial hyper-responsiveness testing
- 2- Radioallergosorbent testing

- 3- Serial peak flow measurement including weekdays and weekends
- 4- Skin testing
- 5- Specific bronchial provocation testing

Answer & Comments

Answer: 3- Serial peak flow measurement including weekdays and weekends

The most obvious initial investigation is to get the patient to keep a peak flow diary with multiple measurements at different times in the day and involving both weekdays and weekends.

Detailed pulmonary function tests, and radioallergosorbent (RAST) or skin testing may also be part of the work up, but the peak flow diary is the best way to establish the temporal relationship between asthma and the paint spraying. Once the specific trigger is identified he may either need to be given special equipment to protect him from exposure, or moved to a different role.

Simply treating his asthma with appropriate medication is not appropriate.

[Q: 3037] OnExamination 2012 - Respiratory

A 45-year-old man presents to the clinic for review.

Over the past few months he has suffered increasing night sweats, fatigue, weight loss and a chronic cough. In addition he has presented to his GP with bilateral parotid swelling and red, painful eyes on three occasions in the past year. Most recently he has suffered a weakness of the left side of his face.

On examination his BP is 135/75 mmHg, pulse is 80 and regular, there are bilateral scattered crackles on auscultation of the chest and bilateral parotid swellings. He has a left lower motor neurone seventh nerve palsy.

Investigations show:

Haemoglobin 14.1 g/dl(13.5-17.7)

White cell count $6.2 \times 10^9/L$ (4-11)

Platelets $312 \times 10^9/L$ (150-400)

Sodium 139 mmol/l (135-146)

Potassium 3.8 mmol/l (3.5-5)

Creatinine 110 micromol/l (79-118)

Which of the following is the most likely diagnosis?

- 1- Felty's syndrome
- 2- Heerfordt's syndrome
- 3- Lofgren's syndrome
- 4- Meig's syndrome
- 5- Turner's syndrome

Answer & Comments

Answer: 2- Heerfordt's syndrome

Felty's syndrome is the association of rheumatoid arthritis and hypersplenism.

Lofgren's syndrome is the association of erythema nodosum and arthritis.

Meig's syndrome is the association of a benign ovarian tumour and pleural effusion.

Turner's is the syndrome associated with the XO sex chromosome type.

[Q: 3038] OnExamination 2012 - Respiratory

An 18-year-old female is admitted with a depression of her conscious level.

Arterial blood gas analysis revealed:

pH 7.26 (7.36-7.44)

pO₂ 12.1 kPa (11.3-12.6)

pCO₂ 3.9 kPa (4.7-6.0)

Standard bicarbonate 14.7 mmol/L (20-28)

Which one of the following would account for these results?

- 1- Analytical error
- 2- Metabolic acidosis
- 3- Persistent vomiting
- 4- Respiratory acidosis
- 5- Respiratory alkalosis

Answer & Comments

Answer: 2- Metabolic acidosis

This patient has a metabolic acidosis with an effort at respiratory compensation as reflected by elevated pO₂ and reduced pCO₂.

This could be due to poisoning or a condition such as diabetic ketoacidosis.

Vomiting would cause a metabolic alkalosis.

[Q: 3039] OnExamination 2012 - Respiratory

A 16-year-old girl presents with an acute exacerbation of asthma.

On examination her respiratory rate was 30 per minute, her heart rate was 120 beats per minute and a peak expiratory flow rate (PEFR) was 30% of the predicted value.

Her blood gas analysis on air shows:

paO₂ 9 kPa(11.3-12.6)

paCO₂ 3.5 kPa(4.7-6.0)

After the administration of oxygen and corticosteroids what is the most appropriate next step in management?

- 1- Intravenous aminophylline
- 2- Intravenous salbutamol
- 3- Ipratropium bromide via oxygen-driven nebuliser
- 4- Salbutamol via oxygen-driven nebuliser
- 5- Salmeterol via breath-actuated inhaler

Answer & Comments

Answer: 4- Salbutamol via oxygen-driven nebuliser

This patient has severe asthma as revealed by the low PEFr, low P02 and signs.

The next stage in the management is the administration of nebulised beta 2 agonists with supplementation of high flow oxygen (minimum of 6 l/minute). Beta 2 agonists can be administered in 15-30 minute intervals if required.

Intravenous therapy with beta 2 agonists should only be used if inhaled therapies cannot be reliably administered.

[Q: 3040] OnExamination 2012 - Respiratory

A 50-year-old male presented with acute respiratory failure during an episode of acute pancreatitis and was thought to have developed adult respiratory distress syndrome (ARDS).

Which of the following would support a diagnosis of ARDS?

- 1- High protein pulmonary oedema
- 2- High pulmonary capillary wedge pressure
- 3- Hypercapnia
- 4- Increased lung compliance
- 5- Normal chest x ray

Answer & Comments

Answer: 1- High protein pulmonary oedema

ARDS is characterised by:

Hypoxaemia

Reduced lung compliance

Pulmonary hypertension

Pulmonary infiltrates on the chest x ray.

There is damage to the capillary and endothelial cell linings resulting in oedema and leakage of proteins and cells into the interstitial and alveolar spaces at normal pulmonary capillary hydrostatic pressures.

Wedge pressure, unlike the high pressures seen with left ventricular failure and pulmonary oedema, is often normal.

Hypercapnia, often a late feature of ARDS, does not distinguish from any other cause of type 2 respiratory failure.

[Q: 3041] OnExamination 2012 - Respiratory

Which of the following is true concerning whooping cough (pertussis)?

- 1- Is a greater threat to children during the second six months of life, after maternal antibody has declined, than during the first six months
- 2- Is associated with convulsions less frequently than is the case with other febrile conditions
- 3- Is characteristically associated with a polymorph leucocytosis
- 4- May lead to hemiplegia
- 5- Rapidly resolves with antibiotic treatment

Answer & Comments

Answer: 4- May lead to hemiplegia

Whooping cough (pertussis) is caused by the bacterium *Bordetella pertussis*.

B. pertussis is a very small gram-negative aerobic coccobacillus that appears singly or in pairs.

Infection is characterised by paroxysms of coughing.

Lymphocytosis is typically found.

Hemiplegia is a recognised effect of severe whooping cough.

The pertussis vaccine is estimated to be 63% to 94% effective in the diphtheria-pertussis-tetanus (DPT) shot.

[Q: 3042] OnExamination 2012 - Respiratory

A 67-year-old patient with a history of COPD is being assessed by the community COPD team for his suitability for treatment at home (under the Hospital at Home scheme) for his latest exacerbation.

Which of the following is a contraindication to Hospital at Home (HaH) treatment?

- 1- Acute changes on a chest x ray
- 2- Dementia
- 3- Increasing age
- 4- Long term oxygen therapy (LTOT)
- 5- Longer duration of COPD

Answer & Comments

Answer: 1- Acute changes on a chest x ray

A specific subtype of intermediate care is Hospital at Home (HaH), where active treatment is provided by healthcare professionals in the patient's home for a condition that otherwise would require hospital care.

BTS has issued recommendations as to whom HaH should be offered. It recommends that HaH should not be offered in the below instances;

Impaired level of consciousness

Acute confusion

pH 7.35, if arterial blood gases have been measured

Acute changes on chest radiograph

Concomitant medical problem requiring inpatient stay

Insufficient social support, no telephone, residence geographically removed from hospital

New hypoxaemia (SpO₂ 90%) - a contraindication if oxygen cannot be provided at home.

Although factors such as increasing age and duration of COPD have been shown in studies to identify those at increased risk of relapse, they have only a moderate sensitivity and specificity, and hence are not included in the listed contraindications.

[Q: 3043] OnExamination 2012 - Respiratory

A 47-year-old woman with a history of asthma is referred with deteriorating symptoms from a lower respiratory tract infection.

She has been laid up in bed for the whole of the previous week with influenza, but most recently, as her upper respiratory symptoms have improved, she has begun to develop a cough productive of purulent blood stained sputum and has severe right lower pleuritic chest pain.

On examination she is pyrexial 38.2°C, her BP is 105/65 mmHg, and her pulse is 108. There is right-sided consolidation.

Investigations show

Hb 12.9 g/dl (13.5-18)

WCC 15.2 x 10⁹/L (4-10)

PLT 213 x 10⁹/L (150-400)

Na 135 mmol/l (134-143)

K 4.5 mmol/l (3.5-5)

Cr 139 µmol/l (60-120)

CRP 210 mg/l (<10)

CXR Extensive right lower lobe consolidation with cavitation

Which of the following is the most likely infective organism?

- 1- Chlamydia

- 2- Klebsiella
- 3- Legionella
- 4- Staphylococcus
- 5- Streptococcus

Answer & Comments

Answer: 4- Staphylococcus

This woman has pre-existing chest disease and has suffered a severe bout of influenza. Staphylococcal pneumonia is known to cause cavitation, and occurs with increased frequency after influenza. As such it is the most likely cause here.

Klebsiella pneumonia occurs with increased frequency in alcoholics. This may be due to a specific deficiency in bacterial immunity related to alcohol abuse.

Flucloxacillin or IV vancomycin may be reasonable antibiotic choices in this case.

[Q: 3044] OnExamination 2012 - Respiratory

A 15-year-old girl was admitted eight hours after taking an overdose of diazepam 30 mg and methotrexate 400 mg which her mother had been prescribed for rheumatoid arthritis.

On examination her Glasgow coma score (GCS) was 10.

Which one of the following is the most appropriate immediate action?

- 1- Assess respiratory function
- 2- Perform immediate gastric lavage
- 3- Treat with activated charcoal
- 4- Treat with folinic acid
- 5- Urgent liver function tests

Answer & Comments

Answer: 1- Assess respiratory function

Her depressed GCS is due to the diazepam and the most appropriate initial treatment would be to assess her respiratory function prior to giving her folinic acid.

Methotrexate overdose is extremely rare but potentially fatal with hepatotoxicity and renal toxicity reported.

The most appropriate treatment is folinic acid (leucovorin).

It is too late to consider gastric lavage or activated charcoal.

[Q: 3045] OnExamination 2012 - Respiratory

A new publication describes a new test for cystic fibrosis.

You want to know what proportion of patients with cystic fibrosis would be correctly identified by this new test.

Which one of the following values would identify this?

- 1- Accuracy
- 2- Negative predictive value
- 3- Positive predictive value
- 4- Sensitivity
- 5- Specificity

Answer & Comments

Answer: 4- Sensitivity

The proportion of patients with the disease who would be identified by the new test is the sensitivity. This refers to the proportion with the disease who truly have cystic fibrosis and are identified as such by the test.

Positive predictive value refers to the percent of people having a positive test who actually have the disease interpreted in conjunction to the prevalence of the disease (true positives/true positives+false positives).

[Q: 3046] OnExamination 2012 - Respiratory

The morphological appearance of Pneumocystis carinii infection in the lung is best characterised as which one of the following?

- 1- A bronchopneumonia with abscess formation
- 2- A haemorrhagic and necrotising pneumonia
- 3- An acute respiratory distress syndrome (ARDS) with widespread hyaline membrane formation
- 4- An interstitial pneumonitis with foamy intra-alveolar exudate
- 5- An organising bronchopneumonia

Answer & Comments

Answer: 4- An interstitial pneumonitis with foamy intra-alveolar exudate

Pneumocystis carinii (PC) is a fungal organism.

In PC pneumonia, the organism is confined to the alveolar space of the lung and produces debris and cysts in the alveolar space with interstitial infiltration of lymphocytes and plasma cells.

As a result, it can cause profound disturbance of oxygen exchange and fatal hypoxaemia if left untreated.

[Q: 3047] OnExamination 2012 - Respiratory

A 48-year-old woman presented with shortness of breath, cough with heavy sputum production, and a low grade fever. She has smoked 20 cigarettes per day for 30 years.

Her arterial blood gases revealed:

pH 7.4 (7.36-7.44)

pCO₂ 45 mmHg (35-45)

pO₂ 78 mmHg (90-110)

What is the most likely diagnosis?

- 1- Bronchial asthma
- 2- Chronic bronchitis
- 3- Cryptogenic fibrosing alveolitis
- 4- Paraneoplastic syndrome
- 5- Pulmonary embolism

Answer & Comments

Answer: 2- Chronic bronchitis

Together with emphysema, chronic bronchitis is part of the spectrum of respiratory disease described as chronic obstructive pulmonary disease (COPD). Chronic bronchitis itself is defined as chronic cough and sputum production for at least three months of two consecutive years in the absence of other disease which could explain these symptoms.

This lady has an extensive smoking history, making her at risk of COPD, and although we are not given a timeframe for her symptoms the significant hypoxia associated with borderline hypercapnia (i.e. borderline type 2 respiratory failure) are suggestive of a diagnosis of chronic bronchitis.

If the diagnosis were bronchial asthma you would expect wheeze to be a predominant symptom. In addition, these patients typically have a low PaCO₂ secondary to hyperventilation.

Cryptogenic fibrosing alveolitis presents with a dry cough and breathlessness, and blood gas analysis typically shows type 1 respiratory failure with hypoxaemia and a normal or low pCO₂.

The symptoms of a pulmonary embolus can be varied, but the low-grade fever and productive cough make bronchitis a more likely diagnosis.

The history does not fit with a paraneoplastic syndrome.

[Q: 3048] OnExamination 2012 - Respiratory

A 23-year-old man is taking part in an expedition in the Andes and has recently ascended to above 3000 metres. Even accounting for sleeping in a small expedition tent he has a very poor night's sleep and begins to vomit profusely with a severe headache.

On examination his BP is 145/72 mmHg, pulse is 85 and regular. There are bilateral crackles on auscultation of his chest.

You are the expedition doctor and suspect he is suffering from acute altitude sickness.

Which of the following is the optimal next step?

- 1- Acetazolamide
- 2- Descent
- 3- Dexamethasone
- 4- Furosemide
- 5- Oxygen therapy

Answer & Comments

Answer: 2- Descent

The headache, nausea and vomiting is thought to relate to cerebral oedema, which occurs because of changes in cerebral blood flow at altitude. Optimal treatment is clearly to descend to lower altitude if possible. If individuals have previously suffered altitude sickness they may be able to avoid it in future by slowing the rate of ascent to altitude or treatment with acetazolamide.

Acetazolamide, dexamethasone and hyperbaric oxygen may all impact on symptoms of altitude sickness, but they are subsidiary to descent in their degree of efficacy.

Acetazolamide is preferred to loop diuretics such as furosemide.

[Q: 3049] OnExamination 2012 - Respiratory

Which one of the following statements is true of chronic obstructive pulmonary disease (COPD)?

- 1- Patients show at least a 15% improvement in the FEV₁ after nebulised bronchodilator
- 2- Inhaled corticosteroid usage does not improve long-term prognosis
- 3- Breathlessness is uncommon until the FEV₁ falls to approximately 50% of predicted
- 4- Emphysema is associated with increased transfer factor
- 5- In advanced cases there is reduced pulmonary vascular resistance

Answer & Comments

Answer: 2- Inhaled corticosteroid usage does not improve long-term prognosis

A. This level of improvement would mean the presence of asthma.

B. High dose inhaled steroids have been shown (ISOLDE) to improve quality of life and reduce hospitalisation rates by reducing the number of exacerbations, but they do not slow the rate of decline of FEV₁ (hence do not affect prognosis).

C. Breathlessness is common but subjective. Mild chronic obstructive pulmonary disease (COPD) (60-79% predicted FEV₁) is often unknown to their GP. Those with moderate COPD (40-59% predicted) are seen intermittently seen by GP, whilst those with severe disease (less than 40% predicted) have frequent hospital and GP visits.

D. It is asthma which is associated with normal or increased transfer factor. COPD is associated with decreased transfer factor.

E. COPD is associated with secondary pulmonary hypertension.

[Q: 3050] OnExamination 2012 - Respiratory

Which of the following is true of cystic fibrosis?

- 1- A sweat chloride concentration of 80 mmol/l is diagnostic
- 2- Is an autosomal dominant condition.
- 3- Is associated with mental retardation.
- 4- Is due to mutation of CFTR gene on chromosome 17
- 5- Median survival rate is 10 to 15 years.

Answer & Comments

Answer: 1- A sweat chloride concentration of 80 mmol/l is diagnostic

Cystic fibrosis is an autosomal recessive condition and is due to mutation of CFTR gene on chromosome 7.

Twenty per cent develop bronchopulmonary aspergillosis.

The median survival rate is 25 to 35 years and is currently improving.

[Q: 3051] OnExamination 2012 - Respiratory

With which of the following is obstructive sleep apnoea characteristically associated?

- 1- Hypersomnolence
- 2- Impotence
- 3- Insomnia
- 4- Macrognathia
- 5- Polydipsia

Answer & Comments

Answer: 1- Hypersomnolence

The dominant symptom is hypersomnolence (sleepiness).

Other more common symptoms include

Apparent personality changes

Witnessed apnoeas

True nocturnal polyuria.

Reduced libido is less common.

Sleep apnoea may be associated with

Acromegaly

Myxoedema

Obesity

Micrognathia/retrognathia.

[Q: 3052] OnExamination 2012 - Respiratory

A 45-year-old seaman presents with cough and fever.

A CXR demonstrates a cavitating lung lesion.

Which of the following is the most likely cause?

- 1- Amoebiasis
- 2- Brucellosis
- 3- Histoplasmosis
- 4- Sarcoidosis
- 5- Syphilis

Answer & Comments

Answer: 3- Histoplasmosis

Histoplasmosis normally evolves slowly over as long as 20 years but may follow a more rapid course in the immunocompromised (seamen may be more prone to sexually transmitted diseases such as HIV).

Amoebic abscesses can develop in the right lower lobe following transdiaphragmatic spread from amoebic liver abscess (tender hepatomegaly, malaise, spiking temperature).

Amoebiasis is also a fresh water pathogen.

[Q: 3053] OnExamination 2012 - Respiratory

A 35-year-old woman presents with a three month history of arthralgia, increasing fatigue and occasional nose bleeds. More recently she has become short of breath and has had two episodes of haemoptysis.

On investigation she is found to have acute kidney injury, with a creatinine of 656 $\mu\text{mol/L}$ and urine dipstick is positive for blood and protein. A chest x ray is performed which shows several nodules throughout both lung fields.

The treating physician suspects Wegener's granulomatosis.

Which of the below autoantibodies are most associated with this condition?

- 1- Anti-dsDNA
- 2- Anti-GBM
- 3- MPO-ANCA
- 4- p-ANCA
- 5- PR3-ANCA

Answer & Comments

Answer: 5- PR3-ANCA

Anti-neutrophil cytoplasmic antibodies (ANCA) are diagnostic markers for vasculitis, although they may not be pathological. They are characterised by neutrophil staining; cytoplasmic staining uptake (c-ANCA) and peri-nuclear (p-ANCA).

These are largely synonymous with PR3-ANCA (targeting peroxidase-3) and MPO-ANCA (targeting myeloperoxidase).

PR3-ANCA has 60-90% sensitivity and more than 90% specificity for Wegener's granulomatosis.

Churg-Strauss and microscopic polyangiitis are more commonly associated with MPO-ANCA or p-ANCA, although may be positive for PR3 ANCA also.

Goodpasture's is associated with anti-glomerular basement membrane antibody (anti-GBM).

Systemic lupus erythematosus (SLE) is associated with anti-dsDNA antibodies.

[Q: 3054] OnExamination 2012 - Respiratory

A 72-year-old man is referred to the lung cancer MDM by his respiratory physician for discussion of treatment following his recent diagnosis with stage IIIa non-small cell lung cancer (NSCLC).

According to NICE guidelines, what is the first choice treatment in eligible patients with this stage of NSCLC?

- 1- Chemotherapy
- 2- Chemotherapy and radical radiotherapy
- 3- Radical radiotherapy
- 4- Surgery
- 5- Symptomatic management including palliative RT

Answer & Comments

Answer: 2- Chemotherapy and radical radiotherapy

Sequential chemo-radiotherapy should be offered to patients with stage III NSCLC who are not suitable for surgery but are eligible for radical radiotherapy.

Surgery alone should be the first line option for patients with stage I and II provided there are no medical contraindications and they have adequate lung function.

Radical radiotherapy is indicated for patients with stage I, II or III NSCLC who have good performance status (WHO 0, 1) and whose disease can be encompassed in a radiotherapy treatment volume without undue risk of normal tissue damage.

Symptomatic treatment should be considered as the most appropriate management in patients with stage IV disease and poor WHO performance status.

The NICE guidelines are just that, and treatment decisions will be based on clinical status and performance status of the patient.

NICE guidelines.

[Q: 3055] OnExamination 2012 - Respiratory

A 65-year-old obese man presents with night time sweats, nocturia, poor concentration and day time somnolence.

To which of the following conditions does this diagnosis predispose?

- 1- Hypoglycaemia
- 2- Hypotension
- 3- Insulin sensitivity
- 4- Osteoporosis
- 5- Sudden death

Answer & Comments

Answer: 5- Sudden death

This history is typical of sleep apnoea.

Sleep apnoea is an independent risk factor for stroke (and death from all causes), and is associated with hypertension, impaired glucose tolerance (IGT), and insulin resistance.

NEJM. 2005. 353. 2070-2073

[Q: 3056] OnExamination 2012 - Respiratory

A 52-year-old woman who complains of exertional breathlessness presents to the clinic as she is desperate to stop smoking. She has had a number of unsuccessful attempts to stop smoking over the years and has tried nicotine patches.

Which of the following would be an appropriate choice to assist in her attempts at smoking cessation?

- 1- Acupuncture
- 2- Hypnotism
- 3- Nicotine gum
- 4- Nortriptyline
- 5- Varenicline

Answer & Comments

Answer: 5- Varenicline

Varenicline (Champix) is an oral anti-smoking agent with dual action, reducing the craving for cigarettes and also making the smoking of cigarettes less pleasurable. ASH, Action on Smoking and Health have released guidance on its use. It appears to be effective and safe with the main side effect being nausea.

Varenicline appears to be more effective in clinical trials than either bupropion or placebo and is prescribed for 12 weeks in the first instance with further 12 week course if craving still persists.

[Q: 3057] OnExamination 2012 - Respiratory

A 52-year-old man presented to the Emergency Unit with a two day history of increasing breathlessness, productive cough and fever. He was previously fit and well with no past history of note. He was not a cigarette smoker.

On examination he was febrile, temperature was 38.5°C, pulse rate 100/ minute and regular, blood pressure 120/80 mmHg and respiratory rate of 25 breaths/ minute.

Investigations:

Hb 15.0 g/dl (13.0-18.0)

WBC 18.5 x 10⁹/L (4-11)

Platelets 350 x 10⁹/L (150-400)

Serum sodium 137 mmol/l (137-144)

Serum potassium 4.5 mmol/l (3.5-4.9)

Serum urea 5.1 mmol/l (2.5-7.5)

Serum creatinine 110 µmol/l (60-110)

paO₂ (Arterial blood, on air) 9.0 kPa (11.3-12.6)

Chest x ray showed right middle lobe consolidation

What is the most appropriate choice of antibiotics?

- 1- Amoxicillin
- 2- Amoxicillin plus erythromycin
- 3- Ceftriaxone
- 4- Ciprofloxacin
- 5- Co-amoxiclav

Answer & Comments

Answer: 1- Amoxicillin

This gentleman has a community acquired pneumonia

Community acquired pneumonia (CAP) is defined as symptoms and signs consistent with an acute lower respiratory tract infection associated with new radiological signs consistent with consolidation, not explained by another cause.

The severity of each case of CAP should be assessed using the CURB-65 tool in conjunction with clinical judgement.

Patients score 1 point for each of:

- Confusion
- Respiratory rate > 30/min
- Blood pressure: systolic <90 or diastolic < 60 mmHg
- Age > 65 years

A CURB-65 score of 0 or 1 (as in this case) are at low risk of death, and can be treated at home if the social circumstances are compatible. A score of 2 usually indicates

inpatient treatment is required, but hospital-supervised outpatient treatment can be considered. Patients who have a CURB-65 score of 3 or more are at high risk of death. Those with scores of 4 and 5 should be considered for treatment in a critical care unit (HMU, ITU).

In the majority of patients CAP should be confirmed by chest radiography before the commencement of antibiotics. However, if patients are critically unwell they should be treated for the presumptive diagnosis. Antibiotic treatment should be initiated within 4 hours of presentation.

Low severity CAP (CURB 0-1) can be treated with amoxicillin 500mg TDS PO. CURB 2 CAP should be treated with amoxicillin 500mg-1g TDS and clarithromycin 500mg TDS. Alternatives are available if patients are allergic to any of the above combinations. High severity CAP (CURB 3-5) should be treated as soon as possible with co-amoxiclav 1.2g TDS and clarithromycin 500mg BD.

The oral route is recommended in those with low and moderate severity CAP. Patients treated with parenteral antibiotics initially should be switched to an oral regimen once clinical improvement is seen and the patients has been afebrile for at least 24 hours. For most patients with uncomplicated CAP 7 days of antibiotic treatment is recommended. For those with high severity pneumonia where an organism has not been identified, 7-10 days treatment is indicated and extended to 14-21 days where clinically needed.

[Q: 3058] OnExamination 2012 - Respiratory

A 70-year-old man presented with increasing dyspnoea.

In his history he had suffered a myocardial infarction two years previously which had been complicated by ventricular arrhythmias.

At admission his oxygen saturations were 85% on air and a chest x ray revealed bilateral patchy infiltration of both lung fields with a cardiothoracic ratio of 20/30 cm.

Which of the following drugs that he has been prescribed is most likely to explain these findings?

- 1- Amiodarone
- 2- Aspirin
- 3- Atorvastatin
- 4- Furosemide
- 5- Ramipril

Answer & Comments

Answer: 1- Amiodarone

This patient has desaturation with patchy infiltration on CXR suggesting a diagnosis of amiodarone-induced lung disease.

Usually the presentation is insidious and the disorder associated with the cumulative dose.

Treatment depends on withdrawing amiodarone and initiation of steroid therapy.

Differential diagnosis is any lymphangitis/pneumonitis but high resolution CT can help by demonstration of radio-dense plaques, etc.

[Q: 3059] OnExamination 2012 - Respiratory

A 74-year-old man is admitted to the Emergency department after collapsing in church.

On reviewing his notes you see this is the third time that it has happened in the past eight months, and each time it is when he is dressed in a suit. There is a past medical history of hypertension but nil else of note. According to a bystander his pulse seemed very slow at the time of the collapse.

On examination his BP is 135/70 mmHg, his pulse is 80 and regular. General physical review is unremarkable.

Investigations show:

Haemoglobin 13.2 g/dl (13.5-17.7)

White cell count $7.8 \times 10^9/L$ (4-11)

Platelets $282 \times 10^9/L$ (150-400)

Sodium 135 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 123 $\mu\text{mol/l}$ (79-118)

ECG - Old inferior myocardial infarction

CXR - Unremarkable

Which of the following is the most appropriate next investigation?

- 1- Ambulatory ECG monitoring
- 2- CT head
- 3- EEG
- 4- Exercise test
- 5- Tilt table test

Answer & Comments

Answer: 1- Ambulatory ECG monitoring

The history of collapse raises the possibility of a rhythm disturbance, although the fact he collapses only when wearing his suit raises the possibility of carotid sinus hypersensitivity, with attacks related to the wearing of a tight collar. The first step when each of these diagnoses is considered is the same however, with ambulatory ECG monitoring to discharge the risk of arrhythmia.

A TIA or fit is unlikely, as his recovery period is short, and we have the collateral history of slow pulse which comes from a bystander. As such, EEG or CT head are not next step investigations.

A tilt table test is the definitive investigation for carotid sinus hypersensitivity, but would only be considered after other cardiac causes have been excluded.

Whilst myocardial ischaemia is a possibility, an exercise test would not necessarily be the next investigation of choice.

[Q: 3060] OnExamination 2012 - Respiratory

A 72-year-old lifelong smoker presents with progressive dyspnoea on exertion. He has a chronic, non-productive cough.

On examination he is thin, breathing with pursed lips, respiratory rate 25/min, with mild wheezing on chest auscultation.

Investigations show

FEV₁ 0.8 L

FVC 1.6 L

pH 7.35

paCO₂ 6kPa (45mmHg)

paO₂ 7.2kPa (55mmHg)

What is the predominant mechanism of the airflow limitation in this gentleman?

- 1- Bronchospasm
- 2- Foreign body obstruction
- 3- Increased airways resistance
- 4- Loss of elastic recoil
- 5- Mucus plugging in the small airways

Answer & Comments

Answer: 4- Loss of elastic recoil

This patient has typical features of chronic obstructive airways disease (COAD) with a predominant emphysematous element.

The pathology is centrilobular or panacinar with loss of elastic tissue.

[Q: 3061] OnExamination 2012 - Respiratory

A 65-year-old woman, has smoked 50 cigarettes a day for 40 years.

She has had increasing dyspnoea for the several years, but no cough. A chest x ray shows increased lung size along with flattening of the diaphragms, consistent with emphysema.

Over the next several years she develops worsening peripheral oedema. Her vital signs show T 36.7 C, P 80, RR 15, and BP 120/80 mm Hg.

Which of the following cardiac findings is most likely to be present?

- 1- Constrictive pericarditis
- 2- Left ventricular (LV) aneurysm
- 3- Mitral valve stenosis
- 4- Non-bacterial thrombotic endocarditis
- 5- Right ventricular hypertrophy

Answer & Comments

Answer: 5- Right ventricular hypertrophy

The most likely finding in this woman is pulmonary hypertension as a result of emphysema secondary to long term cigarette smoking.

Peripheral oedema is due to right heart dilatation and failure.

Mitral stenosis is not supported by the history.

Constrictive pericarditis could be caused by a lung malignancy in this patient, but again, there is no suggestion of this in the history.

Constrictive pericarditis would be characterised by soft heart sounds, a diastolic "pericardial knock", and gross signs of right heart failure.

LV aneurysm would lead to symptoms and signs of left heart failure and again is not the most likely finding suggested by the history.

[Q: 3062] OnExamination 2012 - Respiratory

Which of the following recognised associations is correct?

- 1- Bronchopulmonary aspergillosis and wheezing
- 2- Lung carcinoids and pleural effusion
- 3- Pneumoconiosis and clubbing
- 4- Pulmonary embolus and left bundle branch block
- 5- Pulmonary fibrosis and hypercapnia

Answer & Comments

Answer: 1- Bronchopulmonary aspergillosis and wheezing

Pulmonary fibrosis is associated with type 1 respiratory failure, which is associated with ventilation/perfusion mismatch.

Allergic bronchopulmonary aspergillosis is caused by *Aspergillus fumigatus*, which can present with asthma and eosinophilia.

[Q: 3063] OnExamination 2012 - Respiratory

A 22-year-old woman recently returned from a holiday in Malta was admitted with a three day history of fever, generalised lymphadenopathy and a macular rash over the trunk and legs.

Which of the following is the most likely diagnosis?

- 1- Actinomycosis
- 2- Familial Mediterranean fever
- 3- Infectious mononucleosis
- 4- Sarcoidosis
- 5- Tuberculosis

Answer & Comments

Answer: 3- Infectious mononucleosis

Infectious mononucleosis occurs most commonly in adolescents and young adults.

Clinical features occur after a two to five week incubation period and include:

Fever

Malaise

Pharyngitis

Lymphadenopathy.

Rashes occur more commonly in patients who have received penicillin or ampicillin.

[Q: 3064] OnExamination 2012 - Respiratory

A 67-year-old man with severe COPD managed with tiotropium, high dose Seretide and salbutamol nebulisers comes to the clinic for review. He tells you that he is increasingly short of breath and finds it very difficult to do anything at all around the house, and asks about long term oxygen therapy (LTOT).

Which of the following features would permit long term home oxygen therapy to be initiated under current NICE guidance?

- 1- FEV₁ 45% of predicted
- 2- paCO₂ 5.8kPa repeated whilst stable
- 3- paO₂ 7.1kPa repeated whilst stable
- 4- pH 7.35
- 5- Two or more exacerbations in the past year

Answer & Comments

Answer: 3- PaO₂ 7.1kPa repeated whilst stable

NICE guidance is very clear with respect to requirements for home oxygen therapy.

Offer LTOT to people with PaO₂ less than 7.3 kPa when stable, or greater than 7.3 and less than 8 kPa when stable and with secondary polycythaemia, peripheral oedema, nocturnal hypoxaemia or pulmonary hypertension.

Measurements should be repeated whilst stable at least three weeks apart.

NICE guidance does not allow home O₂ therapy based on pH, CO₂, FEV₁ or exacerbation criteria.

Apart from criteria based on PaO₂ alone, secondary features of COPD such as polycythaemia, peripheral oedema, nocturnal hypoxia or pulmonary hypertension are included.

[Q: 3065] OnExamination 2012 - Respiratory

You are reviewing use of non-invasive ventilation (NIV) by the acute medical admissions team as part of a hospital audit.

According to the latest BTS guidelines, which of the following features on history, examination or investigations would be a criterion for considering NIPPV?

- 1- pH 7.42
- 2- pCO₂ 6.5 kPa
- 3- Na 139 mmol/l
- 4- Respiratory rate 32
- 5- pO₂ 9.2 kPa

Answer & Comments

Answer: 2- pCO₂ 6.5 kPa

pH<7.35 is considered acidotic, therefore pH 7.42 is not a consideration for NIV. Hypoxia per se, and respiratory rate are not considered reasons for instigating NIV.

According to the guidelines, maximal medical therapy is:

Controlled oxygen to maintain SaO₂ 88-92%

Nebulised salbutamol 2.5-5 mg

Nebulised ipratropium 500 ?g

Prednisolone 30 mg

Antibiotic agent (when indicated).

[Q: 3066] OnExamination 2012 - Respiratory

A 57-year-old smoker presents to the Emergency department with right sided pleuritic chest pain and dyspnoea. He has no previous medical history.

His BP is 120/75 mmHg. A CXR is done and confirms a right sided pneumothorax with a rim of 2.5 cm.

What is the best plan of action?

- 1- Advise to stop smoking and discharge
- 2- Aspirate
- 3- Check arterial blood gases and only if hypoxic aspirate
- 4- Insert a chest drain
- 5- Repeat the CXR in two hours

Answer & Comments

Answer: 4- Insert a chest drain

If patient is more than 50 years of age, he is treated as for secondary pneumothorax.

Therefore age is very important: in a young person, aspiration would be the treatment of choice.

Please read the guidelines carefully:

[Q: 3067] OnExamination 2012 - Respiratory

According to current guidelines, which of the below is the recommended duration of warfarin therapy in a patient recently diagnosed with their first pulmonary embolism (PE) in the presence of temporary risk factors?

- 1- 4-6 weeks
- 2- 3 months
- 3- 6 months
- 4- 12 months
- 5- Lifelong

Answer & Comments

Answer: 1- 4-6 weeks

According to current British Thoracic Society guidelines, anticoagulation with warfarin for four to six weeks is sufficient when a PE has occurred in the presence of a temporary risk factor.

BTS recommends three months anticoagulation in a patient with their first idiopathic PE, although in America the treatment is usually extended to six months.

There is insufficient evidence, according to BTS, accurately to recommend duration of treatment in the event of recurrent venous thromboembolism (VTE) or variable risk factors, and it is often left to clinical judgement.

There is no evidence to suggest that the duration of treatment should be influenced by severity of PE or the presence of a co-existing DVT.

Management of suspected acute pulmonary embolism

[Q: 3068] OnExamination 2012 - Respiratory

A 62-year-old man with non-small cell lung cancer is being considered for surgical resection.

Which of the following would be regarded as a contraindication to surgery?

- 1- FEV₁ 1.2L
- 2- Horner's syndrome
- 3- Hypercalcaemia
- 4- Peripheral neuropathy
- 5- Previous history of myocardial infarction

Answer & Comments

Answer: 1- FEV₁ 1.2L

Non-small cell lung cancer (NSCLC) is a heterogeneous aggregate of at least three distinct histologies of lung cancer including epidermoid or squamous carcinoma, adenocarcinoma, and large cell carcinoma. These histologies are often classified together because, when localised, all have the potential for cure with surgical resection.

Resection should be performed in the absence of contraindications, namely,

Evidence of spread beyond the lung

Endobronchial location of tumour too close to the trachea, and

Other serious conditions such as poor pulmonary function.

As a general guideline, most patients with a preoperative forced expiratory volume in one second of greater than 2.5 L are able to tolerate pneumonectomy. With a forced expiratory volume in one second of less than 1.5 L, patients are not considered candidates for surgery.

Hypercalcaemia and peripheral neuropathy may be paraneoplastic phenomena and are not of themselves contraindications to surgery. Nor would a previous myocardial infarction be a contraindication to surgery.

Horner's does not signify spread beyond the chest.

The British Thoracic Society published guidelines on selection of patients for lung cancer surgery in thorax in 2001.

[Q: 3069] OnExamination 2012 - Respiratory

A 49-year-old man with a long history of alcoholism presents with cough, haemoptysis and pleuritic chest pain. He has had night sweats and 10 kg weight loss in the last three months. On chest x ray there is a subtle nodular pattern throughout the lung.

He underwent a transbronchial biopsy which showed multinucleated giant cells, epithelioid cells and necrotic debris.

Which of the following is the most likely diagnosis?

- 1- Aspergillosis
- 2- Pneumocystis carinii pneumonia
- 3- Small cell carcinoma
- 4- Squamous cell carcinoma
- 5- Tuberculosis

Answer & Comments

Answer: 5- Tuberculosis

The history, in itself, of night sweats, haemoptysis and the miliary shadowing in an alcoholic is highly suggestive of TB.

The giant cells, part of granulomas would again be supportive of TB.

[Q: 3070] OnExamination 2012 - Respiratory

A 16-year-old girl presented with acute Guillain-Barré syndrome and has developed worsening proximal muscle weakness.

Which one of the following tests should be used to monitor her respiratory function?

- 1- Arterial blood gas
- 2- Chest expansion
- 3- FEV₁/FVC ratio
- 4- Peak expiratory flow rate
- 5- Vital capacity

Answer & Comments

Answer: 5- Vital capacity

Diaphragmatic weakness occurs in one-third of patients with patients with Guillain-Barré syndrome and involvement of the neck muscles, tongue and palate leads to further respiratory compromise.

Respiratory muscle function is best monitored by frequent assessment of the vital capacity. The other investigations are of limited use.

[Q: 3071] OnExamination 2012 - Respiratory

A 35-year-old man presents after three months of chronic cough with purulent sputum and shortness of breath on exertion.

He gives a history of at least two sinus or bronchial infections per year requiring treatment with antibiotics. He also says he and his wife have been unable to have children. He smokes 15 cigarettes per day.

Examination is normal except for some wheezing and an area of focal crackles at the left lung base. Chest x ray shows patchy infiltrates at both bases.

Investigations revealed

FEV₁ 2.0 L

FVC 2.7 L

pH 7.38

paCO₂ 40 mmHg

paO₂ 82 mmHg

What is the most likely diagnosis?

- 1- Alpha-1-antitrypsin (antiprotease) deficiency
- 2- Asthma
- 3- Cystic fibrosis
- 4- Hypogammaglobulinaemia
- 5- Immotile cilia syndrome

Answer & Comments

Answer: 5- Immotile cilia syndrome

Immotile cilia syndrome, also known as primary ciliary dyskinesia and includes Kartagener's syndrome, is an inherited condition where the cilia lining the airways fail to function or function ineffectively.

A defect in the dynein molecule causes the cilia either totally to cease to function or to function ineffectively.

Kartagener's syndrome is a subset of patients that account for about half of all people with immotile cilia syndrome.

Other associated conditions of immotile cilia syndrome are

Male infertility

Congenital heart defects

Deafness

Hydrocephalus.

Cystic fibrosis is unlikely to present at this age.

Infertility is not typically associated with hypogammaglobulinaemia.

[Q: 3072] OnExamination 2012 - Respiratory

A 63-year-old woman presents with a five day history of progressive shortness of breath. Her family brought her in because she was increasingly sleepy during the last 24 hours.

She was diagnosed with chronic obstructive pulmonary disease (COPD) three years ago and has a FEV₁ less than 50% of predicted. She has an oxygen concentrator at home.

Examination revealed depressed consciousness and a respiratory rate of 24 with shallow breaths. There were decreased breath sounds with minimal air movement.

If an arterial blood gas on room air were to be performed which of the following results would you expect?

- 1- pH 7.16 paCO₂ 70 paO₂ 50 HCO₃ 24
- 2- pH 7.24 paCO₂ 80 paO₂ 55 HCO₃ 30
- 3- pH 7.32 paCO₂ 60 paO₂ 70 HCO₃ 30
- 4- pH 7.41 paCO₂ 40 paO₂ 50 HCO₃ 24
- 5- pH 7.48 paCO₂ 30 paO₂ 85 HCO₃ 24

Answer & Comments

Answer: 2- pH 7.24 paCO₂ 80 paO₂ 55 HCO₃ 30

This patient's presentation suggests that she has developed acute carbon dioxide retention and would be expected to have a low pH, low pO₂, high pCO₂ and a high HCO₃ because she has longstanding COPD.

Consequently the last three options really do not fit.

The first option has a pretty much normal bicarbonate and this would be expected to be much higher in chronic COPD (as there would be metabolic alkalosis to compensate for the respiratory acidosis). Therefore this leaves the best fit as option B.

[Q: 3073] OnExamination 2012 - Respiratory

A 20-year-old male student is assessed for shortness of breath that occurs whilst running. He has no other symptoms and does not smoke. Examination, full blood count, and chest x ray are normal.

Which of the following is most likely to be helpful in confirming the suspected diagnosis?

- 1- Arterial blood gas studies before and after exercise
- 2- Determination of lung volumes and diffusing capacity
- 3- Measurement of venous blood lactate before and after exercise
- 4- Spirometry before and after administration of bronchodilators
- 5- Spirometry before and after exercise

Answer & Comments

Answer: 5- Spirometry before and after exercise

The most likely diagnosis is exercise-induced asthma and this would be best diagnosed with

spirometry before and after exercise, where a typical obstructive pattern may be displayed following exercise.

No abnormalities may be displayed following bronchodilator therapy if it is true exercise-induced asthma. Similarly lung volumes and diffusion capacity are likely to be unaffected.

Blood gas analysis would be relatively unhelpful in this scenario as little change in partial pressures would be expected.

This patient does not have a glycogen storage disease where weakness rather than shortness of breath is more typical, hence lactate measurements are unnecessary.

[Q: 3074] OnExamination 2012 - Respiratory

Which of the following statements regarding cryptogenic fibrosing alveolitis (CFA) is correct?

- 1- Active inflammation may be suggested by a CTscan
- 2- 80% of patients initially respond well to immunosuppression
- 3- Lung volumes show a raised residual volume/total lung capacity ratio
- 4- Peak flow rate is a good guide to severity
- 5- Peak incidence seen in the fourth decade

Answer & Comments

Answer: 1- Active inflammation may be suggested by a CTscan

A. The presence of a predominantly ground glass appearance is also an independent predictor of survival.

B. About 50% of patients have an improvement in their symptoms with steroids and 25% have improved lung function.

C. Residual volume (RV) increases with airways obstruction; total lung capacity (TLC) reduces with restrictive disorders like CFA. A

raised RV/TLC ratio suggests a combination of airways obstruction and restrictive defect not just CFA as mentioned in this question.

D. Peak flow measure airway obstruction. CFA is characterised by a restrictive defect on lung function testing.

E. Peak incidence is in the sixth decade.

[Q: 3075] OnExamination 2012 - Respiratory

A 25-year-old woman is referred to the respiratory clinic as two of the children in her kindergarten class have recently been diagnosed with tuberculosis.

Clinical examination reveals a BP of 125/72 mmHg, pulse is 70 and regular. Her chest is clear. A Mantoux test results in a reaction measured at 17 mm.

Which of the following is the correct way to manage her?

- 1- Arrange for a bronchoscopy
- 2- Arrange for sputum samples to be collected
- 3- Reassure her she is immune to TB and requires no further action
- 4- Start anti-tuberculous chemotherapy
- 5- Vaccinate her with BCG

Answer & Comments

Answer: 2- Arrange for sputum samples to be collected

The Mantoux test replaced the Heaf test in 2005 in the UK. One of its uses is for patients who have had close contact with a person known to have tuberculosis.

The injection site should be reviewed 48-72 hours following intradermal inoculation of tuberculin. The left forearm is typically used. Only the induration, not surrounding erythema, is used in the measurement and the longest diameter is measured in millimetres:

- Less than 6mm: negative test, previously unvaccinated individuals can be given the BCG (within three months) provided there are no contraindications
- More than 6mm but less than 15mm: hypersensitive to tuberculin protein (may be due to previous TB infection, BCG, or atypical mycobacteria). Patients are not given the BCG if part of an immunisation programme. However, in other contexts (e.g. immigrant screening and contact tracing), further investigation should and follow-up may be indicated.
- More than 15mm: strongly hypertensive to tuberculin, suggestive of TB infection. Patients should be referred for further investigation and treatment

The reaction to tuberculin protein may be suppressed by viral infections, live viral vaccines, sarcoidosis, corticosteroids, immunosuppression, severe tuberculous disease and poor nutrition.

Bronchoscopy would not usually be considered unless other investigations have proved inconclusive.

Anti-tuberculous therapy is commenced only after infection is confirmed, and patients with a positive Mantoux do not require BCG vaccination.

[Q: 3076] OnExamination 2012 - Respiratory

A 30-year-old patient attends the hospital's asthma clinic.

She has had asthma since childhood and her control is variable. At present she is on low dose beclomethasone inhaler, and is using her salbutamol inhaler at least eight times a day. She has recently been commenced on a long acting beta 2 agonist and noticed some improvement in her symptoms.

On questioning she also reports her asthma symptoms are waking her at night once or twice a week.

On examination she is not acutely dyspnoeic and her oxygen saturations through pulse oximetry are 98% on air. She has scattered wheeze throughout her lung fields on auscultation.

Accordingly to the current British Thoracic Society guidelines what adjustments should be made to her asthma regime?

- 1- Add a leukotriene receptor antagonist
- 2- Add oral corticosteroids
- 3- Arrange admission to medical assessment unit
- 4- Increase the dose of the inhaled corticosteroid
- 5- Stop the long acting beta 2 agonist

Answer & Comments

Answer: 4- Increase the dose of the inhaled corticosteroid

According to the BTS guidelines, the patient needs adjustment in step 3 to achieve greater symptom control.

According to the guidelines a long acting B2 agonist (LABA) should be initiated first, which has already happened.

If the patient has good response to this then a LABA should be continued. If there is a partial response, then continue LABA and the increased the dose of the inhaled steroid. If there is no response to LABA, then it should be stopped, the dose of inhaled corticosteroids increased, and then possibly a trial of a leukotriene receptor antagonist or SR theophylline.

Oral corticosteroids form step 5.

BTS guidelines for asthma management can be found at:

<http://www.brit-thoracic.org.uk/Portals/0/Guidelines/AsthmaGuidelines/sign101%20Sept%202011.pdf>

[Q: 3077] OnExamination 2012 - Respiratory

Based on the current British Thoracic Society (BTS) guidelines, *which is the first line empiric antibiotic therapy regime for patients with moderate severity community acquired pneumonia (CAP) based on a CURB-65 score of 2?*

- 1- Amoxicillin 500 mg TDS
- 2- Amoxicillin 1 g TDS and clarithromycin 500 mg BD
- 3- Benzylpenicillin 1.2 g QDS and levofloxacin 500 mg BD
- 4- Co-amoxiclav 1.2 g TDS and clarithromycin 500 mg BD
- 5- Doxycycline 200 mg loading dose and then 100 mg OD

Answer & Comments

Answer: 2- Amoxicillin 1 g TDS and clarithromycin 500 mg BD

Community acquired pneumonia (CAP) is defined as symptoms and signs consistent with an acute lower respiratory tract infection associated with new radiological signs consistent with consolidation, not explained by another cause.

The severity of each case of CAP should be assessed using the CURB-65 tool in conjunction with clinical judgement. Patients score 1 point for each of:

- Confusion
- Respiratory rate > 30/min
- Blood pressure: systolic <90 or diastolic < 60 mmHg
- Age > 65years

A CURB-65 score of 0 or 1 are at low risk of death, and can be treated at home if the social circumstances are compatible. A score of 2 usually indicates inpatient treatment is required, but hospital-supervised outpatient treatment can be considered. Patients who have a CURB-65 score of 3 or more are at high risk of death. Those with scores of 4 and 5 should be considered for treatment in a critical care unit (HMU, ITU).

In the majority of patients CAP should be confirmed by chest radiography before the commencement of antibiotics. However, if patients are critically unwell they should be treated for the presumptive diagnosis. Antibiotic treatment should be initiated within 4 hours of presentation.

Low severity CAP (CURB 0-1) can be treated with amoxicillin 500mg TDS PO. CURB 2 CAP should be treated with amoxicillin 500mg-1g TDS and clarithromycin 500mg TDS. Alternatives are available if patients are allergic to any of the above combinations. High severity CAP (CURB 3-5) should be treated as soon as possible with co-amoxiclav 1.2g TDS and clarithromycin 500mg BD.

The oral route is recommended in those with low and moderate severity CAP. Patients treated with parenteral antibiotics initially should be switched to an oral regimen once clinical improvement is seen and the patients has been afebrile for at least 24 hours. For most patients with uncomplicated CAP 7 days of antibiotic treatment is recommended. For those with high severity pneumonia where an organism has not been identified, 7-10 days treatment is indicated and extended to 14-21 days where clinically needed.

[Q: 3078] OnExamination 2012 - Respiratory

A 21-year-old woman presents to the Emergency department with a one hour history of shortness of breath, and chest tightness.

The symptoms occurred acutely, and she has suffered identical attacks previously which are increasing in frequency.

Her GP has treated her with a salbutamol inhaler, although she has not had any formal pulmonary function testing. Usage of her salbutamol inhaler has not helped her shortness of breath.

On examination she is distressed and chest examination shows vesicular breath sounds with an elevated respiratory rate. Oxygen saturation is 98% on air which is sustained on exertion.

Chest x ray is normal and arterial blood gas analysis shows:

pH 7.52 (7.35-7.45)

pCO₂ 2.2 kPa(4.7-7.45)

pO₂ 18 kPa (increased from 15)(10.0-13.0)

HCO₃ 25(22.0 - 30.0)

Which of the following would be your diagnosis?

- 1- Acute asthma attack (mild)
- 2- Hyperventilation (psychogenic)
- 3- Pulmonary embolism
- 4- Respiratory muscle disease
- 5- Volume depletion

Answer & Comments

Answer: 2- Hyperventilation (psychogenic)

This patient's blood gas sample shows a respiratory alkalosis, as demonstrated by the raised pH, low pCO₂ and normal bicarbonate.

The most likely cause therefore is hyperventilation, possibly due to high levels of anxiety.

Other causes include pain, altitude and excessive mechanical ventilation.

In acute asthma, the pCO₂ may be low, as the patient has an elevated respiratory rate, however in this instance there should be a

history of the condition, clinical signs or a reduced pO₂.

Pulmonary embolism can also present similarly, but in the absence of any disclosed risk factors, a normal pO₂ and oxygen saturations maintained on exertion, this becomes less likely.

Respiratory muscle disease typically results in a respiratory acidosis.

Volume depletion (from a number of causes) would typically cause a metabolic alkalosis.

[Q: 3079] OnExamination 2012 - Respiratory

A 42-year-old man presented to his GP with increasing shortness of breath.

He has been previously noted to have a raised ALT, which was put down by the GP to a problem with excessive drinking. He was given a salbutamol inhaler which brought about some relief, particularly when he was playing football with his friends, but most recently he has had to give up due to reduced exercise tolerance.

On examination his BP is 142/82 mmHg. He is thin with a BMI of 19 kg/m², and his chest looks hyper-expanded. There is scattered wheeze throughout both lung fields. Abdominal examination is normal.

Investigations show

Hb 12.9 g/dl(13.5-18)

WCC 8.1 x 10⁹/L (4-10)

PLT 203 x 10⁹/L (150-400)

Na 138 mmol/l (134-143)

K 4.4 mmol/l (3.5-5)

Cr 110 µmol/l (60-120)

FEV₁ 70% of predicted

FEV₁/FVC60% of predicted

Which of the following is the most likely diagnosis?

- 1- Alpha-1 antitrypsin deficiency
- 2- Asthma
- 3- Chronic bronchitis
- 4- Idiopathic pulmonary fibrosis
- 5- Primary biliary cirrhosis

Answer & Comments

Answer: 1- Alpha-1 antitrypsin deficiency

This man's abnormal alanine aminotransferase (ALT) raises the possibility of accelerated liver disease, characterised by accelerated hepatic fibrosis/cirrhosis as a result of alpha-1 antitrypsin deficiency.

Additionally, his lung function tests fit the diagnosis of chronic obstructive pulmonary disease (COPD). As such, emphysema is the most likely underlying respiratory diagnosis. It is likely that he has the PiMS, PiMZ or PiSS genotype.

Replacement alpha-1 antitrypsin is available, although its cost effectiveness and long term clinical effectiveness is yet to be established.

[Q: 3080] OnExamination 2012 - Respiratory

A 31-year-old female with pulmonary hypertension complains of increasing shortness of breath. She is 36 weeks gestation in her first pregnancy.

Which of the following statements is correct?

- 1- Chest x ray is contraindicated
- 2- Elevated D-dimers rule out PE
- 3- Enoxaparin dose should be halved in pregnancy
- 4- Nifedipine is contraindicated in pregnancy
- 5- Risk of maternal mortality in patients with pulmonary hypertension is 30%

Answer & Comments

Answer: 5- Risk of maternal mortality in patients with pulmonary hypertension is 30%

A chest x ray is not contraindicated in pregnancy.

Any pregnant female presenting with shortness of breath should be reviewed by a senior member of the obstetric team, advice which comes from the RCOG.

Enoxaparin dose should be doubled in pregnancy, due to the increased glomerular filtration rate (GFR) in pregnancy.

D-dimers are always elevated in pregnancy, and are not helpful as a diagnostic aid, unless of course they are low (very unlikely), thereby making the clinical suspicion of pulmonary embolism (PE) low.

Nifedipine is not contraindicated in pregnancy, but should be used judiciously.

Labetalol and methyldopa are the commonest antihypertensives used in pregnancy.

Patients with pulmonary hypertension have a high mortality of at least 30% - some authors put it at 50% - seemingly highest immediately after delivery.

[Q: 3081] OnExamination 2012 - Respiratory

A 42-year-old restaurateur who has been human immunodeficiency virus (HIV) positive for eight years presents with progressive shortness of breath on exercise.

The chest x ray shows normal lung fields with prominent pulmonary arteries. Pulse oximetry demonstrates that he desaturates on exercise.

Which is the most likely diagnosis?

- 1- Anaemia
- 2- Intracardiac shunt across an atrial septal defect
- 3- Pneumocystis jiroveci pneumonia (PCP)

4- Primary pulmonary hypertension

5- Pulmonary embolic disease

Answer & Comments

Answer: 3- Pneumocystis jiroveci pneumonia (PCP)

The history of dyspnoea and desaturation on exercise in an HIV-positive patient would suggest PCP.

Pneumocystis jiroveci is a eukaryotic microorganism. In immunosuppressed patients it can cause a pneumonia, which is most recognised in patients with AIDS but can also be seen in those with organ transplants or when undergoing chemotherapy. A CD4 count of less than 200 is associated with significant risk. In Europe, the USA and Australia P. jiroveci pneumonia in HIV-positive patients is seen largely in those unaware of their HIV status. Unfortunately it is a major cause of death in Africa, especially in children. Previously it was thought that disease was caused by reactivation of latent infection acquired in childhood, but de novo infection is increasingly recognised.

The pneumonia caused by P. jiroveci is potentially severe and fatal in immunosuppressed patients. Clinically it presents with several weeks' history of dry cough, fever and dyspnoea. Examination findings are often subtle, but include tachypnoea, tachycardia, cyanosis and fine respiratory crackles. Typically, patients desaturate markedly on exertion. There may be reduced transfer factor, vital capacity and total lung capacity on spirometry. Bronchoalveolar lavage or induced sputum can be used to demonstrate the organism (open lung biopsy is gold standard, but rarely performed in clinical practice). Giemsa, Papanicolaou and Grocott's stains are used.

There are a variety of different chest radiograph findings. Typically it causes bilateral symmetrical perihilar reticular or

granular interstitial shadowing. Less often there can be asymmetric shadowing, or progression to a reticular-alveolar pattern. Occasionally lobar consolidation, nodular lesions, prominent pulmonary arteries, pneumothorax, pneumomediastinum, cysts or pneumatocoles can be seen. In patients who have been on prophylactic inhaled pentamidine the infiltrates may predominantly affect the upper lobes. A normal chest x-ray does not exclude the diagnosis. Pleural effusions and lymphadenopathy are not typical, but be aware of the possibility of multiple disease processes in an immunosuppressed patient.

If allowed to progress, P.jiroveci can disseminate via the lymphatic and haematogenous routes to affect the thyroid, liver, bone marrow, lymph nodes and spleen.

If PCP is suspected, treatment with full dose co-trimoxazole should be started as soon as possible. It should be given for 21 days in HIV-positive cases, but shorter doses can be used in other causes of immunosuppression. In patients who are intolerant or co-trimoxazole, intravenous pentamidine can be used. Some studies have shown that that corticosteroids can reduce the risk of respiratory failure, and they are therefore used in some cases.

Prophylaxis should be used in immunosuppressed patients who are at risk of developing PCP: all those with a CD4 count of <200, patients started on high dose steroids, and those on chemotherapeutic regimens associated with significant immunosuppression. Co-trimoxazole is also the first line prophylactic agent.

Pulmonary hypertension does develop with increased frequency in patients with HIV, but this is secondary rather than primary. Primary pulmonary hypertension is rare, and more commonly affects females.

Anaemia is a possibility, but the chest x-ray findings and history of HIV make PCP more likely.

Atrial septal defects with intracardiac shunting can eventually lead to hypoxia (Eisenmenger syndrome), but this is less likely than PCP in patients known to be HIV-positive.

This history may also be consistent with multiple small pulmonary emboli, but again this is less likely than PCP in an HIV-positive patient.

[Q: 3082] OnExamination 2012 - Respiratory

A 62-year-old man is found to have squamous cell carcinoma of the lung after being investigated for haemoptysis.

Which one of the following would be a contraindication to surgical resection?

- 1- Finger clubbing
- 2- Hypercalcaemia
- 3- Hypertrophic pulmonary osteoarthropathy
- 4- Pleural effusion
- 5- Superior vena cava obstruction

Answer & Comments

Answer: 5- Superior vena cava obstruction

Superior vena cava obstruction (SVCO) interrupts venous return from the head, arms and thorax to the right atrium resulting in facial swelling, stridor, cough, breathlessness, hoarseness, headache, etc. It was first described by William Hunter in 1757 in a case of syphilitic aortic aneurysm but these days the commonest cause is malignancy and in particular bronchial carcinoma and lymphoma.

Treatment is of the underlying condition, chemotherapy for small cell lung cancer and lymphoma and radiotherapy for non-small cell lung cancer. Sometimes patients require

stenting of the SVCO for symptomatic relief prior to more definitive treatment.

Pleural effusions are a contraindication to surgery if they are malignant but effusions in patients with bronchial carcinoma may be reactive.

Absolute contraindications for surgery include:

- Patient refusal
- Metastases

Relative contraindications include:

- Cell type: small cell carcinoma are usually inoperable
- Poor respiratory reserve: $FEV_1 > 1.2l$ is necessary for lobectomy, and $> 1.8l$ for pneumonectomy
- Raised $PaCO_2$ is a contraindication for surgery
- Other disease - especially myocardial
- Mediastinal involvement
- Age - in patients over 70, surgery is usually inadvisable because the benefits are outweighed by operative morbidity and mortality

[Q: 3083] OnExamination 2012 - Respiratory

A 70-year-old male presents with haemoptysis.

Bronchoscopy reveals a tumour in the proximal right main bronchus.

Which of the following is a contraindication to radical radiotherapy?

- 1- Adenocarcinoma
- 2- FEV_1 of 25% predicted
- 3- Involvement of the pulmonary artery
- 4- Ischaemic heart disease
- 5- Superior vena caval obstruction

Answer & Comments

Answer: 2- FEV₁ of 25% predicted

Patients with potentially operable tumours that are either too unfit for surgery or refuse surgery may be suitable for radical radiotherapy, that is, radiotherapy with intention to cure using doses of at least 60 Gy.

Using continuous hyperfractionated accelerated radiotherapy (CHART) can improve two year survival significantly from 20% to 29% compared with conventional radiotherapy (Saunders M et al. Lancet 1997 350: 161-165).

Contraindications are tumours larger than 4 cm and poor pulmonary function (generally taken as FEV₁ less than 50% predicted).

[Q: 3084] OnExamination 2012 - Respiratory

A 36-year-old woman presents with dyspnoea, cough and fever.

Crackles are heard on auscultation of the lungs. Circulating precipitans to *Micropolyspora faeni* are positive.

Which of the following is the most likely diagnosis?

- 1- Allergic bronchopulmonary aspergillosis
- 2- Brucellosis
- 3- Farmer's lung
- 4- Malt worker's lung
- 5- Pigeon fancier's lung

Answer & Comments

Answer: 3- Farmer's lung

Spores of *Micropolyspora faeni* found in moldy hay/straw are responsible for farmer's lung.

[Q: 3085] OnExamination 2012 - Respiratory

A 40-year-old worker presents with wheezing and breathlessness which seem to improve over weekends and holiday periods when he is not working.

To which of the following is he most likely to be exposed at work?

- 1- *Aspergillus clavatus*
- 2- Avian bloom
- 3- Exposure to spores of *Actinomyces*
- 4- Platinum salts
- 5- Work in the silver industry

Answer & Comments

Answer: 4- Platinum salts

Disinfectants and preservatives including

Glutaraldehyde

Chlorhexidine and

Formaldehyde

can cause occupational asthma.

Metals causing occupational asthma include

Isocyanate cobalt

Aluminium

Chrome

Manganese

Nickel

Zinc and

Platinum.

Exposure to

Actinomyces (farmer's lung, mushroom worker's lung)

Avian bloom (bird fancier's lung) and

Aspergillus clavatus (malt worker's lung)

cause extrinsic allergic alveolitis.

[Q: 3086] OnExamination 2012 - Respiratory

A 28-year-old man who works on a local mushroom farm comes to the clinic with increased shortness of breath. In addition to feeling increasingly short of breath, he has suffered intermittent fevers and sweats over the past few months.

On examination his BP is 135/72 mmHg, pulse is 72 and regular. There are fine inspiratory crackles at both bases on auscultation of his chest.

Investigations show:

Haemoglobin 13.5 g/dl(13.5-17.7)

White cell count $9.3 \times 10^9/L$ (4-11)

Platelets $204 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 116 $\mu\text{mol/l}$ (79-118)

CXR - Diffuse interstitial shadowing.

Spirometry - mixed restrictive / obstructive picture.

Which of the following is the most appropriate course of action for the longer term?

- 1- Change of job plan
- 2- Inhaled anticholinergics
- 3- Inhaled high dose Seretide
- 4- Oral prednisolone
- 5- Regular azithromycin

Answer & Comments

Answer: 1- Change of job plan

This man's occupation as a mushroom picker raises the possibility of mushroom picker's lung, a form of extrinsic allergic alveolitis. Optimal management is removal of exposure to the antigen, although in the short term a

course of oral corticosteroids is likely to be appropriate.

Inhaled anticholinergics are used in the management of chronic obstructive pulmonary disease (COPD) and are therefore not appropriate here.

Inhaled corticosteroids are not as effective as oral corticosteroids in managing subacute or chronic extrinsic allergic alveolitis, so oral prednisolone is the treatment of choice after removal of exposure to the antigen has occurred.

There is no role for antibiotic therapy.

[Q: 3087] OnExamination 2012 - Respiratory

A 22-year-old woman is brought to the Emergency room by her boyfriend. She has been suffering from a heavy cold over the past few days and now has worsening wheeze and a dry cough.

There is a past history of asthma for which she takes high dose Seretide and salbutamol prn.

On examination her BP is 135/72 mmHg, her pulse is 95 and regular. She has severe wheeze on auscultation of the chest and her respiratory rate is 34/ min.

Investigations show:

pH 7.42(7.35-7.45)

pCO₂ 4.5 kPa(4.8-6.1)

pO₂ 12.9 kPa(10-13.3)

PEFR 170ml / min (32% of predicted)

Which of the following features in her presentation is consistent with life - threatening asthma?

- 1- pH 7.42
- 2- pO₂ 12.9 kPa
- 3- pCO₂ 4.5 kPa
- 4- Peak flow 170 ml/min
- 5- Respiratory rate 34/min

Answer & Comments

Answer: 4- Peak flow 170 ml/min

Peak flow less than 33% predicted is recognised as being a feature of life-threatening asthma. Other features listed in the BTS asthma guidelines include:

SpO₂ <92%

PaO₂ <8 kPa

Normal PaCO₂ (4.6-6.0 kPa)

Silent chest

Cyanosis

Poor respiratory effort

Arrhythmia

Exhaustion

Altered conscious level.

The pH and O₂ are both in the normal range and as such are not features consistent with life-threatening asthma.

The CO₂ is slightly below the normal range, which is as expected and consistent with increased respiratory effort.

Respiratory rate >25 is a feature consistent with acute severe asthma.

[Q: 3088] OnExamination 2012 - Respiratory

A 42-year-old rough sleeper is admitted from the local park where he has been found collapsed after drinking a flask of amyl nitrate.

On examination his skin is blue grey in colour, his pulse is 100 and regular, and his BP is 105/60 mmHg. He is unconscious, respiratory examination is unremarkable apart from an increased respiratory rate of 31. The pulse oximeter reads 90%.

Which of the following is the most appropriate treatment?

1- Ascorbic acid

2- Cimetidine

3- Hyperbaric oxygen

4- Methylene blue

5- Omeprazole

Answer & Comments

Answer: 4- Methylene blue

Amyl nitrate is known to lead to oxidation of haemoglobin, particularly when ingested in large quantities.

The presentation seen here is typical of that for methaemoglobinemia, when oxidation of the Fe²⁺ component of haemoglobin to Fe³⁺ leads to a significant left shift in the oxygen dissociation curve. Methylene blue is the initial treatment of choice for methaemoglobinemia.

Ascorbic acid may be considered as a second line therapy to reduce cyanosis in methaemoglobinemia although some debate exists as to its efficacy.

Cimetidine can be used to inhibit metabolism of agents such as dapsone which are known to lead to methaemoglobinemia.

Hyperbaric oxygen is used for cases which are resistant to initial medical therapy.

Omeprazole is not thought to have a role in the treatment of the condition.

[Q: 3089] OnExamination 2012 - Respiratory

You are examining rates of *Aspergillus* positive sputum samples received at the hospital as part of an audit.

*With respect to increasing the positive test rate, which of the following is most likely to be associated with *Aspergillus* colonisation?*

1- Asthma

2- Bronchial carcinoma

3- COPD

4- Cystic fibrosis

5- HIV

Answer & Comments

Answer: 4- Cystic fibrosis

Allergic bronchopulmonary aspergillosis (ABPA) rates are lower in patients with obstructive lung disease at around 1%.

HIV patients with a known history of *P. jirovecii* are at increased risk of aspergilloma.

Bronchial carcinoma is not particularly associated with aspergillus positivity.

[Q: 3090] OnExamination 2012 - Respiratory

A 70-year-old lady with a significant smoking history is referred to the rapid access chest clinic with a three month history of weight loss, a cough and three episodes of haemoptysis. She is otherwise fit and well.

On questioning she has a troublesome cough, some mild right sided chest pain which she describes as an ache and finds she gets fatigued more easily. However she is still able to complete the majority of her usual tasks unaided, although she finds these take her longer than before.

According to the World Health Organisation (WHO) classification, what is her performance status?

1- 0

2- 1

3- 2

4- 3

5- 4

Answer & Comments

Answer: 2- 1

WHO (Zubrod) Scale Description

0 Asymptomatic

1 Symptomatic but ambulatory (can carry out light work)

2 In bed less than 50% of the day. Unable to work but can live at home with some assistance

3 In bed more than 50% of the day (unable to care for self)

4 Bedridden.

As taken from NICE lung cancer guidelines

[Q: 3091] OnExamination 2012 - Respiratory

A 48-year-old man with a history of cirrhosis comes to the respiratory clinic for a consultation because of increased shortness of breath. He smokes 10 cigarettes per day and has done so since the age of 17.

Medication of note includes propranolol, but nil else of note. On examination his BP is 112/70 mmHg, pulse is 62 and regular. Apart from signs of chronic liver disease, you also notice that he has scattered wheeze throughout both lung fields.

Investigations show:

Haemoglobin 12.9 g/dl (13.5-8)

White cell count $5.7 \times 10^9/L$ (4-10)

Platelets $203 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (134-143)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 110 $\mu\text{mol/l}$ (60-120)

Chest x ray Evidence of hyperexpanded lung fields

Pulmonary function tests FEV_1 55% of predicted

FVC 90% of predicted

Reduced KCO

Which of the following is the most likely diagnosis?

- 1- Asthma
- 2- Chronic bronchitis
- 3- Emphysema
- 4- Hypoventilation
- 5- Pulmonary fibrosis

Answer & Comments

Answer: 3- Emphysema

This man has hyperexpanded lung fields on CXR, reduced transfer factor and an FEV₁/FVC of 61%.

Despite smoking a relatively small number of cigarettes he has significant chronic obstructive pulmonary disease (COPD) on pulmonary function tests; the reduced transfer factor and CXR appearance pointing towards a predominantly emphysematous picture.

The fact that he has cirrhosis raises the possibility of alpha-1 antitrypsin deficiency as the underlying diagnosis.

[Q: 3092] OnExamination 2012 - Respiratory

What is the most likely cause of upper lobe fibrosis on chest x ray?

- 1- Ankylosing spondylitis
- 2- Cryptogenic fibrosing alveolitis
- 3- Rheumatoid arthritis
- 4- Scleroderma
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 1- Ankylosing spondylitis

Cryptogenic fibrosing alveolitis (which may be associated with connective tissue disorders) affects lower lobes and is associated with clubbing.

Extrinsic allergic alveolitis is not associated with clubbing and affects middle/upper zones.

[Q: 3093] OnExamination 2012 - Respiratory

A 16-year-old girl presents with shortness of breath and insomnia prior to an examination.

Clinical examination is normal. CXR and PEFr are normal.

Which of the following investigations is most suggestive of asthma?

- 1- Diurnal variation in PEFr >20%
- 2- Increased total IgE
- 3- Past medical history of hay fever and eczema
- 4- Positive skin prick test to common allergens
- 5- Resolution of symptoms the day after the examination

Answer & Comments

Answer: 1- Diurnal variation in PEFr >20%

The history of atopy in this patient is consistent with a diagnosis of asthma.

IgE being elevated really tells you little, other than suggesting atopy and the skin prick would suggest allergy.

The resolution of symptoms after the examination suggests anxiety.

However, diurnal variation of peak expiratory flow rate (PEFR) greater than 20% is one of the diagnostic criteria for asthma, and this is the most appropriate answer in this case.

[Q: 3094] OnExamination 2012 - Respiratory

An 18-year-old female presents with an acute exacerbation of asthma associated with a chest infection. She is unable to complete a sentence and her peak flow rate was 35% of her normal level.

She is treated with high flow oxygen, nebulised bronchodilators and oral steroids but this is associated with little change in her condition.

Which of the following treatments, given intravenously, would be the most appropriate for this patient?

- 1- Aminophylline
- 2- Augmentin
- 3- Hydrocortisone
- 4- Magnesium
- 5- Salbutamol

Answer & Comments

Answer: 4- Magnesium

This patient has acute severe asthma (PEFR 33-50% predicted/best, unable to complete sentences in one breath, respiratory rate >25 breaths/min, pulse rate >110 beats/minute).

She has not responded to initial treatment and the treatment of choice now is intravenous magnesium 1.2-2 g over 20 minutes.

*BTS guidelines on the Management of Asthma
British Thoracic Society
British Guideline on the Management of Asthma
(Guideline 101) Scottish Intercollegiate
Guidelines Network*

[Q: 3095] OnExamination 2012 - Respiratory

An 80-year-old coal miner who stopped working 16 years previously presents with deteriorating dyspnoea.

Investigations show:

FEV 11.4 L (predicted 2.5)

FVC 2.8L (predicted 3.0)

What is the most likely diagnosis?

- 1- Chronic obstructive pulmonary disease

- 2- Cryptogenic fibrosing alveolitis
- 3- Extrinsic allergic alveolitis
- 4- Silicosis
- 5- Simple pneumoconiosis

Answer & Comments

Answer: 1- Chronic obstructive pulmonary disease

Both this man's forced expiratory volume in one second (FEV₁) and forced vital capacity (FVC) are reduced. The ratio of FEV₁/FVC is also reduced at 50%. This indicates airways obstruction.

Chronic obstructive pulmonary disease (COPD) is the only condition above that results in airways obstruction.

Although no smoking history is given this may be expected and with his occupation these are risk factors for the development of COPD.

[Q: 3096] OnExamination 2012 - Respiratory

In which of the following cases of lung cancer would surgical resection of the tumour be a reasonable therapeutic option?

- 1- A 56-year-old woman with an adenocarcinoma of the right lung. CT scan shows enlarged lymph nodes in the right and left hilum. PFTs show an FEV₁ of 2.25 L. (55% predicted).
- 2- A 59-year-old man who is found at bronchoscopy to have a tumour in the right mainstem bronchus extending to within 1 cm of the carina. Pulmonary function tests (PFTs) show an FEV₁ of 2.1 litres (65% of predicted normal).
- 3- A 62-year-old lady with a small peripheral mass who has elevated liver enzymes and a computed tomography (CT) scan showing probable metastatic deposits in the liver. Lung function tests show an FEV₁ of 3.5 litres (80% of predicted normal).

- 4- A 70-year-old man with a right lower lobe tumour 2 cm in diameter with no evidence of regional adenopathy or distant spread of disease. Lung function studies show an FEV₁ of 0.8 litres (28% predicted).
- 5- A 71-year-old man with a 3 cm tumour obstructing the right lower lobe bronchus. Lung function tests show an FEV₁ of 2.1 L. (60% predicted).

Answer & Comments

Answer: 5- A 71-year-old man with a 3 cm tumour obstructing the right lower lobe bronchus. Lung function tests show an FEV₁ of 2.1 L. (60% predicted).

Surgical resection of a lung tumour may be expected to have increased success with limitation of disease spread.

In the first case with hilar LAP and reduced lung function surgery would be futile.

In the second case the tumour is too close to the bifurcation of the bronchi to permit resection.

The third case has metastatic disease and would clearly be unsuitable for surgery. Generally a positron emission tomography (PET) scan would confirm this.

The fourth case has a tumour that would be potentially resectable but lung function is too poor.

The final case has a tumour that would be suitable for resection and has good lung function.

[Q: 3097] OnExamination 2012 - Respiratory

Which of the following statements is true of the diffusion capacity of carbon monoxide?

- 1- Depends on the thickness of the alveolar wall.
- 2- Is a specific measure of lung perfusion.

- 3- Is increased in cigarette smokers.
- 4- Is increased in emphysema.
- 5- Is not affected by changes in the surface area available for gas exchange.

Answer & Comments

Answer: 1- Depends on the thickness of the alveolar wall.

By Fick's law, the volume of gas diffusing across a membrane equals $A/T \times D \times$ difference in partial pressure.

In life it is impossible to measure accurately the area (A) or the thickness (T), and these are subsumed into a single constant, the diffusion capacity for carbon monoxide.

DL = volume of transferred carbon dioxide divided by partial pressure difference between the alveoli and the capillary blood. Since the capillary blood normally does not contain carbon dioxide this term disappears.

Diffusion will be increased in healthy compared with unhealthy lungs, where the thickness is likely to increase and the surface area available for gas exchange to decrease.

VQ imbalances can indirectly interfere with carbon dioxide diffusion capacity by decreasing the available area of lung for gas exchange, but it is not a specific measure of lung perfusion.

[Q: 3098] OnExamination 2012 - Respiratory

A 25-year-old woman is admitted with a four month history of cough productive of mucoid sputum streaked with bright red blood, wheezing and diarrhoea.

Her chest and abdominal examination are normal.

Which of the following investigations is the most discriminatory?

- 1- Bronchoscopy

- 2- Chest x ray
- 3- Computed tomography (CT) of chest
- 4- Echocardiogram
- 5- Ventilation-perfusion scan

Answer & Comments

Answer: 1- Bronchoscopy

Bronchial carcinoid is a highly vascular 'cherry-like' tumour causing recurrent haemoptysis and bronchial obstruction.

It may rarely produce the classical symptoms of carcinoid syndrome such as cyanotic flushings, intestinal cramps and diarrhoea following liver metastases in 5% cases.

Bronchoscopy identifies up to 80% of carcinoid tumours in the main bronchi.

Biopsy is usually followed with brisk bleeding and should be done via rigid bronchoscopy.

[Q: 3099] OnExamination 2012 - Respiratory

A 41-year-old man with a history of nasal congestion, breathlessness, cough and wheeze presents with a left foot drop.

Which of the following is the most likely diagnosis?

- 1- Churg-Strauss syndrome
- 2- Diabetes mellitus
- 3- Polyarteritis nodosa
- 4- Pulmonary eosinophilia
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 1- Churg-Strauss syndrome

Churg-Strauss syndrome (CSS) is a rare form of small-vessel vasculitis, characterised by asthma, allergic rhinitis and prominent peripheral blood eosinophilia. Rarely, it can cause either an anterior or a posterior

ischaemic optic neuropathy, which presents with visual loss.

The most commonly involved organ is the lung, followed by the skin. CSS, however, can affect any organ system, including the cardiovascular, gastrointestinal, renal, and central nervous systems. The unifying feature of patients presenting with CSS is asthma. Vasculitis involving the peripheral nervous system is also a characteristic feature, and mononeuritis multiplex occurs in 75% of patients, which accounts for the foot drop in this case.

Vasculitis of extrapulmonary organs is largely responsible for the morbidity and mortality associated with CSS. 40-60% are associated with positive ANCA, usually pANCA/MPO.

Intravenous glucocorticoid is used for initial therapy of acute multi-organ disease, followed by oral glucocorticoid therapy, often with azathioprine as a steroid-sparing agent. Loss of vision must be treated aggressively.

Wegener's granulomatosis is a multi-organ autoimmune disease, which can be fatal. The classical triad consists of necrotising granulomatous inflammation of the respiratory tract, glomerulonephritis and a small-vessel vasculitis. A prolonged history of epistaxis or sinusitis is commonly found in Wegener's granulomatosis, which in some patients is also associated with an eosinophilia.

Hypereosinophilic syndrome is characterised by a peripheral blood eosinophil count of >1.5 for more than 6 months. Generalised symptoms are fatigue, myalgia, fever, night sweats, diarrhoea and pruritis. Other symptoms depend on the organ involved: cardiac disease causes chest pain and dyspnoea, respiratory disease presents with a dry cough.

Diabetes mellitus can cause a mononeuritis multiplex (and therefore a foot drop),

however the other features do not fit with this diagnosis.

Polyarteritis nodosa is a vasculitis which affects medium and small arteries, resulting in microaneurysms, aneurysmal rupture, thrombosis and subsequently organ ischaemia and infarction. It most commonly affects skin, joints, peripheral nerves, the gastrointestinal tract and the kidney. The lungs are usually spared. A typical presentation is with fever, night sweats, weight loss, skin ulceration and tender nodules, and severe muscle and joint pains.

[Q: 3100] OnExamination 2012 - Respiratory

A patient with rheumatoid arthritis complains of progressive breathlessness.

Which of the following is the most likely cause?

- 1- Asthma
- 2- Fibrosing alveolitis
- 3- Pulmonary embolus
- 4- Pulmonary eosinophilia
- 5- Pulmonary nodules

Answer & Comments

Answer: 2- Fibrosing alveolitis

Fibrosing alveolitis associated with rheumatoid arthritis is indistinguishable from cryptogenic fibrosing alveolitis. It presents with progressive breathlessness and cough.

Signs include

Finger clubbing

Cyanosis

Bilateral end inspiratory crackles.

Other pulmonary complications of rheumatoid arthritis include

Pleural effusions

Empyema

Cryptogenic organising pneumonia

Bronchiectasis

Pulmonary nodules.

The latter are usually asymptomatic but may cavitate, resulting in haemoptysis, and when occurring with coal workers pneumoconiosis (Caplan's syndrome) are associated with breathlessness.

[Q: 3101] OnExamination 2012 - Respiratory

A patient who is listed for excision of his operable squamous cell lung cancer, suffers a life threatening haemoptysis on the ward.

Which of the following is the most appropriate treatment?

- 1- Antibiotics
- 2- Bronchial embolisation
- 3- Conservative care
- 4- Radiotherapy
- 5- Tranexamic acid

Answer & Comments

Answer: 2- Bronchial embolisation

Life threatening haemoptysis is a medical emergency that requires prompt action.

Pulmonary angiography will identify the blood supply to the tumour and embolisation of this vessel(s) will immediately stem the bleeding.

The other options are also important in the long term management.

Antibiotics are used to prevent secondary bacterial infection.

[Q: 3102] OnExamination 2012 - Respiratory

Which is the most likely explanation for the high prevalence of cystic fibrosis in European populations?

- 1- Heterozygotes may have an advantage because of increased resistance to cholera.
- 2- Inbreeding is common among Europeans.
- 3- Many different mutations can cause cystic fibrosis.
- 4- Most of the disease genes are hidden in heterozygotes.
- 5- The locus has a high mutation rate.

Answer & Comments

Answer: 1- Heterozygotes may have an advantage because of increased resistance to cholera.

The prevalence of the cystic fibrosis gene at around 1 in 20 of the population would suggest that this provides some evolutionary survival advantage. Like sickle cell trait offering a survival advantage to malaria, it is believed that the cystic fibrosis gene offers a possible survival advantage against cholera and enteropathogenic bacteria.

"Cholera opens chloride channels, letting chloride and water leave cells. The CFTR protein does just the opposite, closing chloride channels and trapping salt and water in cells, which dries out mucus and other secretions. A person with CF cannot contract cholera, because the toxin cannot open the chloride channels in the small intestine.

Carriers of CF enjoy the mixed blessing of a balanced polymorphism. They do not have enough abnormal chloride channels to cause the labored breathing and clogged pancreas of cystic fibrosis, but they do have enough of a defect to prevent the cholera from taking hold. During the devastating cholera epidemics that have peppered history, individuals carrying mutant CF alleles had a

selective advantage, and they disproportionately transmitted those alleles to future generations. However, because CF arose in Western Europe and cholera in Africa, perhaps an initial increase in CF heterozygosity was a response to a different diarrheal infection." (Read more about balanced polymorphism).

[Q: 3103] OnExamination 2012 - Respiratory

A 54-year old woman was admitted with acute breathlessness.

On examination she had a temperature of 37°C, a respiratory rate of 32 breaths per minute, a pulse of 120 beats per minute, a blood pressure of 100/60 mmHg, and a peak expiratory flow rate of 250 litres per minute.

Auscultation of the heart and chest was normal.

The chest x ray was normal and blood gases on air showed:

pH 7.35 (7.36-7.44)

paO₂ 6.0 kPa(11.3-12.6)

PaCO₂ 3.9 kPa(4.7-6.0)

Serum bicarbonate 20 mmol/l (20-28)

She was started on high flow oxygen.

What is the most important next treatment?

- 1- Aminophylline intravenously
- 2- Amoxicillin intravenously
- 3- Intravenous fluids
- 4- Low molecular weight heparin (LMWH)
- 5- Nebulised salbutamol

Answer & Comments

Answer: 4- Low molecular weight heparin (LMWH)

This patient has features of a type 1 respiratory failure with mixed acid-base disturbances.

The differential diagnosis here lies between pulmonary embolism (PE) and acute severe asthma.

On the basis of the reasonable peak expiratory flow rate (PEFR) of 250, the tachycardia and hypotension, PE seems the more likely explanation and LMWH would be the treatment of choice.

Intravenous (IV) fluids are potentially harmful since the cause of the shock is an obstructed right ventricle. Fluids may dilate the ventricle further and reduce cardiac output.

There is a role for fluids in those patients with rapidly falling blood pressure but this should preferably be done (if there is time) with central pressure monitoring.

[Q: 3104] OnExamination 2012 - Respiratory

A 16-year-old girl presents with a two day history of deteriorating breathlessness and dyspnoea.

Blood gas analysis on admission shows:

pH 7.257.35-7.45

pCO₂ 7.0kPa4.7-6.0

pO₂ 8.5kPa9.3-13.3

base excess-4 mmol/l 3 to +3

Which of the following interpretations is correct?

- 1- Bicarbonate may be necessary to correct the acidosis.
- 2- Blood gases suggest type 1 respiratory failure.
- 3- Immediate intubation is required.
- 4- Results are consistent with bronchopulmonary dysplasia.
- 5- Results are consistent with late severe asthma.

Answer & Comments

Answer: 5- Results are consistent with late severe asthma.

In interpreting blood gas results, the following sequence may be useful:

Inspect the pH: Is it low, normal or high?

Inspect the CO₂: Is it low, normal or high?

Inspect the PO₂: Is it low, normal or high?

If the pH is low then an acidosis is present, and inspecting the CO₂ will enable you to determine whether this is due to respiratory or metabolic causes.

Inspecting the PO₂ will tell you whether the patient is hypoxic or not.

In this case, the pH is reduced, and the CO₂ is high, with a base deficit of only -4, insufficient to explain the acidosis from metabolic causes.

This is, therefore, a respiratory acidosis, and the PO₂ is also low suggesting type 2 respiratory failure.

Possible causes would include severe pneumonia, end stage asthma or neurogenic causes such as Guillain-Barre.

In asthma, the initial stages show a low CO₂, with this climbing only to accompany failing respiration. The results would therefore be consistent with late severe asthma. There are high risks associated with intubation and ventilation of asthmatics, due to the high pressures required. Intensive therapy (incl. IV aminophylline or salbutamol and Magnesium) would precede this.

In bronchopulmonary dysplasia, there is usually long-term CO₂ retention with compensatory increase in bicarbonate leading to a positive base excess and normal pH.

Bicarbonate is usually only considered if the base deficit exceeds about -8.

[Q: 3105] OnExamination 2012 - Respiratory

A 17-year-old boy with known cystic fibrosis is under regular follow up at his local specialist centre.

Which one the following conditions (associated with cystic fibrosis), is he most likely also to have?

- 1- Biliary cirrhosis
- 2- Delayed puberty
- 3- Gallstones
- 4- Nasal polyps
- 5- Sinusitis

Answer & Comments

Answer: 2- Delayed puberty

Almost 100% of children with cystic fibrosis will have delayed development and puberty.

Dysfunctional gallbladder and gallstones can be seen in 10-30% of cases.

Symptomatic sinusitis is seen in 10% of children and 20% of adult patients.

Nasal polyps are less common with an estimated incidence of 15-20% (most of these occurring in the second decade).

Biliary cirrhosis is far rarer with approximately 5% of adults affected.

Almost all male CF patients will be infertile; there is a 20% incidence amongst female patients.

Pancreatic insufficiency is also common, with 85% of patients affected.

Other associated conditions include vitamin D deficiency resulting in bone demineralisation, hypertrophic osteoarthropathy and rectal prolapse.

[Q: 3106] OnExamination 2012 - Respiratory

A 75-year-old man with squamous cell carcinoma is thought to have resectable disease.

Which of the following would be a contraindication to surgery?

- 1- Clubbing
- 2- Forced expiratory volume (FEV) 1 of 0.75 L
- 3- His age of 75 years
- 4- Pleural effusion
- 5- Syndrome of Inappropriate ADH

Answer & Comments

Answer: 2- Forced expiratory volume (FEV)1 of 0.75 L

Contraindications to surgery are:

Proven metastases

Mediastinal organ involvement

Malignant pleural effusion (that is, straw coloured, reactive effusions are not a contraindication if cytology is negative)

Contralateral mediastinal node involvement

A predicted post-operative FEV₁ <0.8l (often a preoperative FEV₁ of 2l)

Severe cardiac or other significant disease (for example, cerebrovascular, renal, liver, etc).

[Q: 3107] OnExamination 2012 - Respiratory

A 32-year-old woman is admitted from a party complaining of extreme light-headedness and pleuritic chest pain she also says she has pins and needles in both hands.

She has a past history of asthma which is controlled with a beclomethasone inhaler and prn salbutamol.

On examination her BP is 110/72mmHg, her pulse is 95 and regular. There is scattered

wheeze on auscultation of her chest but good air entry bilaterally. Her peak flow is 500, (580 predicted).

Investigations show:

pH 7.52 (7.35-7.45)

pCO₂ 3.5 kPa(4.8-6.1)

pO₂ 12.9 kPa(10-13.3)

Which of the following is the most appropriate therapy with respect to reducing the likelihood of future attendance in the Emergency department?

- 1- Diaphragmatic breathing exercises
- 2- Diazepam
- 3- Fluoxetine
- 4- Montelukast
- 5- Seretide

Answer & Comments

Answer: 1- Diaphragmatic breathing exercises

This patient is hyperventilating as judged by her symptoms, (peripheral numbness, pleuritic chest pain and shortness of breath), and arterial blood gasses. There is only a minor reduction in peak flow.

In this case, teaching diaphragmatic breathing, (as opposed to thoracic breathing which is practised by many asthmatics), may significantly impact on symptoms.

Diazepam is not recommended in this case as it does not address the underlying problem responsible for her presentation, (likely thoracic breathing).

Fluoxetine is effective in treating anxiety but from the presentation described it does not appear that anxiety / depression is a significant driver.

Whilst montelukast and Seretide are appropriate steps up in asthma therapy, there is only a small reduction in peak flow from

that predicted; as such neither is indicated here.

[Q: 3108] OnExamination 2012 - Respiratory

An otherwise healthy 78-year-old female presents complaining of a three day history of tiredness and breathlessness.

Her pulse oximetry shows oxygen saturation of 90%.

Arterial blood gas analysis performed on air shows

pH 7.3(7.36-7.44)

pO₂ 7.8 kPa(11.3-12.6)

pCO₂ 7.5 kPa(4.7-6.0)

Bicarbonate 30 mmol/L(20-28)

What is the most likely cause?

- 1- Bronchial asthma
- 2- Left ventricular failure
- 3- Lobar pneumonia
- 4- Neuromuscular weakness
- 5- Pulmonary embolism

Answer & Comments

Answer: 4- Neuromuscular weakness

This patient has type 2 respiratory failure as evidenced by hypoxia PaO₂ of <8.0kPa and hypercapnia PaCO₂ >6.0kPa.

This occurs when alveolar ventilation is insufficient to excrete the amount of CO₂ produced by metabolism. This is due to

Reduced ventilatory effort

Failure to overcome increased resistance to ventilation

Failure to compensate for an increase in CO₂ production

or a combination of these factors.

The commonest cause is chronic obstructive airway disease, other causes include respiratory muscle weakness, for example, Guillain-Barre syndrome, chest wall deformity, respiratory centre weakness.

The other causes listed here produce type 1 respiratory failure with a mismatch between ventilation and perfusion.

[Q: 3109] OnExamination 2012 - Respiratory

An otherwise healthy 32-year-old man was the driver of a car involved in a high speed RTA three days ago.

He has sustained a closed fracture of his femur which has been treated surgically with an intramedullary nail, as well as fractures of his right clavicle and left radius.

He was managed according to ATLS protocol when he attended the emergency department.

On examination, he is acutely short of breath and has a temperature of 37.5°C. The patient seems confused when you speak to him, and as you examine him, you note petechial haemorrhages.

What do you think is the most likely diagnosis?

- 1- Asthma attack
- 2- Chest infection
- 3- Fat embolism
- 4- Pulmonary embolism
- 5- Tension pneumothorax

Answer & Comments

Answer: 3- Fat embolism

The two diagnoses which should be considered first in this scenario are pulmonary embolism and fat embolism.

Although the patient is at high risk of pulmonary embolism, and appropriate measures should be undertaken to reduce

this, the clinical scenario is more suggestive of fat embolism.

Fat embolism is thought to occur as a result of release of lipid globules from damaged bone marrow fat cells.

Another mechanism that has been suggested is the increased mobilisation of fatty acids peripherally.

The effects that are seen clinically depend on what part of the microvasculature is affected by the lipid globules.

Pulmonary symptoms are caused by ventilation perfusion mismatch.

Confusion (cerebral effects) may be seen, as well as a petechial rash caused by capillary damage in the skin.

[Q: 3110] OnExamination 2012 - Respiratory

A 45-year-old man is seen in the Emergency department complaining of cough and dyspnoea.

On examination he is disorientated and febrile at 38.5°C. He has a pulse of 100/min and his blood pressure is 85/55 mmHg. He has oxygen saturations of 89% on air and has a respiratory rate of 36/min.

Chest x ray shows left basal consolidation.

Results show:

Sodium 140 mmol/l (137-144)

Potassium 4.0 mmol/l (3.5-4.9)

Urea 10.2 mmol/l (2.5-7.5)

Creatinine 96 µmol/l (60-110)

Which of the following is not part of the CURB score?

- 1- Blood urea concentration
- 2- Confusion
- 3- Consolidation on chest x ray
- 4- Hypotension

5- Tachypnoea

Answer & Comments

Answer: 3- Consolidation on chest x ray

The CURB score is calculated by assessment of core adverse prognostic features which are used in assessment of severity of pneumonia.

Two from four features indicate a severe pneumonia and hospital admission is advised.

The CURB score is calculated using:

Confusion abbreviated mental test score <8.

Urea >7 mmol/l.

Respiratory rate >30/min.

Blood pressure: systolic BP <90 mmHg or diastolic BP <60 mmHg.

[Q: 3111] OnExamination 2012 - Respiratory

A 70-year-old man presents with weight loss and dyspnoea and is diagnosed with small cell lung cancer.

Which one of the following is an adverse prognostic feature?

- 1- Cavitation on x ray
- 2- Finger clubbing
- 3- Hypernatraemia
- 4- Hypertrophic pulmonary osteoarthropathy
- 5- Increased alkaline phosphatase

Answer & Comments

Answer: 5- Increased alkaline phosphatase

The following are adverse prognostic factors in small cell lung cancer:

Serum sodium < 132 mmol/l

Weight loss > 10%

WHO performance status > 2

Alkaline phosphatase > 1.5 times upper limit of normal

Lactate dehydrogenase (LDH) > 1.5 times upper limit of normal

Extensive disease (disease occurring outside one hemithorax and ipsilateral supraclavicular fossa nodes).

[Q: 3112] OnExamination 2012 - Respiratory

A 61-year-old heavy smoker with a BMI of 37 presents with impotence, nocturia and depression.

He is hypoxic at rest on air and has ankle oedema.

Which is the most appropriate investigation to determine the aetiology?

- 1- Arterial blood gas
- 2- Chest x ray
- 3- Sleep study
- 4- Thyroid function test
- 5- Ventilation-perfusion scan

Answer & Comments

Answer: 3- Sleep study

The combination of obesity and hypoxia in this scenario should lead you to consider obstructive sleep apnoea (OSA) as a diagnosis.

Sleep apnoea is defined as repeated episodes of obstructive apnoea and hypopnoea during sleep, together with daytime sleepiness or altered cardiopulmonary function. It affects 2-4% of middle aged adults, although it is important to note that a significant proportion of cases probably go undiagnosed.

Obstructive sleep apnoea has been increasingly implicated in the initiation and progression of cardiovascular diseases. The repeated nocturnal hypoxaemia is associated with activation of a number of neural, humoral, thrombotic, metabolic and

inflammatory mechanisms. Patients have an increased risk of diurnal hypertension, nocturnal dysrhythmias, pulmonary hypertension, right and left ventricular failure, myocardial infarction and stroke.

The hypoxaemia, catecholamine surges and increased blood pressure during sleep, together with daytime hypertension may predispose to hypertensive heart disease, which can manifest as either systolic or diastolic dysfunction. Systolic dysfunction can also be induced by inflammatory cytokines, and increases in afterload and myocardial wall stress caused by negative intrathoracic pressure during episodes of obstruction.

Fatigue, irritability and personality change have also been attributed to nocturnal desaturation and chronic sleep deprivation. Nocturia and erectile dysfunction are also symptoms of OSA.

A sleep-study is used to confirm the presence of upper airway closure during sleep, and lab-based polysomnography is the gold standard for diagnosis. Increasingly, home monitoring systems may be used.

Arterial blood gases vary depending on the time taken, and whether cor pulmonale has developed. The findings are not specific.

Whilst a chest x ray is important when presented with a patient with hypoxia, it will not help with the diagnosis of OSA.

Hypothyroidism could account for this gentleman's depression and erectile dysfunction, but OSA is a much more likely diagnosis.

Ventilation-perfusion scans are used in the diagnosis of pulmonary emboli, although are being increasingly replaced by CTPAs. Whilst recurrent pulmonary thromboembolism can lead to cor pulmonale this does not fit the clinical scenario presented here.

Therapeutic strategies for OSA are behavioural (avoid alcohol and strategies, weight loss etc.),

medical (positive airway pressure, oral appliances) and surgical (tracheostomy, palatal and maxillofacial procedures). Treatment decisions are based on daytime symptoms and cardiopulmonary function. The goals are to establish normal nocturnal oxygenation and ventilation, abolish snoring and eliminate disruption of sleep.

[Q: 3113] OnExamination 2012 - Respiratory

A 40-year-old male, with disseminated malignancy and unknown primary, presents with oedema of the arms and face, with dilated neck veins.

You suspect superior vena cava obstruction (SVCO).

Which of the following statements is correct?

- 1- IV dexamethasone is of no benefit
- 2- Loss of pulsation in the venous system of the neck is of no clinical use in the diagnosis of SVCO
- 3- Mediastinal radiotherapy relieves symptoms in 90% of patients
- 4- Palliative treatment alone is indicated
- 5- Small cell lung cancer is unlikely to be the cause

Answer & Comments

Answer: 3- Mediastinal radiotherapy relieves symptoms in 90% of patients

This is an oncological emergency.

Mediastinal radiotherapy leads to symptomatic relief in 90% of patients within two weeks.

If possible, an attempt should be made to obtain a tissue diagnosis, as some tumours respond to radiotherapy whereas others are more sensitive to chemotherapy.

Therefore the active pursuit of a diagnosis with active treatment of the SVCO is indicated and not merely palliative measures.

Non-small cell cancer (SCC) and small cell malignancy may both cause SVCO.

Intravenous dexamethasone at high dose is of benefit in severe cases of SVCO.

[Q: 3114] OnExamination 2012 - Respiratory

A 28-year-old man who had had tuberculosis of the mediastinal lymph nodes diagnosed two weeks previously and who had been started on chemotherapy with rifampicin, isoniazid and pyrazinamide was admitted because of the increasing dyspnoea and stridor.

Chest x ray showed compression of both main bronchi by carinal lymph node enlargement.

What is the next step in management?

- 1- Mediastinoscopy and biopsy
- 2- Refer for tracheal stent insertion/tracheostomy
- 3- Refer for urgent CT scan of the mediastinum
- 4- Start corticosteroids
- 5- The addition of ethambutol

Answer & Comments

Answer: 4- Start corticosteroids

The treatment of TB mediastinal lymphadenitis is the same as pulmonary TB.

The phenomenon of a 'paradoxical reaction' during treatment for TB has been recognised for many years. This can result in new lesions, or worsening of existing lesions. It is unpredictable in its timing, and can occur anything from a few days to many months after the start of treatment. Duration and severity is highly variable, and it can be difficult to differentiate from treatment

failure, drug resistance or a superadded infection. Most cases are recognised in the setting of lymph node or cerebral disease. Enlargement is seen in 30% of cases. Occurrences are usually self-limiting.

Corticosteroids are effective in reducing lymph node enlargement and inflammation, and hence will help the stridor and breathlessness.

As the compression is at the carina, tracheal stent or tracheostomy will not relieve the obstruction.

The diagnosis is already known, therefore mediastinoscopy and biopsy will not give any extra information. The same applies to a CT.

Whilst standard TB treatment is usually with ethambutol, rifampicin, isoniazid and pyrazinamide initially for two months, when the organism is known to be fully sensitive ethambutol need not necessarily be used. It is unlikely the omission of this drug has caused treatment failure, and therefore adding it at this time is unlikely to relieve the symptoms.

[Q: 3115] OnExamination 2012 - Respiratory

Which of the following statements regarding prognosis in lung cancer is true?

- 1- Combined modality therapy (chemotherapy, radiation therapy and surgery) has improved overall lung cancer survival to 40% at five years.
- 2- Overall lung cancer survival is less than 15% at five years.
- 3- Patients undergoing radiation therapy have a five year survival of 40%.
- 4- Patients who qualify for surgery have a 50% five year survival.
- 5- With chemotherapy, overall survival in small cell (oat cell) carcinomas has risen to 60% at five years.

Answer & Comments

Answer: 2- Overall lung cancer survival is less than 15% at five years.

Prognosis is related to staging and tumour type.

It is obviously higher with a lesion that is confined and resectable (no LAP with no distant metastases) and is not of the small cell/oat cell type.

However, overall five year survival for patients is still of the order of 14%. (American Cancer Society 1998). This contrasts with approximately 50% for cancer of the breast and around 70% for cancer of the cervix.

Overall, only about 20% of cases of non-small cell lung cancer (NSCLC) are regarded as suitable candidates for resection at presentation. Prognosis after surgery however is about 50-67% at five years with stage 1 disease.

Prognosis for small cell cancer despite chemotherapy is grim - 10% at five years.

[Q: 3116] OnExamination 2012 - Respiratory

A 65-year-old female presents with a three week history of malaise and blood in her sputum.

Bronchoscopy reveals a mass in the right main bronchus, and histology demonstrates it to be a small cell carcinoma. Further investigation fails to show any metastases.

What is the most appropriate step in management?

- 1- Chemotherapy
- 2- Endobronchial laser therapy
- 3- Palliative therapy
- 4- Radiotherapy
- 5- Surgery

Answer & Comments

Answer: 1- Chemotherapy

In patients with limited-stage small cell lung cancer, as this patient appears to present with, combination chemotherapy produces results that are clearly superior to single-agent treatment, and moderately intensive doses of drugs are superior to doses that produce only minimal or mild haematologic toxic effects.

Current programmes yield overall objective response rates of 65% to 90% and complete response rates of 45% to 75%.

Because of the frequent presence of occult metastatic disease, chemotherapy is the cornerstone of treatment for patients with limited-stage small cell lung cancer.

Radiotherapy may be considered during the first or second course of chemotherapy.

There is no current clinical trial evidence that adjuvant surgical therapy improves prognosis in these patients, although if a tumour is deemed amenable to surgical resection then it may be offered to the patient.

Source: National Cancer Institute (USA)

[Q: 3117] OnExamination 2012 - Respiratory

Which of the following is not a recognised feature of Pancoast's tumour?

- 1- Erosion of the first rib
- 2- Ipsilateral Horner's syndrome
- 3- Pain in the arm radiating to the fourth and fifth fingers
- 4- Wasting of the dorsal interossei
- 5- Weakness of abduction at the shoulder

Answer & Comments

Answer: 5- Weakness of abduction at the shoulder

The tumour causes pain in the C8 and T1 distribution and Horner's syndrome.

It may cause small muscle wasting of the hands and erosion of the first rib.

The nerve root for abduction of shoulder is C5.

[Q: 3118] OnExamination 2012 - Respiratory

A 23-year-old man presents to the Emergency department with sudden onset left sided pleuritic chest pain. He has had a chronic cough over the past few days and says the pain came on after a coughing fit.

On examination his BP is 148/82 mmHg, pulse is 82 and regular, his saturations are 95% on air. Chest sounds appear normal.

Investigations show:

pH 7.42(7.35-7.45)

pCO₂ 4.8 kPa(4.8-6.1)

pO₂ 10.2 kPa(10-13.3)

CXR Small left sided pneumothorax (<5%)

Which of the following is the most appropriate way to manage him?

- 1- Admit for overnight oxygen therapy
- 2- Chest drain
- 3- Discharge and review in 24 hours
- 4- Discharge and review in the clinic in two to three weeks
- 5- Pleural aspiration

Answer & Comments

Answer: 4- Discharge and review in the clinic in two to three weeks

A more significant pneumothorax could be managed with needle aspiration in the first instance, with formal chest drain the next step if re-inflation does not occur.

Simple aspiration with a venflon needle is only considered for very large pneumothoraces which require immediate intervention.

[Q: 3119] OnExamination 2012 - Respiratory

Based on the current British Thoracic Society (BTS) guidelines, which is the first line empiric antibiotic therapy regime for patients with severe community acquired pneumonia (CAP) based on a CURB-65 score of 4?

- 1- Amoxicillin 500 mg TDS
- 2- Amoxicillin 1 g TDS and clarithromycin 500 mg BD
- 3- Benzylpenicillin 1.2 g QDS and levofloxacin 500 mg BD
- 4- Co-amoxiclav 1.2 g TDS and clarithromycin 500 mg BD
- 5- Doxycycline 200 mg loading dose and then 100 mg OD

Answer & Comments

Answer: 4- Co-amoxiclav 1.2 g TDS and clarithromycin 500 mg BD

BTS has issued clear guidelines on the most appropriate antibiotic regime to treat community-acquired pneumonia, according to the severity, which is often based on the CURB-65 score.

BTS guidelines recommend the use of amoxicillin and clarithromycin as the first line antibiotic regime in the treatment of moderate severity CAP. If the oral route is not possible, benzylpenicillin and clarithromycin should be used.

Amoxicillin alone is recommended for low severity CAP (CURB-65 <2) whether treated at home or in hospital.

Doxycycline may be used as an alternative antibiotic regime, but is not the preferred treatment according to these guidelines.

Co-amoxiclav and clarithromycin use should be reserved for severe community acquired pneumonia (CURB-65 3-5).

BTS guidelines

[Q: 3120] OnExamination 2012 - Respiratory

A 17-year-old girl with known cystic fibrosis presents with a chest infection.

What antibiotic would be most suitable for her?

- 1- Amoxicillin
- 2- Augmentin
- 3- Cefotaxime
- 4- Ceftazidime
- 5- Gentamicin

Answer & Comments

Answer: 4- Ceftazidime

In cystic fibrosis the airways become obstructed by thick mucus due to defective chloride secretion and increased sodium resorption. This leads to bacterial colonisation early in life.

The bacteria present depend on the age of the patient: infants and young children become colonised by *Staphylococcus aureus* and then *Haemophilus influenzae*. In teenagers, *Pseudomonas aeruginosa* colonisation occurs.

Other organisms which can cause infection include *Streptococcus pneumoniae*, *Burkholderia cepacia* (which confers a worse prognosis), *Mycobacterium tuberculosis*, other mycobacteria, *Aspergillus fumigatus* and viruses.

In the UK, antibiotics are usually given when the sputum becomes purulent, pulmonary function deteriorates, or the patient is unwell (e.g. weight loss). In this age groups, Pseudomonal cover is needed and a combination of intravenous antibiotics is used

to reduce the risk of resistance developing. The usual combination is ceftazidime and tobramycin, for a period of two weeks.

Cefotaxime, augmentin and amoxicillin do not have pseudomonal cover. Gentamicin can be used in place of tobramycin, but has poorer pseudomonal cover and is associated with significant side effects (nephrotoxicity and ototoxicity).

Sputum samples should be obtained, and organism identification and sensitivities can be used to guide treatment of future exacerbations.

[Q: 3121] OnExamination 2012 - Respiratory

A 38-year-old man presents with episodic wheeze and non-productive cough which occurs particularly at night. He has been employed in the plastics industry.

Which of the following suggests a diagnosis of occupational lung disease?

- 1- Absent family history of asthma
- 2- Commencement of symptoms on his first day in this employment
- 3- Elevated serum IgE concentration
- 4- Improved symptomatology when on holiday
- 5- Increased bronchial reactivity

Answer & Comments

Answer: 4- Improved symptomatology when on holiday

Episodic cough and wheeze with nocturnal symptoms are classical of asthma.

Occupational asthma is the commonest industrial lung disease with over 400 causes and accounts for up to 10% of adult onset asthma. The commonest occupations affected are spray painters, bakers, chemical

processors, plastics workers and welders and soldering.

Patients are characteristically better when on holiday.

The diagnosis is confirmed by serial peak expiratory flow (PEF) measurements at home and at work. Recordings should be performed two hourly for four weeks or if this is not possible metacholine/histamine challenges can be undertaken after days at work and away from work.

Following objective confirmation of the diagnosis the underlying cause should be identified.

[Q: 3122] OnExamination 2012 - Respiratory

A 40-year-old man presents with a long history of productive cough and breathlessness. He had complained of halitosis and exacerbations of productive sputum, chest pain and haemoptysis.

Examination revealed bilateral inspiratory crackles.

Which of the following treatments is likely to decrease the frequency of his exacerbations?

- 1- Cyclical antibiotic therapy
- 2- Inhaled corticosteroids
- 3- Nebulised bronchodilators
- 4- Postural drainage
- 5- Surgical resection

Answer & Comments

Answer: 4- Postural drainage

This man has bronchiectasis as evidenced by his regular production of sputum associated with breathlessness, his repeated lung infections and the signs of bilateral inspiratory crackles.

Retained mucus is the most important reason why bronchiectatic patients become infected.

Postural drainage is therefore the cornerstone to treating bronchiectasis and should be undertaken at least once per day and more frequently during exacerbations.

There have been trials looking at regular antibiotic therapy versus symptomatic treatment in patients with cystic fibrosis colonised with *Pseudomonas* (for example, Elborn JS et al. Thorax 2000;55: 355-358) but there is currently no evidence that this approach is of benefit in bronchiectasis.

Similarly inhaled corticosteroids should not be used routinely in bronchiectasis until further evidence of their effect on lung function and exacerbation frequency is available.

Surgical resection as a curative procedure can be performed for localised disease when underlying causes such as primary ciliary dyskinesia have been excluded.

In this patient the bilateral crackles suggests widespread disease.

[Q: 3123] OnExamination 2012 - Respiratory

A 48-year-old man with a known history of chronic alcohol abuse presented with a three day history of fevers, night sweats and a cough productive of purulent sputum.

There was no past history of respiratory disease.

On examination he was febrile (39.1°C). Percussion note was dull over the right apex and there was bronchial breathing in this area on auscultation.

The chest x ray showed right upper lobar consolidation.

Other investigations revealed:

WBC $23 \times 10^9/L$ ($4-11 \times 10^9$)

Neutrophils $18.3 \times 10^9/L$ ($1.5-7 \times 10^9$)

What is the most likely diagnosis?

- 1- Aspiration pneumonia

- 2- Klebsiella pneumonia
- 3- Legionella pneumonia
- 4- Mycoplasma pneumonia
- 5- Primary tuberculosis

Answer & Comments

Answer: 2- Klebsiella pneumonia

Community-acquired Klebsiella pneumonia is a disease of debilitated middle-aged and older men with alcoholism. Mortality rates are as high as 50% regardless of treatment.

Klebsiella pneumonia characteristically affects one of the upper lobes of the lung, although infection of the lower lobes is not uncommon. There is an increased tendency toward abscess formation.

Aspiration pneumonia typically affects in right lower lobe in persons with impaired swallowing.

Legionnaires' disease is associated with contaminated air conditioning and water delivery systems.

Mycoplasma pneumoniae infections have an insidious onset with malaise, myalgia, sore throat and headache. Cough is characteristically dry.

Chest x ray (CXR) changes are usually patchy and involve the lower or middle lobes.

[Q: 3124] OnExamination 2012 - Respiratory

A 63-year-old woman with diabetes presents with a pyrexia, productive cough and shortness of breath for five days.

She has RLL consolidation and a small unilateral pleural effusion on CXR.

Which is a marker of poor prognosis?

- 1- Her age
- 2- Her CXR signs
- 3- Her diabetes

- 4- Temp >38°C
- 5- WCC > 15

Answer & Comments

Answer: 3- Her diabetes

Indicators of poor prognosis in pneumonia include

Age more than 65

Co-existing morbidity including diabetes mellitus

Chronic renal failure

Stroke

Coronary artery disease

Respiratory rate more than 30 and

Mental impairment.

Biochemical/haematological markers include

White count less than 4 or more than 30

Hypoxia needing CPAP or FiO₂ greater than 60%

Positive blood culture and

Blood urea more than 7.

[Q: 3125] OnExamination 2012 - Respiratory

A 65-year-old woman presented with increasing fatigue, dyspnoea and a dry cough.

Her chest x ray shows an area of dense pneumonia-like consolidation in the right lower lobe.

A course of antibiotics did not improve her symptoms or chest x ray. Bronchioalveolar lavage (BAL) retrieved 'atypical' cells.

What is the most likely diagnosis?

- 1- Bronchioloalveolar cell carcinoma
- 2- Mycoplasma pneumonia
- 3- Pulmonary alveolar proteinosis

- 4- Pulmonary embolism with infarction
5- Sarcoidosis

Answer & Comments

Answer: 1- Bronchioloalveolar cell carcinoma

"Bronchoalveolar carcinoma accounts for between 1-20% of pulmonary neoplasms. The population most affected is middle-aged, with no predilection for either sex. Interestingly, there is an increased incidence in patients with scleroderma or other diseases causing localized parenchymal scarring or diffuse interstitial fibrosis. Diffuse bilateral involvement in bronchoalveolar cell carcinoma occurs late in the disease and is usually spread by the bronchial tree. Manifestations include both local and diffuse forms. The local form may grow very slowly changing little for several years. The diffuse form simulates an airspace filling disease with air bronchograms and air broncholograms. A pleural effusion develops in 8-10% of cases." More ...

[Q: 3126] OnExamination 2012 - Respiratory

In which of the following have randomised controlled trials shown that long term oxygen therapy (LTOT) reduces mortality?

- 1- Asthma
2- Cor pulmonale due to chronic airflow obstruction
3- Cryptogenic fibrosing alveolitis
4- Cystic fibrosis
5- Pulmonary sarcoidosis

Answer & Comments

Answer: 2- Cor pulmonale due to chronic airflow obstruction

Adequate data for LTOT prolonging survival exists only for chronic obstructive pulmonary disease (COPD) although in practice it is

assumed to apply in other chronic hypoxaemic lung conditions.

[Q: 3127] OnExamination 2012 - Respiratory

Which one of the following cells in the lung parenchyma produces surfactant?

- 1- Alveolar macrophage
2- Endothelial cell
3- Goblet cell
4- Type I pneumocyte
5- Type II pneumocyte

Answer & Comments

Answer: 5- Type II pneumocyte

Surfactant is produced by type 2 pneumocytes and is responsible for the ability of the air-filled alveoli to expand without collapse.

[Q: 3128] OnExamination 2012 - Respiratory

A 43-year-old man with asthma develops worsening breathlessness and his full blood count has revealed an eosinophilia. A diagnosis of allergic bronchopulmonary aspergillosis (ABPA) is suspected.

Which of the following statements is true with regard to this diagnosis?

- 1- Circulating IgG precipitins to *Aspergillus fumigatus* are positive
2- Pleural effusion is a complication
3- Recurrent haemoptysis is a characteristic feature
4- The CO transfer factor is unaffected
5- The immediate skin test to an extract of *Aspergillus fumigatus* is negative

Answer & Comments

Answer: 1- Circulating IgG precipitins to *Aspergillus fumigatus* are positive

Immediate (type I) reactions occur in virtually all patients with ABPA following intradermal injections of *A. fumigatus* extracts, with only 16% developing delayed (type IV) reactions.

Precipitating IgG antibodies are present in 70% of patients.

Transfer factor may be affected in the later fibrotic stage of the disease.

Haemoptysis is symptom of aspergilloma and bronchiectasis, but is not characteristic of ABPA.

[Q: 3129] OnExamination 2012 - Respiratory

A 28-year-old woman comes to see you with her partner. She has a brother who has been diagnosed with cystic fibrosis and her partner has tested positive as a carrier for the disease.

They want to know about what the future holds if one of their children is born with cystic fibrosis.

Which of the following is true?

- 1- Constipation is common in patients with CF
- 2- Diabetes only occurs in those patients who are overweight
- 3- Females with the disease are infertile
- 4- Median survival is expected to be around 27 years
- 5- Pancreatic enzyme supplements are only required if patients cannot maintain their weight

Answer & Comments

Answer: 1- Constipation is common in patients with CF

Constipation even after the initial few days of life during which meconium ileus occurs is common in patients with cystic fibrosis. It usually responds to an increase in fluids coupled with adequate soluble fibre in the diet and pancreatic enzyme supplementation.

Pancreatic endocrine, as well as exocrine, failure occurs in patients with cystic fibrosis.

Diabetes mellitus occurs in >65% of patients by age 25 and this is independent of weight gain.

Females with CF have a relatively minor reduction in their fertility, and many have now gone on to have successful pregnancies.

Median survival has increased significantly over the past 10 years, and is now around 37 years.

Pancreatic enzyme supplements are required to help patients maintain weight.

[Q: 3130] OnExamination 2012 - Respiratory

A 64-year-old patient is discussed at the lung cancer MDT following a recent diagnosis of non-small cell lung cancer (squamous sub-type).

He is a current smoker, and is known to have COPD for which he takes inhalers.

The lesion appears confined to the right middle lobe, but surgical resection would require a pneumonectomy.

Which of the following is a contraindication to his having radical surgery?

- 1- Clubbing
- 2- FEV₁ 1.8L
- 3- Hypertrophic pulmonary osteo-arthritis (HPOA)
- 4- Hyponatraemia
- 5- Mediastinal lymph node measuring 0.9 cm on staging CT

Answer & Comments

Answer: 2- FEV₁ 1.8L

For an intervention to be considered curative there should be no evidence of metastatic spread, and practical considerations such as a

patient's respiratory function reserve need to be considered prior to any operation.

The BTS recommends that pre-operatively a patient's FEV₁ should be greater than 1.5L for a lobectomy and greater than 2L for a pneumonectomy. This ensures that the risk of difficulty in ventilation weaning is reduced, and that post-operatively the patient's respiratory function is not severely compromised.

By CT criteria, lymph nodes greater than 1 cm are deemed to be malignant unless proven otherwise.

Paraneoplastic phenomena including clubbing, HPOA and electrolyte disturbances are not contraindications.

[Q: 3131] OnExamination 2012 - Respiratory

Which of the following is classified as a minor risk factor in the development of venous thromboembolism (relative risk 2-4)?

- 1- Caesarean section
- 2- Fracture
- 3- Institutional care
- 4- Oral contraceptive pill
- 5- Varicose veins

Answer & Comments

Answer: 4- Oral contraceptive pill

All patients presenting with possible pulmonary embolism (PE) or venous thromboembolism (VTE) should have the clinical probability assessed. Therefore it is important to note the major and minor risk factors.

Accordingly to the latest British Thoracic Society (BTS) guidelines for pulmonary embolism, use of the oral contraceptive pill is classed as a minor risk factor with a relative risk of 2-4.

Other minor risk factors include

Occult malignancy

Long distance travel

Hypertension

Congestive cardiac failure and

Thrombotic disorder.

Lower limb problems including a fracture or varicose veins are classed as a major risk factor (relative risk 5-20) in the development of VTE.

Other major risk factors include

Post-operative intensive care

Hospitalisation

Abdominal/pelvic or advanced malignancy

Previous VTE and

Pregnancy.

www.brit-thoracic.org.uk/Portals/0/Clinical%20Information/Pulmonary%20Embolism/Guidelines/PulmonaryEmbolismJUN03.pdf

[Q: 3132] OnExamination 2012 - Respiratory

A 31-year-old motorcyclist becomes confused and dyspnoeic on the orthopaedic ward 24 hours after fracturing his right femur in an accident.

Which of the following skin lesions may be found on examination?

- 1- Multiple petechiae in both axilla
- 2- Palpable purpura on buttocks and legs
- 3- Target lesions on his chest
- 4- Tender red nodules on his shins
- 5- Vesicular lesions on his torso

Answer & Comments

Answer: 1- Multiple petechiae in both axilla

The appearance of multiple petechiae in the distribution of the axilla or upper body is characteristic of a fat embolism. Unlike emboli that arise from a thrombus, fat emboli are small and multiple producing widespread effects. They may occur one to three days following a fracture and are more common in closed fractures on the long bones or pelvis.

The clinical features of fat emboli are predominately:

Pulmonary (shortness of breath, hypoxia)

Neurological (confusion and agitation)

Dermatological (petechiae) and

Haematological (thrombocytopenia, anaemia).

The petechial rash is pathognomonic of this syndrome, but only occurs in 30-50% of cases.

[Q: 3133] OnExamination 2012 - Respiratory

Which of the following is classified as a major risk factor in the development of venous thromboembolism (relative risk 5-20)?

- 1- COPD
- 2- Hormone replacement therapy (HRT)
- 3- Obesity
- 4- Oral contraceptive pill
- 5- Varicose veins

Answer & Comments

Answer: 5- Varicose veins

Accordingly to the latest British Thoracic Society (BTS) guidelines for pulmonary embolism, lower limb problems including a fracture or varicose veins are classed as a major risk factor in the development of VTE.

Other major risk factors include

Postoperative intensive care

Hospitalisation

Abdominal/pelvic or advanced malignancy

Previous VTE and

Pregnancy.

The other risk factors listed in the question are classed as minor risk factors with a relative risk of 2-4.

Other minor risk factors include

Occult malignancy

Long distance travel

Hypertension

Congestive cardiac failure and

Thrombotic disorder.

Management of suspected acute pulmonary embolism

[Q: 3134] OnExamination 2012 - Respiratory

A 20-year-old female with cystic fibrosis presents in early pregnancy wanting advice.

Genetic analysis reveals that her partner is a carrier of the cystic fibrosis gene.

Which of the following percentages best represents the chance of her child having cystic fibrosis?

- 1- 10%
- 2- 25%
- 3- 50%
- 4- 75%
- 5- 100%

Answer & Comments

Answer: 3- 50%

The patient is homozygous for CF (CF/CF) and the father is heterozygous for CF (CF/N).

Thus there is a 50% chance that her child will be homozygous for CF and a 50% chance that the child will be a carrier.

[Q: 3135] OnExamination 2012 - Respiratory

A 60-year-old man was admitted with community-acquired pneumonia and deteriorated over the next few hours.

Which one of the following indicates a poor prognosis?

- 1- A total white cell count of $17 \times 10^9/L$ (4-11)
- 2- Blood pressure of 110/70 mm Hg
- 3- Respiratory rate of 35 breaths/min
- 4- Rigors
- 5- Temperature of $39^\circ C$

Answer & Comments

Answer: 3- Respiratory rate of 35 breaths/min

The presence of:

Raised urea ($>7\text{mM}$)

Hypotension (diastolic BP equal or $<60\text{ mmHg}$) and

Respiratory rate equal or $>30/\text{min}$

is associated with significantly increased risk of death.

Other less important features of severe pneumonia include:

Older age (>60)

Comorbidity

Confusion

Cyanosis

White blood cells <4000 or >30000

Hypoxia and

Chest x ray with multilobe involvement.

[Q: 3136] OnExamination 2012 - Respiratory

Which of the following would be the least likely finding in a patient with sarcoidosis?

- 1- Hepatic granulomas
- 2- Restrictive pulmonary function tests
- 3- Skin lesions
- 4- Uveitis
- 5- X bodies on bronchoalveolar lavage (BAL) fluid

Answer & Comments

Answer: 5- X bodies on bronchoalveolar lavage (BAL) fluid

Sarcoidosis is associated with:

Uveitis

Arthritis

Pulmonary fibrosis

Lymphadenopathy and

Skin changes - lupus pernio/erythema nodosum.

It is characterised histologically by the presence of non-caseating granulomas which may occur anywhere. These granulomas have the capacity to produce 1,25 vitamin D explaining the associated hypercalcaemia.

Pentalaminar X bodies (Birbeck granules) found on BAL are considered diagnostic of pulmonary histiocytosis X and so would not be expected with sarcoidosis.

[Q: 3137] OnExamination 2012 - Respiratory

Which one of the following is correct regarding severe bullous emphysema?

- 1- Helium dilution is more accurate than body plethysmography in measuring residual volume.

- 2- Hypoxaemia at rest will improve with exercise.
- 3- Pulmonary compliance is reduced.
- 4- Reduced elastic recoil opposes airway collapse in expiration.
- 5- The carbon monoxide transfer factor is reduced.

Answer & Comments

Answer: 5- The carbon monoxide transfer factor is reduced.

Whole body plethysmography also measures trapped gas, that is, intrathoracic gas (including within bullae and other poorly ventilated areas) which barely communicates with the airway. Standard gas dilution measures gas that communicates with the airway. Mixing in helium dilution is more difficult in airways obstruction requiring multibreath methods lasting five minutes rather than single breath test.

Exertion will exacerbate breathlessness and hypoxia.

The characteristic changes of severe emphysema are increase in static compliance and reduction in lung recoil pressure.

Loss of lung recoil causes a reduction of alveolar pressure (elastic recoil pressure of lung + pleural pressure) leading to collapse of peripheral airways on expiration. Emphysematous patients purse their lips in expiration to increase airway pressure to prevent this collapse.

CO transfer factor is reduced.

[Q: 3138] OnExamination 2012 - Respiratory

A 55-year-old female is admitted with a chest infection.

Investigations reveal consolidation in the right base on the chest x ray and urinary legionella antigen is found to be positive.

Which one of the following is the most appropriate treatment for this woman?

- 1- Cefotaxime
- 2- Clarithromycin
- 3- Co-amoxiclav
- 4- Minocycline
- 5- Vancomycin

Answer & Comments

Answer: 2- Clarithromycin

The most appropriate treatment for legionellosis is clarithromycin.

Ciprofloxacin is also a useful drug in combination with clarithromycin for severe infections or alone in those intolerant of macrolides.

[Q: 3139] OnExamination 2012 - Respiratory

A 51-year-old businessman complains of dyspnoea on exertion. He recently returned from a business trip to the USA.

He has distant heart sounds on auscultation of the chest. A chest radiograph reveals that there is a thin rim of calcification surrounding the cardiac outline.

Which of the following conditions is most likely responsible for these findings?

- 1- Group B coxsackie virus
- 2- Metastatic carcinoma
- 3- Sarcoidosis
- 4- Tuberculosis
- 5- Uraemia

Answer & Comments

Answer: 4- Tuberculosis

The most likely diagnosis is a constrictive pericarditis.

The most probable cause for this is prior tuberculous (TB) infection which may have occurred many years previously. Acute TB would usually cause a constrictive pericarditis secondary to a pericardial effusion, but is not normally associated with calcification.

Uraemia can cause a constrictive pericarditis, as can a pericardial malignancy and coxsackie virus (secondary to a pericarditis), but calcification would be unusual.

Sarcoid can cause both pericardial as well as restrictive cardiomyopathy but calcification would be unusual.

[Q: 3140] OnExamination 2012 - Respiratory

A 22-year-old student who is known to have severe asthma is brought to the Emergency department by his flatmates. He has been suffering from influenza over the past few days, and been getting progressively increasing cough, wheeze and shortness of breath.

He takes regular high dose Seretide and montelukast. His usual peak flow is 460 (predicted 590).

On examination his BP is 123/80 mmHg, his pulse is 105 and regular, respiratory rate is 35. There is marked wheeze on auscultation of his chest.

Investigations show:

pH 7.43(7.35-7.45)

pCO₂ 6.4 kPa(4.8-6.1)

pO₂ 10.3 kPa(10-13.3)

Which of the features is consistent with near fatal asthma according to BTS guidelines?

- 1- Pulse 100
- 2- Peak flow 280
- 3- pO₂ 10.3
- 4- pCO₂ 6.4
- 5- Respiratory rate 35

Answer & Comments

Answer: 4- pCO₂ 6.4

Raised CO₂ or the need for mechanical ventilation with raised pressures is indicative of near fatal asthma.

Indications of life threatening asthma are also defined in the guidelines, these are:

PEF <33% best or predicted

SpO₂ <92%

PaO₂ <8 kPa

Normal PaCO₂ (4.6-6.0 kPa)

Silent chest

Cyanosis

Poor respiratory effort

Arrhythmia

Exhaustion, altered conscious level.

Therefore, D is the only possible correct answer.

[Q: 3141] OnExamination 2012 - Respiratory

A 19-year-old smoker presents to the Emergency department with right sided pleuritic chest pain and dyspnoea. He has no previous medical history.

His BP is 120/75 mmHg. A CXR is done and confirms a right sided pneumothorax with a rim of 2.5 cm.

What is the pathogenesis of pneumothorax?

- 1- Leak from pulmonary alveoli
- 2- Oesophageal rupture
- 3- Ruptured apical bullae on lung surface
- 4- Underlying asthma
- 5- Underlying emphysema

Answer & Comments

Answer: 3- Ruptured apical bullae on lung surface

Spontaneous rupture of bullae or after minimal trauma causes primary pneumothorax in the young.

Smoking cessation should be advised.

[Q: 3142] OnExamination 2012 - Respiratory

A 75-year-old woman with a productive cough was admitted by her GP.

She has a temperature of 38.2°C. She is not oriented to time or place. On examination she right basal crackles. Her BP is 110/60 mmHg and respiratory rate is 34/min. Pulse is 105 and regular. O₂ saturation is 92%. Chest x ray shows right basal consolidation.

The patient was given IV antibiotics for the first three days, improved and she was switched to oral antibiotics.

Investigations show:

White cell count $15 \times 10^9/L$ ($4 - 11 \times 10^9/L$)

CRP 75 mg/L (<10 mg/L)

Na 140 mmol/L (137 - 144 mmol/L)

K 3.8 mmol/L (3.5 - 4.9 mmol/L)

Urea 9.4 mmol/L (2.5 - 7.5 mmol/L)

Serum Creatinine 100 $\mu\text{mol/L}$ (60 - 110 $\mu\text{mol/L}$)

The patient is now ready for discharge.

What is the best plan of action?

- 1- Check full blood count , U/E and CRP in four weeks
- 2- Chest x ray in six weeks
- 3- CT chest
- 4- Discharge with a prescription of oral antibiotics for five to seven days
- 5- Refer to a respiratory physician

Answer & Comments

Answer: 2- Chest x ray in six weeks

It is important for patients who had pneumonia and had a consolidation on chest x ray to have a follow up chest x ray to ensure complete resolution. This is to exclude any underlying cause especially malignancy.

Not all patients need referral to a respiratory physician; only those who have persistent shadowing on the lung.

[Q: 3143] OnExamination 2012 - Respiratory

A 67-year-old man with a 35 pack/year history is referred to the rapid access lung cancer clinic by the GP following a suspicious chest x ray.

He undergoes a CT scan of his thorax. The report is as follows:

'There is a 4.5 cm mass in the right upper lobe which is involving the right main bronchus. There are several ipsilateral lymph nodes, the largest measuring 2.3 cm. There is no evidence of distant metastases. The overall appearance is in keeping with a lung carcinoma, most likely non-small cell'.

Based on the TNM (tumour, nodes, and metastases) classification, what is the radiological staging of this patient's lung cancer?

- 1- T2N1M0
- 2- T2N2M0
- 3- T2N3M0
- 4- T3N1M0
- 5- T3N2M0

Answer & Comments

Answer: 1- T2N1M0

This patient has a T2N1M0 lung cancer. TMN staging is used by the multidisciplinary team to aid the choice of treatment.

T2 = Tumour with any of the following features of size or extent:

Greater than 3 cm in greatest dimension

Involves main bronchus

Greater than 2 cm distal to the carina

Invades the visceral pleura.

Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung.

N1 = Metastases to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes involved by direct extension of the primary tumour.

M0 = No distant metastases.

As taken from NICE lung cancer guidelines 2005.

Full TMN classification

[Q: 3144] OnExamination 2012 - Respiratory

A 19-year-old man presents with sudden onset left-sided pleuritic chest pain and dyspnoea. He has no past medical history of note and takes no regular medication.

On examination he looks in pain. He has a respiratory rate of 35 and his BP is 110/70 mmHg, with a pulse of 95. His chest sounds appear normal.

Investigations show

Haemoglobin 14.8 g/dl(13.5-18)

White cell count $5.0 \times 10^9/L$ (4-10)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 94 $\mu\text{mol/l}$ (60-120)

CXR Small rim of air <2 cm on the left hand side

Which of the following is the most appropriate management?

1- Air aspiration

2- Discharge for review the following day

3- Large bore chest drain

4- Observe and give oxygen

5- Small bore chest drain

Answer & Comments

Answer: 1- Air aspiration

Only primary pneumothoraces (less than 2 cm) which are not associated with dyspnoea should be managed with discharge and instructions to return if they become dyspnoeic.

In this case, aspiration should be considered.

If air aspiration is unsuccessful, then small bore chest drain insertion is the treatment of choice; repeat air aspiration should not be attempted.

It is recommended that if there is a previous history of chest disease, all pneumothoraces are managed with a chest drain, rather than attempting air aspiration.

[Q: 3145] OnExamination 2012 - Respiratory

A 32-year-old female smoker presents with acute severe asthma. The SaO_2 are 80% on 15 L of oxygen and the pO_2 is 8.2kPa (10.5-13).

There is widespread expiratory wheeze throughout the chest. She is given IV hydrocortisone, 100% oxygen and 5 mg of nebulised salbutamol.

What is the next step in your management?

1- IV Augmentin

2- IV magnesium

3- IV potassium

4- IV theophylline

5- Oral prednisolone

Answer & Comments

Answer: 2- IV magnesium

This question focuses on acute treatment of asthma.

Your initial approach should be SOS - salbutamol, oxygen and steroids intravenously (IV).

In the meantime a chest x ray should be organised to rule out pneumothorax.

You should then consider further efforts to treat bronchoconstriction - a silent chest, or a tiring patient should suggest ITU review.

The recommended dose of magnesium is 2 g over 30 minutes. The mechanism by which it has its effect is not fully understood, but it is thought that low magnesium levels in bronchial smooth muscle favour bronchoconstriction.

IV theophylline may be considered, but magnesium would be higher on the list.

IV antibiotic may be indicated, but your initial focus should be promoting bronchodilation.

IV potassium may be required as the beta agonists push down the potassium.

Oral prednisolone can wait, as you have already given IV hydrocortisone as part of your SOS approach.

[Q: 3146] OnExamination 2012 - Respiratory

A 21-year-old gentleman with cystic fibrosis presents with infertility.

What is the most likely cause for this?

- 1- Chronic prostatic insufficiency
- 2- Failure of development of the vas deferens
- 3- Increasing alkalinisation of semen
- 4- Primary failure of testosterone production

5- Production of anti-sperm antibodies

Answer & Comments

Answer: 2- Failure of development of the vas deferens

Infertility occurs in 98% of adult men secondary to maldevelopment of the vas deferens or to other forms of obstructive azoospermia.

In women, fertility is decreased secondary to viscid cervical secretions.

[Q: 3147] OnExamination 2012 - Respiratory

A 28-year-old man had been treated for pulmonary tuberculosis with rifampicin, isoniazid, pyrazinamide and ethambutol for four weeks.

Pre-treatment liver function tests (LFTs) were normal but his most recent investigations revealed:

Serum total bilirubin 98 µmol/l (0-18)

Serum alanine aminotransferase 620 u/l (5-45)

Serum aspartate aminotransferase 450 u/l (5-45)

Serum alkaline phosphatase 720 u/l (40-110)

Which one of the following is the most appropriate next step?

- 1- Stop all treatment
- 2- Stop ethambutol
- 3- Stop isoniazid
- 4- Stop pyrazinamide
- 5- Stop rifampicin

Answer & Comments

Answer: 1- Stop all treatment

All tuberculosis patients should have pre-treatment LFTs, should be supervised by a chest physician and should be informed of possible side-effects of treatment.

If there is no pre-existing liver disease, LFTs are only repeated (and treatment stopped) if fever, malaise, vomiting, jaundice or unexplained deterioration occurs during treatment.

Regular LFTs should be performed in patients with previously known chronic liver disease. If AST/ALT levels rise by five times normal/bilirubin level rises, then rifampicin/isoniazid/pyrazinamide should be stopped.

If the patient is not unwell and/or has non-infectious TB, no treatment until LFT returns to normal.

If clinically unwell or sputum smear is positive within two weeks of starting treatment, consider streptomycin and ethambutol until LFT returns to normal.

Once LFT is back to normal, challenge dosages can be reintroduced sequentially in order of isoniazid, rifampicin and pyrazinamide with daily monitoring of patient's condition and LFT.

If there is a further reaction the offending drug should be excluded and a suitable alternative regimen used.

[Q: 3148] OnExamination 2012 - Respiratory

An 18-year-old boy is suspected of having cystic fibrosis (CF).

Which of the following results would be most suggestive of this condition?

- 1- Abnormalities in lung function tests
- 2- Abnormal pancreatic function tests
- 3- Bronchiectasis on a chest x ray
- 4- Elevated sweat chloride concentration
- 5- Low immunoreactive plasma trypsinogen

Answer & Comments

Answer: 4- Elevated sweat chloride concentration

The sweat test is the most important test for CF.

Up to 99% of children with CF have sweat chloride and sodium levels above 70 and 60 mM respectively. In normal children, sweat sodium is higher than chloride. The reversed ratio is another pointer to CF.

Two sweat tests should be performed spontaneously on both arms with pilocarpine iontophoresis. Older children with CF and pancreatic insufficiency have low immunoreactive trypsin.

This and the other tests mentioned may be suggestive of CF but are not diagnostic.

[Q: 3149] OnExamination 2012 - Respiratory

A 60-year-old female presents with recent onset dyspnoea and noisy breathing.

Her chest x ray showed right deviation of the trachea due to a retrosternal goitre.

Which of the following tests is most useful in the assessment of airflow obstruction due to the goitre?

- 1- Flow volume curve
- 2- Forced expiratory flow volume in one second
- 3- Forced vital capacity
- 4- Peak expiratory flow rate
- 5- Residual volume

Answer & Comments

Answer: 1- Flow volume curve

Inspection of the maximal expiratory and inspiratory flow-volume curve is currently the simplest method to establish the presence of

upper airway obstruction associated with a retrosternal goitre.

This may be present in up to 40% of patients with retrosternal goitre and generally requires at least 50% obstruction of the airway before symptoms arise.

[Q: 3150] OnExamination 2012 - Respiratory

A 60-year old man with a history of non-small cell lung cancer was treated with a right lower lobectomy 12 months ago.

He had an abdominal CT scan one month ago which revealed hepatic mass lesions and hilar lymphadenopathy. He now presents with malaise and fatigue.

His results show:

Urinalysis Protein +++

24 hour urine protein 2.7 g/24hr

Serum Urea 30 mmol/L (2.5-7.5)

Serum creatinine 450 µmol/L (60-110)

A renal biopsy shows focal deposition of IgG and C3 with a granular pattern.

What is the most likely diagnosis?

- 1- Goodpasture's syndrome
- 2- Membranous glomerulonephritis
- 3- Minimal change glomerulonephritis
- 4- Nodular glomerulosclerosis
- 5- Rapidly progressive glomerulonephritis

Answer & Comments

Answer: 2- Membranous glomerulonephritis

Membranous GN is associated with:

Malignancy

Elderly patients, male more than female

Medications: penicillamine, GOLD, captopril, and heavy metals: mercury and cadmium

Basement membrane thickening

Rheumatoid arthritis

Autoimmune disease: systemic lupus erythematosus (SLE), thyroid

Nephrotic syndrome is the main presentation

Hepatitis B

Odd infections - like syphilis, leprosy, HIV, schistosomiasis, malaria

Immune complex deposition with IgG and C3

Sickle cell disease.

Forty per cent remit without treatment, 30% develop endstage renal failure (ESRF).

[Q: 3151] OnExamination 2012 - Respiratory

A 19-year-old woman became breathless while travelling on an aeroplane.

Which one of the following features most strongly supports a diagnosis of acute hyperventilation related to a panic disorder?

- 1- Carpal spasm
- 2- Finger paraesthesia
- 3- Hypotension
- 4- Light-headedness
- 5- Loss of consciousness

Answer & Comments

Answer: 1- Carpal spasm

We need to distinguish between the signs that may be expected in the tachypnoea associated with the hypoxia from a pulmonary embolism (PE) or any other serious respiratory problem and the hyperventilation with increased pO₂ in a panic attack.

A carpal spasm would be most likely to reflect this.

Finger paraesthesia can occur with PE, as can hypotension, light-headedness and loss of consciousness.

Carpal spasm is found in association with hyperventilation due to the respiratory alkalosis which results in a reduction in ionised calcium concentration.

[Q: 3152] OnExamination 2012 - Respiratory

A 60-year-old man with ankylosing spondylitis presents with cough, weight loss and tiredness.

His CXR shows longstanding upper lobe fibrosis.

Three sputum tests stain positive for acid fast bacilli (AFB) but are consistently negative for Mycobacterium tuberculosis on culture.

Which of the following is the most likely cause?

- 1- Allergic bronchopulmonary aspergillosis
- 2- Micropolyspora faeni
- 3- Mycobacterium avium intracellulare complex
- 4- Sarcoidosis
- 5- Tuberculosis

Answer & Comments

Answer: 3- Mycobacterium avium intracellulare complex

The presence of AFB yet absence of TB suggests an atypical AFB such as M. avium.

[Q: 3153] OnExamination 2012 - Respiratory

A 60-year-old man with breathlessness, fever and headache is suspected of having farmer's lung.

A CXR shows diffuse nodular shadowing predominantly in the mid and lower zones.

What would be the most useful diagnostic test?

- 1- Blood culture

- 2- Sputum culture

- 3- Serum precipitating antibodies to Aspergillus clavatus

- 4- Serum precipitating antibodies to Cryptostroma corticale

- 5- Serum precipitating antibodies to Micropolyspora faeni

Answer & Comments

Answer: 5- Serum precipitating antibodies to Micropolyspora faeni

The diagnosis of extrinsic allergic alveolitis is based on characteristic clinical, radiological and functional changes and confirmed by demonstration of precipitating antibodies (precipitins) in the patient's serum to the causal antigen.

In farmer's lung precipitins to M. faeni or Thermoactinomyces vulgaris are found in 75-100% of cases during an acute episode.

A. clavatus is the antigen causing malt worker's lung and C. corticale the antigen causing maple bark stripper's lung.

[Q: 3154] OnExamination 2012 - Respiratory

A 60-year-old man who has known small cell lung cancer presents to the clinic for 12 month review.

He has completed five cycles of initial intensive chemotherapy and radiotherapy. His six month review showed shrinkage of his primary lung tumour. Over the past few weeks however he has felt increasingly short of breath and has suffered three episodes of haemoptysis.

On examination he is afebrile, his BP is 155/90 mmHg, and his pulse is 70 and regular. There are coarse crackles throughout both lung fields consistent with COPD.

Investigations show:

Haemoglobin 11.7 g/dl(13.5-17.7)

White cell count $8.2 \times 10^9/L$ (4-11)

Platelets $183 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.4 mmol/l (3.5-5)

Creatinine 131 micromol/l (79-118)

Alanine aminotransferase 280 U/l (5-40)

Alkaline phosphatase 245 U/l (39-117)

CXR - Right sided original tumour appears to have increased in size, bilateral hilar lymphadenopathy, two new left sided lung lesions noted.

He suspected he may have a recurrence and brought with him some information on topotecan, downloaded from the internet.

Which of the following is true about topotecan in his case?

- 1- He is only suitable for oral therapy if the first line regime is not appropriate
- 2- He is only suitable for oral therapy if the first line regime is not appropriate and cyclophosphamide, vincristine and doxorubicin (CAV) is inappropriate
- 3- He is suitable for IV therapy
- 4- Small cell carcinoma makes him ineligible for therapy
- 5- Topotecan is recommended for the treatment of all patients with small cell lung cancer

Answer & Comments

Answer: 2- He is only suitable for oral therapy if the first line regime is not appropriate and cyclophosphamide, vincristine and doxorubicin (CAV) is inappropriate

Topotecan is an inhibitor of topoisomerase-1, an enzyme which is involved in DNA replication.

The major study of topotecan in small cell lung cancer used the oral formulation in patients who had relapsed and for whom re-treatment with IV chemotherapy was not considered

appropriate. For this reason NICE guidance recommends it should only be used in patients who have relapsed and cannot be treated with the CAV regime.

Option A does not conform with the current NICE guidance and is therefore inappropriate.

The majority of the IV studies of topotecan were in cervical cancer, so that whilst the IV formulation is an option in cervical cancer, it is not in small cell lung cancer.

Options D and E are inappropriate as topotecan is recommended for a subset of patients with small cell lung cancer.

<http://www.nice.org.uk/nicemedia/live/12348/46330/46330.pdf>

[Q: 3155] OnExamination 2012 - Respiratory

A 71-year-old man presents to the Emergency department with an influenza-like illness.

He says this has been accompanied by a dry cough and diarrhoea over the past few days, and his wife tells you that he is becoming increasingly drowsy and forgetful. They have returned from a hotel in Spain some two days earlier, where they were staying for the winter.

On examination he is pyrexial 38.2 deg C, pulse is 92 and BP is 100/60 mmHg. There is bilateral wheeze on auscultation of the chest.

Investigations show:

Haemoglobin 13.0 g/dl (13.5-17.7)

White cell count $13.0 \times 10^9/L$ (4-11)

Platelets $222 \times 10^9/L$ (150-400)

Sodium 130 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 129 $\mu\text{mol/l}$ (79-118)

Alkaline phosphatase 30 U/l (39-117)

CXR Left sided pleural effusion and patchy consolidation

Which of the following is the most likely diagnosis?

- 1- Klebsiella pneumoniae
- 2- Legionella pneumophila
- 3- Mycoplasma pneumoniae
- 4- Staphylococcus aureus
- 5- Streptococcus pneumoniae

Answer & Comments

Answer: 2- Legionella pneumophila

Klebsiella and Staphylococcus tend to be cavitating pneumonias, with Klebsiella being associated with chronic alcoholism, and Staphylococcus with post-influenza pneumonia.

Mycoplasma tends to affect a single lobe, and is associated with haemolytic anaemia.

[Q: 3156] OnExamination 2012 - Respiratory

A 42-year-old farmer is admitted with a severe cough, fevers and shortness of breath. You understand that he has been clearing out a shed over the past few days which were previously used for over-wintering cattle.

On examination he has a temperature of 38.2°C, his BP is 110/70 mmHg and his pulse is 95 and regular. There are widespread coarse crackles on auscultation.

Investigations show:

Haemoglobin 13.9 g/dl (13.5-17.7)

White cell count $12.8 \times 10^9/L$ (4-11)

Platelets $222 \times 10^9/L$ (150-400)

Sodium 138 mmol/l (135-146)

Potassium 4.1 mmol/l (3.5-5)

Creatinine 110 micromol/l (79-118)

CXR - diffuse consolidation.

Which of the following is the most appropriate treatment?

- 1- Amphotericin B
- 2- Clarithromycin
- 3- Fluconazole
- 4- Penicillin
- 5- Prednisolone

Answer & Comments

Answer: 5- Prednisolone

This man has acute farmer's lung, as a result of exposure to actinomycetes in mouldy hay. It leads to an acute hypersensitivity pneumonitis, the primary treatment of which is with corticosteroids. He should of course avoid repeated exposure because of the risk of chronic farmer's lung.

Whilst the aetiology is hypersensitivity to fungal spores, it is corticosteroids which are the primary treatment modality. As such both amphotericin B and fluconazole are inappropriate answers.

Clarithromycin and penicillin would be considered treatments for bacterial pneumonia.

[Q: 3157] OnExamination 2012 - Respiratory

Which of the following is a recognised treatment for complications of cystic fibrosis?

- 1- DNase to assist in reinflating collapsed lung segments
- 2- Hypotonic saline drinks for hypernatraemic dehydration
- 3- Nebulised tobramycin for Pseudomonas colonisation of the lower respiratory tract
- 4- Pancreatic transplant for diabetes mellitus
- 5- Rectal pull-through and anastomosis for rectal prolapse

Answer & Comments

Answer: 3- Nebulised tobramycin for Pseudomonas colonisation of the lower respiratory tract

Human recombinant DNase given as a single daily aerosol seems to improve pulmonary function, decrease the frequency of chest exacerbations, and promotes a sense of well-being in patients with mild to moderate disease with purulent secretions.

This may be because, in the inflamed airway, the nuclei from dead cells account for much of the viscosity of secretions.

Rectal prolapse is usually idiopathic, occurring between one and five years.

Intestinal parasites

Malnutrition

Acute diarrhoea

Ulcerative colitis

Pertussis

Ehlers-Danlos syndrome

Meningocele

Cystic fibrosis

Chronic constipation

can also predispose to it.

Following defecation the prolapse usually resolves spontaneously, or through manual reinsertion by the patient or parent.

Nebulised tobramycin or gentamicin may be given when airway pathogens are resistant to oral antibiotics, or where infection is difficult to control at home.

Hypernatraemic dehydration should be treated in the usual way.

[Q: 3158] OnExamination 2012 - Respiratory

A 49-year-old man is diagnosed with small cell lung cancer.

Despite a normal brain MRI he develops progressive truncal ataxia.

Which of the following would be most useful in the diagnosis of his condition?

- 1- Anti-Purkinje cell antibody levels
- 2- Lumbar puncture
- 3- Serum calcium
- 4- Serum sodium
- 5- Visual evoked potentials

Answer & Comments

Answer: 1- Anti-Purkinje cell antibody levels

Paraneoplastic syndromes are a result of antibody generation from or against malignant cells attacking normal tissue.

Examples include antineuronal antibodies (anti-Hu, anti-Yo, anti-Ri) directed against the Purkinje cells of the cerebellum leading to the cerebellar syndrome described above.

The Lambert-Eaton myasthenic syndrome (LEMS) is a pre-synaptic disorder of auto-antibody IgG directed against the pre-synaptic calcium channel leading to impaired acetylcholine release. Clinically, patients present with muscle weakness that improves with exercise.

Symptomatic hyponatraemia due to syndrome of inappropriate antidiuretic hormone secretion (SIADH) is treated with demeclocycline which induces nephrogenic diabetes insipidus leading to excretion of excess water.

Both non-small cell and small cell lung cancers are associated with paraneoplastic syndromes, although they are more common with the latter due to its neuroendocrine cell origin.

[Q: 3159] OnExamination 2012 - Respiratory

A 24-year-old man presents to the Emergency department and complains of shortness of breath.

Before his chest x ray is taken he tells the casualty officer that he is known to have an 'azygous lobe'.

In what region of the chest x ray would you expect to see an 'azygous lobe'?

- 1- Left lower zone
- 2- Left mid zone
- 3- Left upper zone
- 4- Right lower zone
- 5- Right upper zone

Answer & Comments

Answer: 5- Right upper zone

An azygous lobe is seen in about 0.5% of routine chest x rays and is a normal variant.

It is seen as a 'reverse comma sign' behind the medial end of the right clavicle.

[Q: 3160] OnExamination 2012 - Respiratory

A 73-year-old male smoker presents with haemoptysis of three weeks duration.

Examination reveals left supraclavicular lymphadenopathy. A chest radiograph reveals a left sided hilar mass.

Which of the following would be an appropriate next step in the investigation of this patient?

- 1- Bronchoscopy
- 2- CT guided biopsy
- 3- Lymph node biopsy
- 4- PET scanning
- 5- Sputum cytology

Answer & Comments

Answer: 5- Sputum cytology

This patient is likely to have lung carcinoma.

A diagnosis may be made on sputum cytology which should be the initial investigation with a positive yield of approximately 70-80% with four samples.

[Q: 3161] OnExamination 2012 - Respiratory

A 68-year-old man presents with a one month history of dyspnoea and a 3 kg weight loss.

On examination there were signs of a large left pleural effusion, confirmed on chest x ray.

Investigations revealed:

Pleural fluid analysis:

Protein 38 g/L

Cytology a few lymphocytes and red blood cells.

Which one of the following investigations should be considered next?

- 1- Bronchoscopy
- 2- CT scan of thorax
- 3- Repeat pleural aspiration with biopsy
- 4- Thoracoscopic pleural biopsy
- 5- Tuberculin test

Answer & Comments

Answer: 2- CT scan of thorax

We assume from the given information that the patient is not symptomatic - in which case a further therapeutic pleural aspiration should be performed. The next most important step would be a contrast CT thorax which can help differentiate between benign and malignant disease and also guide further investigations.

Video-assisted thoracoscopic surgery (VATS) can

Do good pleural biopsies

Clear all the pleural fluid

Allow pleurodesis to prevent recurrence.

It should be considered after other non-invasive tests have proven negative. Usually the surgeons can do bronchoscopy at the same time under general anaesthetic.

Percutaneous pleural biopsies do not produce good samples and are less often done.

BTS guidelines for the investigation of a unilateral pleural effusion in adults.

[Q: 3162] OnExamination 2012 - Respiratory

A 45-year-old solicitor had an onset of severe, crushing, substernal chest pain while attending a football match. He collapsed on his way to the car.

Bystander cardiorespiratory resuscitation was begun immediately and he is cardioverted for VF by the attending paramedics. He arrives intubated and ventilated in the casualty department where his 12 lead ECG shows inferior ST elevation.

Blood gas analysis revealed:

pH 7.13(7.35-7.45)

paO₂ 560 mmHg(90-110)

paCO₂ 18 mmHg(35-45)

Bicarbonate 5.8 mmol/l (20-30)

SaO₂ 98%(>90)

Based on these laboratory values, which of the following statements best describes his current pathophysiology?

- 1- He has a large right to left intracardiac shunt
- 2- He is demonstrating a primary respiratory acidosis
- 3- His anion gap is likely to be normal
- 4- His oxyhaemoglobin curve is shifted to the left

- 5- His pulmonary artery pressure is likely to be elevated

Answer & Comments

Answer: 5- His pulmonary artery pressure is likely to be elevated

This relatively young patient with severe central chest pain has probably arrested due to myocardial infarction and arrhythmia.

His gases reveal high PO₂ following 100% O₂ but severe acidosis due to the arrest and lactic acidosis thus the anion gap would be high.

He does not have a primary ventilatory failure as his PO₂ is high.

There is unlikely to be large right to left shunting as this would cause hypoxaemia/cyanosis which does not correct with oxygen supplementation.

The oxygen dissociation curve is shifted to the right in acute acidosis, i.e. haemoglobin has a decreased affinity for oxygen.

High pulmonary pressures would be expected after this arrest scenario, as the pulmonary arterioles constrict in response to hypoxia.

[Q: 3163] OnExamination 2012 - Respiratory

The parents of a child with cystic fibrosis (CF) consult you wishing to know what is the risk of their next child being a carrier of the condition.

Which one of the following percentages is the correct risk?

- 1- 0%
- 2- 25%
- 3- 50%
- 4- 75%
- 5- 100%

Answer & Comments

Answer: 3- 50%

As both parents are carriers of the CF gene then the chance of another child being affected (homozygote) is 1 in 4 (25%).

The chance of their child being free from the CF gene is also 1 in 4 (25%) and the chance of a child being a carrier (heterozygote) is 1 in 2 (50%).

[Q: 3164] OnExamination 2012 - Respiratory

A 24-year-old asthmatic female is admitted with acute severe asthma.

Which of the following statements regarding the diagnosis is correct?

- 1- A high inspired oxygen concentration should be used routinely
- 2- Agitation should be managed with a benzodiazepine
- 3- Inhaled salmeterol is indicated as first line therapy
- 4- Normal arterial pCO₂ is reassuring
- 5- Pulsus paradoxus is a reliable sign of severity

Answer & Comments

Answer: 1- A high inspired oxygen concentration should be used routinely

A normal or raised arterial pCO₂ is an indication of severe asthma.

Pulsus paradoxus is not reliable and is not part of the criteria in assessing severity of asthma attack.

Salmeterol is used in management of chronic asthma (step 3).

High dose oxygen (40-60%) should be used in severe asthma attack, together with steroids and nebulised bronchodilators.

Sedation must be avoided as it can cause respiratory failure and arrest.

[Q: 3165] OnExamination 2012 - Respiratory

A 37-year-old patient presents with dyspnoea and right pleuritic chest pain.

He previously had right pneumothorax eight months ago for which he had a chest drain. He works as plumber. He is an ex-smoker.

On examination he had decreased air entry on right side and hyper-resonance. A CXR confirms a large pneumothorax. A chest drain was inserted and the lung completely re-expanded.

What is the best plan of action?

- 1- Advise bed rest for two weeks and then repeat CXR
- 2- Chemical pleurodesis through the chest drain
- 3- Recheck if he still smokes and advise to quit.
- 4- Remove drain and discharge
- 5- Video assisted thoracoscopic surgery

Answer & Comments

Answer: 5- Video assisted thoracoscopic surgery

Video assisted thoracoscopic surgery is indicated in:

Second ipsilateral pneumothorax

Bilateral spontaneous pneumothorax

Spontaneous haemothorax

Persistent air leak (more than five to seven days of drainage)

Certain occupations, for example, pilots or divers.

Chemical pleurodesis is used in older patients with recurrent pneumothorax, where surgery

would be high risk. Failure rates can be 10-20%.

[Q: 3166] OnExamination 2012 - Respiratory

A 26-year-old patient presented to the Emergency department with severe shortness of breath.

His BP drops to 80/50 mmHg. He is tachycardic and apyrexial. His O₂ sat is 74%. Examination has revealed raised JVP and trachea deviated to the left side.

What is the immediate next step?

- 1- Aspirate left side of chest using a large bore cannula
- 2- Insert a chest drain on the left side
- 3- Insert a chest drain on the right side
- 4- Request an urgent portable CXR and administer high flow O₂ while waiting
- 5- Request urgent arterial blood gases

Answer & Comments

Answer: 3- Insert a chest drain on the right side

Pneumothorax can be classified as either primary or secondary. However, more important in this case is the presence of tension.

Tension pneumothorax results from progressive build-up of air within the pleural space, which is not able to return. This build-up of pressure pushes the mediastinum to the opposite hemithorax and obstructs venous return. The patient then develops severe breathlessness, hypotension, mediastinal shift and, ultimately, cardiac arrest (often electromechanical dissociation: PEA). The classical signs of a tension pneumothorax are deviation of the trachea away from the side of tension, hyper-expanded chest that moves minimally with respiration and increased percussion note. JVP may be raised. However,

more commonly the only signs are tachycardia, tachypnoea and hypoxia.

Management of tension pneumothorax is immediate chest decompression with needle thoracostomy. A 14-16G intravenous cannula is inserted into the second rib space in the mid-clavicular line, on the side of the pneumothorax. By acting as a valve, this converts a tension pneumothorax into a simple pneumothorax.

Definitive treatment of a tension pneumothorax is chest drain insertion. This is usually done in the Emergency department with ultrasound guidance. Once the pleura is entered, the tension is relieved and the remainder of the procedure can be undertaken with less time pressure.

In this case, the option of needle thoracostomy is on the incorrect side, so the correct option is inserting a chest drain on the right side. High-flow oxygen is indicated whilst performing this, and chest x-ray should be ordered to check the position of the drain. Arterial blood gases may be indicated once the drain is in situ.

Although the above explanation remains correct for the MRCP examination, it is important to be aware that there has been discussion about the use of needle thoracostomy in the medical literature. It has been shown that on occasion it is ineffective in relieving a tension pneumothorax, especially in patients who have very thick chest walls. In addition they are prone to blockage, kinking and dislodging, and can cause a lung laceration which subsequently can lead to air embolisation (especially if a pneumothorax was not present). Some groups are therefore recommending an urgent chest x-ray if there is no haemodynamic compromise.

[Q: 3167] OnExamination 2012 - Respiratory

A 62-year-old man comes to the respiratory clinic. He was diagnosed with COPD several years ago.

He is on regular steroid inhalers, long acting B2 agonist and ipratropium. He has been discharged from hospital following an infective exacerbation two weeks ago.

On examination he is afebrile and his chest is clear. His FEV₁ is 1.2 L. His blood gases on air show the following:

pH 7.4(7.35-7.45)

pCO₂ 5.5 kPa (4.7-6.0)

paO₂ 7.3 kPa (11.3-12.6)

He stopped smoking six months ago.

Which of the following will you consider?

- 1- Discharge from clinic
- 2- Give a course of oral steroids
- 3- Prescribe oral antibiotics
- 4- Repeat blood gases on air in three months
- 5- Start LTOT (long term oxygen therapy).

Answer & Comments

Answer: 4- Repeat blood gases on air in three months

Indications of LTOT in the United Kingdom:

PO₂ <7.3 kPa on air (O₂ saturation <88%) in a stable clinical state. Borderline results should be repeated in three months.

PO₂ 7.3 - 8 kPa if there is pulmonary hypertension, polycythaemia, or additional nocturnal hypoxaemia.

Blood gases should be performed in a stable state, which should be at least four weeks after an exacerbation of the disease.

There is no indication in this scenario for steroids or antibiotics.

[Q: 3168] OnExamination 2012 - Respiratory

A 25-year-old Afro-Caribbean patient presents to the GP with a progressive history of dyspnoea and a cough.

She is initially treated for possible asthma but this fails to alleviate symptoms. The GP organises a CXR and spirometry. The CXR is reported as bilateral hilar lymphadenopathy and upper lobe pulmonary infiltrates.

On review in the chest clinic, spirometry shows a mild restrictive defect and serum angiotensin converting enzyme (SACE) is positive. She is diagnosed with pulmonary sarcoidosis.

What is the stage (radiological) of her disease?

- 1- Stage 0
- 2- Stage I
- 3- Stage II
- 4- Stage III
- 5- Stage IV

Answer & Comments

Answer: 3- Stage II

Chest x ray is abnormal in 85% of lung sarcoid, but 30-60% are asymptomatic (that is, incidental chest x ray finding).

Stage	Finding	Likelihood of spontaneous resolution
0	Normal chest radiograph	>90%
I	Bilat hilar lymphadenopathy (BHL)	60-90%
II	BHL plus pulmonary infiltrates	40-60%
III	Pulmonary infiltrates (no BHL)	10-20%
IV	Pulmonary fibrosis (+/- bullae)	<20%

[Q: 3169] OnExamination 2012 - Respiratory

A 17-year-old patient with known atopic asthma presents to the Emergency department with an acute asthma attack.

He had been over at his friend's house playing with his dog about 10 minutes before he felt wheezy and short of breath. He is given bronchodilators and has a good response. He is discharged later that day following a period of observation with an asthma management plan.

Which of the below immunomodulators is involved in this immediate response (bronchoconstriction)?

- 1- Eosinophil catatonic protein (ECP)
- 2- Leukotriene C4 (LTC4)
- 3- Major basic protein (MBP)
- 4- Platelet activating factor (PAF)
- 5- TH2 lymphocytes

Answer & Comments

Answer: 2- Leukotriene C4 (LTC4)

Inhalation of allergens by individuals with atopic asthma initiates an immediate bronchoconstriction reaction. This usually subsides within two hours and is reversible with bronchodilators.

This is an example of type I hypersensitivity and is caused by degranulation of mast cells and release of histamine, prostaglandin D2 and leukotriene C4 and D4.

The other immunomodulators listed form part of the late phase (or type IV hypersensitivity) response which results in bronchoconstriction, airways inflammation, hyper-responsiveness and oedema. This typically occurs three to 12 hours after the immediate response and is less susceptible to bronchodilators.

The increased hypersensitivity may promote recurrent asthma attacks over the following days.

[Q: 3170] OnExamination 2012 - Respiratory

A known case of chronic obstructive pulmonary disease (COPD) presents to the Emergency department, distressed and cyanosed.

Arterial blood gases reveal:

pH 7.2(7.36-7.44)

paO₂ 8.3 kPa(11.3-12.6 kPa)

paCO₂ 10 kPa(4.7-6.0 kPa)

He is given high concentration oxygen together with a salbutamol nebuliser. Intravenous hydrocortisone is also given.

The patient becomes even worse with poorer breathing effort although pulse oximetry showed SaO₂ of 93%.

What is the cause of patient's deterioration?

- 1- Constriction of bronchioles in response to salbutamol nebuliser
- 2- High concentration oxygen administration
- 3- Pulmonary artery relaxation causing mismatch between perfusion and ventilation
- 4- Pulmonary vein relaxation causing mismatch between perfusion and ventilation
- 5- Reaction to IV hydrocortisone

Answer & Comments

Answer: 2- High concentration oxygen administration

The patient was suffering from hypoxia and hypercapnia as a result of acute exacerbation of COPD.

His respiratory centre was solely stimulated by hypoxia. That is why his respiratory effort

became less and the condition worsened when he was given high concentration oxygen, depriving him of hypoxic drive.

[Q: 3171] OnExamination 2012 - Respiratory

A 45-year-old female presents with a six month history of exertional dyspnoea and is diagnosed with pulmonary fibrosis (PF).

Over the last one year she has received a variety of medications.

Which of the following drugs could be responsible?

- 1- Dexamethasone
- 2- Ibuprofen
- 3- Nalidixic acid
- 4- Penicillamine
- 5- Sulfasalazine

Answer & Comments

Answer: 5- Sulfasalazine

Sulfasalazine as well as other rheumatology drugs such as gold and methotrexate can cause pulmonary fibrosis.

Bleomycin and cyclophosphamide rather than vincristine may be responsible.

Corticosteroids are sometimes given as a trial in pulmonary fibrosis.

Nalidixic acid is associated with seizures and visual disturbances. However nitrofurantoin is well recognised to cause PF.

Other drugs include amiodarone and nitrofurantoin.

[Q: 3172] OnExamination 2012 - Respiratory

A 56-year-old female presents with a six month history of deteriorating non-productive cough and exertional dyspnoea.

On examination she is noted to be cyanosed, has clubbing of the fingers and there are bilateral basal crackles.

A chest x ray reveals bilateral basal shadowing and pulmonary investigations show:

paO₂ (on air) 8.5 kPa (11.5-12.5)

FEV₁/FVC ratio 85%

Which one of the following investigations is most likely to establish the diagnosis?

- 1- Bronchoalveolar lavage
- 2- Chest CT scan
- 3- Diffusion capacity studies
- 4- Echocardiography
- 5- Serum ACE level

Answer & Comments

Answer: 2- Chest CT scan

This patient has restrictive lung disease, most likely cryptogenic fibrosing alveolitis. The cardinal features are breathlessness and cyanosis; clubbing occurs in two-thirds of cases.

She is hypoxic on air, has a restrictive ventilatory defect, and a high resolution CT scan of the chest will show typical changes.

[Q: 3173] OnExamination 2012 - Respiratory

A 60-year-old woman presents with deteriorating dyspnoea and cough productive of a purulent sputum. She has a two year history of recurrent chest infections and is a smoker of 15 cigarettes daily for the last 30 years.

On examination, she appeared breathless with a pulse of 100 bpm and her temperature was 39°C.

Investigations revealed:

Haemoglobin 19.5 g/dl(11.5-16.5)

White cell count 15.7 x 10⁹/L (4-11)

Platelet count $350 \times 10^9/L$ (150-400)

paO₂ 6.8 kPa (11.3-12.6)

CarboxyHaemoglobin 15.5%(3-15)

Red cell mass 147%(75-125)

What is the most likely explanation for these findings?

- 1- Chronic obstructive airways disease
- 2- Ectopic erythropoietin production
- 3- Myelofibrosis
- 4- Primary polycythaemia
- 5- Pseudo-polycythaemia

Answer & Comments

Answer: 1- Chronic obstructive airways disease

This patient has polycythaemia which is likely to be secondary to her hypoxia.

The cause of the hypoxia is most likely to be due to chronic obstructive pulmonary disease as a result of her heavy smoking history. Her history of increasing breathlessness, cough and sputum production and recurrent chest infections is consistent with this diagnosis.

The treatment is for her to stop smoking and long term oxygen therapy (LTOT) (that is, oxygen for more than 15 hours/day), should the hypoxia be confirmed when fully recovered from this exacerbation.

The indications for LTOT are:

paO₂ < 7.3 kPa (55 mmHg) or

paO₂ < 8.0 kPa (60 mmHg)

with evidence of pulmonary hypertension, peripheral oedema or polycythaemia.

[Q: 3174] OnExamination 2012 - Respiratory

A 15-year-old boy presented with wheezing when playing football and nocturnal cough.

Which is the best test to confirm the underlying condition?

- 1- A trial of inhaled corticosteroids
- 2- A trial of inhaled salbutamol
- 3- A trial of oral corticosteroids
- 4- Serial peak expiratory flow rate measurements
- 5- Spirometry alone

Answer & Comments

Answer: 4- Serial peak expiratory flow rate measurements

Demonstration of variable obstruction of the airways provides good evidence for asthma, with its characteristic morning dips.

Failure to respond to bronchodilator therapy does not exclude asthma as response may be small in children, and in adults with persistent or more severe asthma.

Those who fail to respond to inhaled bronchodilator require a steroid trial (either four weeks of high dose inhaled steroids or two weeks of oral prednisolone).

[Q: 3175] OnExamination 2012 - Respiratory

Which of the following is a recognised cause of a phrenic nerve palsy?

- 1- Aortic aneurysm
- 2- Dermoid
- 3- Ganglioneuroma
- 4- Pericardial cyst
- 5- Sarcoidosis

Answer & Comments

Answer: 1- Aortic aneurysm

The diaphragm is innervated by the phrenic nerve (C3,4,5).

Palsy is a recognised complication of thoracic surgery, infection, Guillain-Barre or invasion by an adjacent tumour.

It may also be stretched by an aortic aneurysm.

[Q: 3176] OnExamination 2012 - Respiratory

A 61-year-old man presents with a four day history of dry cough and increasing confusion. He has also suffered diarrhoea and headaches which have increased in severity over the past day.

Past history of hypertension for which he takes perindopril and indapamide is noted as is recent travel to a medical convention in Spain.

On examination his BP is 110/70 mmHg, pulse is 92, he is pyrexial 38.2 C. There are coarse basal crackles bilaterally and signs of a left sided pleural effusion.

Investigations show:

Haemoglobin 13.7 g/dl(13.5-17.7)

White cell count $11.9 \times 10^9/L$ (4-11)

Platelets $173 \times 10^9/L$ (150-400)

Sodium 133 mmol/l (135-146)

Potassium 4.8 mmol/l (3.5-5)

Creatinine 132 micromol/l (79-118)

Alanine aminotransferase 180 U/l (5-40)

Alkaline phosphatase 220 U/l (39-117)

CXR - Patchy bilateral consolidation, left pleural effusion.

Which of the following is the best treatment for him?

- 1- Benzyl penicillin
- 2- Ciprofloxacin
- 3- Clarithromycin
- 4- Doxycycline
- 5- Rifampicin

Answer & Comments

Answer: 3- Clarithromycin

The history of recent travel to a convention, coupled with pneumonia with patchy consolidation, a pleural effusion, hyponatraemia, diarrhoea and non-specific LFT changes raises the possibility of legionnaire's disease.

Macrolides are appropriate first line therapy for the condition, therefore clarithromycin is the logical first choice antibiotic.

Legionella is not sensitive to penicillin, therefore benzyl penicillin is an inappropriate choice in this case.

Both doxycycline and ciprofloxacin are reasonable second line choices for the treatment of Legionella.

Legionella resistance to rifampicin is noted, therefore this is not a first line option.

A small recent study also noted increased liver function abnormalities in patients with legionnaire's exposed to rifampicin.

[Q: 3177] OnExamination 2012 - Respiratory

A 45-year-old woman solicitor presents with shortness of breath and a dry cough. She has been treated by her GP with a salbutamol inhaler but tells you that this has made no difference at all to her symptoms.

In addition she has an itchy raised rash on both shins. On examination her BP is 145/82 mmHg, pulse is 80 and regular. Her BMI is 28. Lungs appear normal on auscultation. There is a rash on her shins consistent with erythema nodosum.

Which of the following investigations is most likely to confirm the diagnosis?

- 1- AAFB staining
- 2- Bronchoalveolar lavage
- 3- CT thorax

4- Serum ACE

5- Transbronchial biopsy

Answer & Comments

Answer: 5- Transbronchial biopsy

AAFB staining would be confirmatory for a diagnosis of tuberculosis.

Given this woman is a solicitor, it is less likely she has had significant TB exposure versus sarcoidosis.

Bronchoalveolar lavage may demonstrate increased lymphocytes, although this is a non-specific finding.

Serum ACE is raised in 60% of patients with sarcoidosis.

Transbronchial biopsy is therefore the definitive route to confirming the diagnosis

[Q: 3178] OnExamination 2012 - Respiratory

A 72-year-old ex-miner with a significant smoking history and proven diagnosis of COPD, is attending chest clinic for review. He currently takes only a short acting beta agonist (salbutamol).

His last FEV₁ was 45%. He feels his symptoms are not currently controlled on his current drug regime.

According to the latest guidelines, what changes should be made to his medication?

- 1- Inhaled corticosteroid (ICS)
- 2- Long acting beta agonist (LABA)
- 3- Long acting beta agonist and inhaled corticosteroid
- 4- Long acting beta agonist and inhaled corticosteroid and long acting muscarinic agonist.
- 5- Long acting muscarinic agonist (LAMA) and long acting beta agonist

Answer & Comments

Answer: 3- Long acting beta agonist and inhaled corticosteroid

NICE have recently published guidelines for the management of chronic obstructive pulmonary disease (COPD).

Initially a short acting beta agonist or a short acting muscarinic agonist is advised. However if the patient is persistently breathless or has exacerbation, then additional therapy should be offered.

This will depend on the FEV₁. If greater than 50%, NICE recommends the addition of either a LABA or LAMA. If FEV₁ is less than 50%, NICE recommends either a LABA plus an inhaled corticosteroid (in a combination device) or a LAMA.

If exacerbations continue despite this management, then a combination of all three (LABA, ICS and LAMA) should be trialled.

Full guidelines can be found at:

<http://www.nice.org.uk/nicemedia/live/13029/49399/49399.pdf>

[Q: 3179] OnExamination 2012 - Respiratory

A 19-year-old girl with known cystic fibrosis is under regular follow up at her local specialist centre.

Which one the following conditions associated with cystic fibrosis is she most likely also to have?

- 1- Biliary cirrhosis
- 2- Infertility
- 3- Nasal polyps
- 4- Pancreatic Insufficiency
- 5- Sinusitis

Answer & Comments

Answer: 4- Pancreatic Insufficiency

Pancreatic insufficiency is very common, with 85% of patients affected.

Almost all male CF patients will be infertile; but there is only a 20% incidence amongst female patients. Almost 100% of children with cystic fibrosis will have delayed development and puberty.

Biliary cirrhosis is far rarer with approximately 5% of adults affected.

Dysfunctional gallbladder and gallstones can be seen in 10-30% of cases.

Symptomatic sinusitis is seen in 10% of children and 20% of adult patients.

Nasal polyps are less common with an estimated incidence of 15-20% (most of these occurring in the second decade).

Other associated conditions include vitamin D deficiency resulting in bone demineralisation, hypertrophic osteoarthropathy and rectal prolapse.

[Q: 3180] OnExamination 2012 - Respiratory

A 65-year-old man with severe COPD is suspected of having pulmonary hypertension (PH) secondary to his underlying lung disease. Following an echocardiogram which was inconclusive, a right heart catheterisation is organised.

Which of the listed values of mean arterial pressure taken at rest is the lowest value associated with a diagnosis of pulmonary hypertension?

- 1- >10 mmHg
- 2- >14 mmHg
- 3- >18 mmHg
- 4- >20 mmHg
- 5- >25 mmHg

Answer & Comments

Answer: 5- >25 mmHg

Pulmonary hypertension is defined as a mean pulmonary arterial (PA) pressure of more than 25 mmHg at rest or more than 30 mmHg during exercise. The normal value is 14 mmHg.

A rise in PA pressure can be due to increased pulmonary vascular resistance (for example, embolism or hypoxia), pulmonary blood flow and back pressure (as seen in left heart failure).

It is most commonly caused by another disorder (secondary PH).

However it may be a disorder of the pulmonary circulation itself (pulmonary arterial hypertension), although this is less common.

[Q: 3181] OnExamination 2012 - Respiratory

A 32-year-old presents to the Emergency department of her local hospital.

She is complaining of increasing breathless on exertion over the last few weeks. She also reports a dry cough and occasional night sweats. Of note, she is under the care of the infectious disease team for HIV and is also 28 weeks pregnant.

Examination reveals that she is hypoxic, with her oxygen saturations falling still when she is asked to walk. A departmental chest x ray demonstrates bilateral infiltrates.

What is the most appropriate antibiotic treatment for this patient given the likely diagnosis?

- 1- Amphotericin
- 2- Clindamycin and primaquine
- 3- Pentamidine
- 4- Rifampicin, ethambutol, isoniazid, pyrazinamide
- 5- Trimethoprim sulfamethoxazole (TMP-SMX)

Answer & Comments

Answer: 5- Trimethoprim sulfamethoxazole (TMP-SMX)

Although Pneumocystis pneumonia (PCP) is officially a fungal infection it does not respond to anti-fungal medications.

Trimethoprim-sulfamethoxazole (TMP-SMX/ co-trimoxazole/ Septrin) has been shown to be as effective as intravenous pentamidine and more effective than other alternative treatment regimens.

TMP-SMX is the preferred initial therapy during pregnancy according to consensus guidelines.

For the treatment of infections that are resistant to TMP-SMX, the combination of clindamycin and primaquine is likely to be more effective than intravenous pentamidine¹.

Rifampicin, ethambutol, isoniazid, pyrazinamide are the first line drugs to treat tuberculosis (TB). Although this woman is at risk from TB infection, the clinical history is more in keeping with a diagnosis of PCP.

Adjuvant steroid therapy is indicated in patients with severe PCP infection who have underlying HIV infection.

Pneumocystis (carinii) jiroveci Pneumonia emedicine.

[Q: 3182] OnExamination 2012 - Respiratory

A 36-year-old man complains of a persistent cough.

A CXR shows fibrosis of both upper lobes.

What is the most likely diagnosis?

- 1- Allergic bronchopulmonary aspergillosis
- 2- Ankylosing spondylitis
- 3- Cystic fibrosis
- 4- Primary pulmonary hypertension

5- Systemic sclerosis

Answer & Comments

Answer: 1- Allergic bronchopulmonary aspergillosis

The persistent cough is likely to be a symptom of asthma.

On the other hand, only about 1% of patients with advanced ankylosing spondylitis develop apical fibrosis, that is, it is rare. Even then, early lesions are asymptomatic.

It is only when cavitation develops that symptoms like cough, infected sputum and haemoptysis start.

With ABPA, fibrosis and loss of volume in the upper lobes are common. Within these upper lobes, there may be bronchiectasis.

[Q: 3183] OnExamination 2012 - Statistics

A large multi-centre secondary prevention study reports a reduction in the annual incidence of recurrent subarachnoid haemorrhage from 10% in a medically treated group to 6% in the group treated with medical therapy plus radiological intervention ($p < 0.005$). The additional cost of the new treatment is £3000 per patient.

In the first year of treatment, what would be the predicted additional cost of preventing a single recurrent subarachnoid haemorrhage?

- 1- £3000
- 2- £12 000
- 3- £30 000
- 4- £75 000
- 5- £90 000

Answer & Comments

Answer: 4- £75 000

This study shows that annual rate of recurrent subarachnoid haemorrhage is reduced from 10% to 6%.

Therefore, if you treated 100 patients for one year you would expect 10 patients with subarachnoid haemorrhage in the medically treated group versus six patients in the medical plus radiological intervention group - a reduction of four patients per hundred.

Therefore you would need to treat 25 patients (4/100) to expect one less case of subarachnoid haemorrhage.

Thus the extra cost of this would be $25 \times 3000 = £75\,000$.

[Q: 3184] OnExamination 2012 - Statistics

A new treatment for osteoarthritis has been developed and shown to be effective in animal

models plus its effects in small numbers of patients appears promising.

However, there are some concerns with regard to possible hepatotoxicity but no cases have been observed in studies thus far.

Which is the most appropriate next step in this drug's development?

- 1- Case control study
- 2- Double blind randomised placebo controlled study
- 3- Drug development should be suspended due to the hepatotoxicity
- 4- Open label study
- 5- Single blind randomised placebo controlled study

Answer & Comments

Answer: 2- Double blind randomised placebo controlled study

This drug has completed animal trials and has been tested in human volunteers (phase 1) and has also been tried in patients (phase 2).

Thus the next stage in its development is a phase 3 study and the best phase 3 study would be a randomised control study.

[Q: 3185] OnExamination 2012 - Statistics

A study of an established antihypertensive agent against placebo reports that the risk of death due to cardiac causes is lower on treatment.

It gives five year mortality due to cardiac causes as 12% on placebo and 8% on treatment. The authors conclude that 'a 33% reduction in cardiac deaths is seen with treatment'.

The figure '33%' represents which of the following?

- 1- Absolute risk reduction
- 2- Control event rate

- 3- Experimental event rate
- 4- Number needed to treat
- 5- Relative risk reduction

Answer & Comments

Answer: 5- Relative risk reduction

An understanding of quantities discussed in 'evidence-based medicine' is becoming increasingly important for the examination.

If a drug reduces the incidence of heart attacks from 12% to 8% then:

The control event rate (CER) is 12%

The experimental event rate (EER) is 8%

The relative risk reduction (RRR) is 33% $[(EER - CER) / CER] \times 100$

The absolute risk reduction (ARR) is 4% $(CER - EER)$

The number needed to treat (NNT) is 25 $[1 / ARR] \times 100$

[Q: 3186] OnExamination 2012 - Statistics

In significance testing which of these statements is correct?

- 1- A type I error is to reject the alternative hypothesis when it should be accepted.
- 2- A type II error is to accept the alternative hypothesis when it should be rejected.
- 3- The probability associated with a type I error is the significance level.
- 4- The significance level is determined at the end of a significance test.
- 5- The significance level is always set to 5%.

Answer & Comments

Answer: 3- The probability associated with a type I error is the significance level.

The null hypothesis is that there is no difference between two groups.

The alternative hypothesis is that there is a difference.

Rejecting the null hypothesis when there really is no difference between the two groups is a type 1 error.

Accepting the null hypothesis (rejecting the alternative hypothesis) when there is a difference is a type 2 error.

Rejection of the null hypothesis depends on the probability - significance level which is usually (but not always) at $p < 0.05$.
Hypothesis testing

[Q: 3187] OnExamination 2012 - Statistics

A study of the intellectually handicapped was performed.

The 112 subjects put through programme A showed an increase in their mean IQ score of 6 points.

The 115 subjects put through programme B showed an increase in their mean IQ score of 4.

The p value was >0.05 .

Which of the following is true?

- 1- The numbers are too large for a Student's t test
- 2- The study demonstrates the usefulness of programme A
- 3- The distribution of individual values is not important
- 4- Even though the difference between the means is not significant it would be appropriate to calculate confidence intervals
- 5- The above results would be found by chance in less than 1:20

Answer & Comments

Answer: 4- Even though the difference between the means is not significant it would be appropriate to calculate confidence intervals

A. The t test could be used in the comparison of data and the larger the sample size the more meaningful the data.

B. A is no more useful than B or even simply repeating an IQ test.

C. and D. This gives us an idea of the distribution of the data. Confidence intervals may provide more meaningful data concerning the study.

E. The chances are greater than 1 in 20 as P is greater than 0.05.

[Q: 3188] OnExamination 2012 - Statistics

A publication assesses a new diagnostic test for thyroid cancer.

Which of the following terms would reflect the number of cases of thyroid cancer correctly identified by this new test?

- 1- Accuracy
- 2- Negative predictive value
- 3- Positive predictive value
- 4- Sensitivity
- 5- Specificity

Answer & Comments

Answer: 4- Sensitivity

The specificity of a test is the probability that a test will produce a true negative result when used on an unaffected population.

The sensitivity of a test is the probability that it will produce a true positive result when used on an affected population (as determined by a reference or "gold standard").

The positive predictive value of a test is the probability that a person is affected when a positive test result is observed.

The negative predictive value of a test is the probability that a person is not affected when a negative test result is observed.

Accuracy is expressed through the above four parameters.

[Q: 3189] OnExamination 2012 - Statistics

A new antiplatelet agent has been proven to reduce the risk of stroke in a year from 10% in patients treated with conventional treatment to 6% in patients treated with conventional treatment plus the new agent.

The cost of this new drug is £100 per month.

How much extra would a hospital need to spend to prevent one stroke?

- 1- £1200
- 2- £6000
- 3- £18000
- 4- £30000
- 5- £100000

Answer & Comments

Answer: 4- £30000

The 'absolute risk reduction' is $10\% - 6\% = 4\%$.

The 'number needed to treat' to prevent a stroke therefore equals $100 / 4 = 25$.

25 patients would need to be treated at a cost of £100/month for 12 months to prevent a stroke which gives the total cost as £30 000.

[Q: 3190] OnExamination 2012 - Statistics

In a study of elderly patients with atrial fibrillation, patients receiving warfarin (n=6000), 6% had strokes or died as a consequence of stroke, whereas in subjects

treated with aspirin (n = 8000), 9% had strokes or death from a stroke over the three year study period (p=0.001). The risk of stroke in an untreated population with atrial fibrillation over this time was 12%.

Which of the following percentages is the approximate annual incidence of stroke in the treated population in this study?

- 1- 2.6%
- 2- 3.3%
- 3- 5.5%
- 4- 6.9%
- 5- 7.7%

Answer & Comments

Answer: 1- 2.6%

One needs to calculate the incidence as follows:

In the group treated with warfarin there were 360 strokes (6% of 6000).

In the aspirin treated group there were 720 strokes (9% of 8000).

Thus, there are 1080 strokes amongst the treated population (n=14000) over a three year time period.

Therefore there are 360 strokes annually in the treated group (14000) giving an annual incidence of stroke of approximately 2.6%

Note: remember to divide by three since the study lasted three years and the figures given are for the three years incidence rates.

[Q: 3191] OnExamination 2012 - Statistics

A new test is developed for the diagnosis of HIV.

Blood from 10,000 patients was analysed by the gold standard technique and by the new method. There were 100 positive results with

the gold standard technique but there were 150 positive results using the new technique.

Approximately which of the following values reflects the positive predictive value of the new technique?

- 1- 33%
- 2- 50%
- 3- 66%
- 4- 75%
- 5- 90%

Answer & Comments

Answer:

It cannot be determined Correct

The positive predictive value is number of true positives/(no of true positives + false positives).

There are 100 people tested positive with gold standard. However, we don't know how many of these are tested positive and how many are tested negative by the new techniques. Similarly, we don't know the number of people tested positive or negative by the gold standard among the 150 people tested positive by the new technique. Therefore, the number of true positives and false positives and hence the positive predictive value cannot be determined.

[Q: 3192] OnExamination 2012 - Statistics

In a study of 1000 subjects with adrenal incidental tumours a new serological marker for adrenal carcinoma was assessed against formal histology.

The following results were obtained:

Test positive Test negative

Histology positive 40 10

Histology negative 50 900

To what does the specificity approximate?

- 1- 50%
- 2- 60%
- 3- 70%
- 4- 80%
- 5- 90%

Answer & Comments

Answer: 5- 90%

Sensitivity relates to the probability that the person with a disease will be correctly identified with the disease.

Therefore in this study 50 subjects have adrenal carcinoma of whom 40 are correctly identified with the disease giving a sensitivity of 80%.

The specificity is the probability that a person without the disease will be correctly identified by the test.

In this case there are 950 subjects without adrenal carcinoma of whom 900 were identified by the test - giving a specificity of ~95%.

Summary of sensitivity and specificity as defined by contingency tables.

[Q: 3193] OnExamination 2012 - Statistics

In a study of elderly patients with atrial fibrillation, patients receiving warfarin (n = 6000), were found to have a rate of stroke of 6%, whereas subjects treated with aspirin (n = 8000), had a stroke rate of 9.9% over the 3 year study period (p = 0.001). The risk of stroke in an untreated population with atrial fibrillation over this time was 12%.

To what do these numbers relate?

- 1- Absolute risk
- 2- Incidence
- 3- Odds risk
- 4- Prevalence

- 5- Relative risk

Answer & Comments

Answer: 2- Incidence

These numbers relate to the INCIDENCE of stroke occurring in the three populations over a specified period of time.

Prevalence is the numbers of patients with a specified disorder at any one time point.

Absolute risk reduction refers to the reduction in the number of patients with stroke following a specific intervention, e.g. ARR of stroke with warfarin vs aspirin is 3.3% over 3 years.

Relative risk reduction is $3.3 / 9.9 \times 100 = 33\%$.

[Q: 3194] OnExamination 2012 - Statistics

Which of the following are correct concerning an intention to treat analysis?

- 1- It is a study comparing the effects of treatment with placebo or active treatment and also a similar group of non-study participants
- 2- It is a study that analyses all patients randomised to the study
- 3- It is a study where all included patients are treated with the active drug
- 4- It is a study where all non-compliant patients are removed from analysis
- 5- It is a variation of a meta-analysis analysing specifically studies employing double blind placebo controlled trials

Answer & Comments

Answer: 2- It is a study that analyses all patients randomised to the study

When one considers a randomised study, although the principles of double blind placebo controlled may apply, the actual

preferential fall out of patients, for instance treated with placebo as they do not perceive a benefit, may itself introduce bias.

Thus, intention to treat studies would argue that one should commit all patients that originally participate in the study to analysis.

The advantages of this approach are that it maintains treatment groups that are similar apart from random variation. This is the reason for randomisation, and the feature may be lost if analysis is not performed on the groups produced by the randomisation process.

Secondly, it permits for non-compliance and deviations from policy by clinicians.

[Q: 3195] OnExamination 2012 - Statistics

In a study of blood pressures in a specific ethnic population, the researcher is concerned that his spread of blood pressures is larger than that described in the general population.

Which of the following terms most appropriately describes the spread of blood pressures?

- 1- Mean
- 2- Median
- 3- Mode
- 4- Standard deviation
- 5- Standard error of the mean

Answer & Comments

Answer: 4- Standard deviation

Standard deviation is a measure of the spread of observations about the mean.

It is based on the deviation of each observation from the mean value.

Each value is squared, summed and divided by the total number of observations less one.

The standard deviation is the square root of this value.

[Q: 3196] OnExamination 2012 - Statistics

In a trial of statin therapy in the secondary prevention of ischaemic heart disease, therapy is shown to reduce cardiovascular mortality from 12% to 8% over the five years duration of the study.

In comparison with standard therapy, what is the number of patients that needs to be treated to prevent one death over five years?

- 1- 5
- 2- 10
- 3- 20
- 4- 25
- 5- 50

Answer & Comments

Answer: 4- 25

The drug has reduced the risk of death post myocardial infarction by 4% over five years.

Therefore if 100 people were treated we could expect the prevention of four deaths.

Therefore in order to prevent one death, 25 individuals would need to be treated.

[Q: 3197] OnExamination 2012 - Statistics

A letter to a medical journal suggested that an established antidepressant may cause photosensitivity. The manufacturer wished to set up a study to determine rapidly and efficiently whether this was a true association.

Which one of the following techniques is most appropriate?

- 1- A case-control study
- 2- A dose ranging study

- 3- A double blind, randomised, placebo controlled study
- 4- A meta-analysis
- 5- A sequential trial

Answer & Comments

Answer: 4- A meta-analysis

A sequential trial is one in which the data are analysed after each participant's results become available, and the trial continues until a clear benefit is seen in one of the comparison groups, or it is unlikely that any difference will emerge.

The main advantage of sequential trials is that they will be shorter than fixed length trials when there is a large difference in the effectiveness of the interventions being compared. Their use is restricted to conditions where the outcome of interest is known relatively quickly.

In a case-control study, patients who have developed a disease are identified and their past exposure to aetiological factors is compared with that of controls who do not have the disease.

A double-blind randomised placebo controlled study does not seem appropriate in this case, and a dose-ranging study would be used in the early stages of drug development to identify common side effects, perhaps toxicity, and threshold efficacy doses.

The most appropriate study would probably be a meta-analysis. This is because:

The drug is in the market place

Large studies will have taken place in order for it to obtain its licence so the data are available relatively rapidly (compared with the other options in this question)

The analysis could be carried out efficiently (cheaply if one were being cynical), and

The results of the trial would also be available rapidly.

[Q: 3198] OnExamination 2012 - Statistics

A publication describes a new diagnostic test for myocardial infarction.

You want to know what proportion of patients with a confirmed myocardial infarction will be identified by the test.

Which one of the following measurements would indicate this?

- 1- Accuracy
- 2- Negative predictive value
- 3- Positive predictive value
- 4- Sensitivity
- 5- Specificity

Answer & Comments

Answer: 4- Sensitivity

The specificity of a test is the probability that a test will produce a true negative result when used on an unaffected population, whereas the sensitivity of a test is the probability that it will produce a true positive result when used on an affected population (as determined by a reference or "gold standard").

The positive predictive value of a test is the probability that a person is affected when a positive test result is observed. The negative predictive value of a test is the probability that a person is not affected when a negative test result is observed.

Accuracy is expressed through the above four parameters.

[Q: 3199] OnExamination 2012 - Statistics

The upper and lower limit of normal, of a biochemical test in the hospital laboratory, is two standard deviations of the population.

What percentage of the population is represented by two standard deviations?

- 1- 85%
- 2- 95%
- 3- 97%
- 4- 99%
- 5- 99.7%

Answer & Comments

Answer: 2- 95%

If one assumes that there is a normal distribution of this test in the population, then:

One standard deviation includes 68% of the population

Two standard deviations include approximately 95% of the population

Three standard deviations include 99.7% of the population.

[Q: 3200] OnExamination 2012 - Statistics

In a study of 950 subjects with a BMI below 25 kg/m², a new serological marker for coeliac disease was assessed against the gold standard test of jejunal biopsy.

The following results were obtained:

	Test positive	Test negative
Biopsy positive	40	10
Biopsy negative	60	840

What is the sensitivity of this test?

- 1- 40%
- 2- 55%
- 3- 66%
- 4- 80%
- 5- 93%

Answer & Comments

Answer: 4- 80%

Sensitivity relates to the probability that the person with a disease will be correctly identified with the disease. Therefore, in this study, 50 subjects have the disease, of whom 40 are correctly identified with the disease giving a sensitivity of 80%.

The specificity is the probability that a person without the disease will be correctly identified by the test. In this case, there are 900 subjects without the disease of whom 840 were identified by the test - giving a specificity of 93%.

[Q: 3201] OnExamination 2012 - Statistics

There is presently no known effective treatment for a chronic disease.

A new treatment is known to be effective in animal models and shows promise in short term studies in patients. There are some theoretical concerns regarding possible hepato- and bone marrow toxicity although, thus far, no toxicity has been observed in studies.

What is the most appropriate next step in the drug's development?

- 1- A case-control study
- 2- A randomised double-blind placebo-controlled study
- 3- A randomised single-blind placebo-controlled study
- 4- An open study
- 5- No further studies should be done and drug development should be stopped

Answer & Comments

Answer: 2- A randomised double-blind placebo-controlled study

It appears that the drug has undergone animal testing and we can surmise that it has also been tested on normal volunteers (phase 1) as we are told that it has been tried in short term studies of patients (phase 2).

After this testing process comes phase 3 studies - broad clinical trials designed to determine whether the drug is of clinical benefit in the disease state.

In particular you wish to know whether the drug is effective or not and you wish to know its safety.

A double-blind placebo-controlled study would be best placed to provide this information.

[Q: 3202] OnExamination 2012 - Statistics

A trial is proposed to see whether excess alcohol use is a risk factor for osteoporosis.

It is decided to perform a case-control study rather than a cohort study.

Which of these is an advantage of a case-control study?

- 1- It can provide information on a wide range of outcomes
- 2- It is expensive to perform
- 3- It is possible to measure the incidence of a disease directly
- 4- It is possible to study diseases that are rare
- 5- The time sequence of events can be assessed

Answer & Comments

Answer: 4- It is possible to study diseases that are rare

A case-control study compares the characteristics of a group of patients with the disease with a control group of patients who do not have the disease.

Advantages of case-control studies are that:

They are particularly suitable for rare diseases

A wide range of risk factors can be investigated

There is no loss to follow up

They are relatively cheap and quick to perform.

Results are usually quoted as an odds ratio.

[Q: 3203] OnExamination 2012 - Statistics

In a study of 26,000 females, 1300 subjects were found to have either overt or subclinical hypothyroidism.

Within this group, the risk of demonstrating either overt or subclinical hypothyroidism was therefore 5%.

What is the best descriptive term of this 5% risk?

- 1- Absolute risk
- 2- Incidence
- 3- Prevalence
- 4- Relative risk
- 5- Specificity

Answer & Comments

Answer: 3- Prevalence

This is the risk of either subclinical or overt hypothyroidism in a female population at any specific time which is the prevalence. This is defined as the rate of a disorder in a specified population at a specified time.

Incidence refers to the number of new cases of a disorder developing over a specific time.

[Q: 3204] OnExamination 2012 - Statistics

In a study of 1000 patients with autoimmune hepatitis a new serological test for the disease was assessed against diagnostic liver biopsy.

The following results were obtained:

	Test positive	Test negative
Histology positive	80	20
Histology negative	100	800

To what does the sensitivity of the new test approximate?

- 1- 50%
- 2- 60%
- 3- 70%
- 4- 80%
- 5- 90%

Answer & Comments

Answer: 4- 80%

Sensitivity relates to the probability that the person with a disease will be correctly identified with the disease.

Therefore in this study 100 subjects have autoimmune hepatitis of whom 80 are correctly identified with the new test giving a sensitivity of 80%.

The specificity is the probability that a person without the disease will be correctly identified by the test.

In this case, there are 900 subjects without autoimmune hepatitis of whom 800 were identified by the test - giving a specificity of ~89%.

Summary of sensitivity and specificity as defined by contingency tables.

[Q: 3205] OnExamination 2012 - Statistics

In a study to find out if concentration of drug X is related to weight, subjects were given 500 mg of the drug and serum levels were measured two hours later.

Which of the following is the best statistical test to evaluate the results?

- 1- Chi squared test
- 2- Log regression analysis
- 3- Pearson's coefficient
- 4- Student's paired t test
- 5- Student's unpaired t test

Answer & Comments

Answer: 3- Pearson's coefficient

Drug concentrations are measured two hours after consumption and the variable of weight is to be factored in on the drugs pharmacokinetics.

Therefore there are two variables to be compared and consequently the most appropriate statistical test would be Pearson's test.

Logistic regression is used to model dichotomous (0 or 1) outcomes. This technique models the log odds of an outcome defined by the values of covariates in your model.

[Q: 3206] OnExamination 2012 - Statistics

Which of the following would invalidate the use of the unpaired t test in the comparison of mean drug concentrations between two groups of subjects?

- 1- Insufficient statistical power
- 2- Non-normal distribution of data
- 3- Small sample size
- 4- Small standard error
- 5- Unequal sample sizes in both groups

Answer & Comments

Answer: 2- Non-normal distribution of data

The t test can only be used for parametric (normally distributed) data.

Insufficient statistical power as a consequence of numbers recruited would not invalidate the results of a t test.

It is probable that the results would be unlikely to show any difference with too few subjects, although it is possible that if the differences were large then irrespective of prior power calculations differences might be seen.

[Q: 3207] OnExamination 2012 - Statistics

A randomised double-blind placebo-controlled study of a cholesterol-lowering drug in the primary prevention of coronary heart disease was conducted over a five year follow up period. The absolute risk of myocardial infarction (MI) in the group receiving placebo during this time was 10%.

The relative risk of those given the cholesterol lowering medication was 0.8.

What number of patients will need to be treated with active drug for five years to prevent one myocardial infarction?

- 1- 20
- 2- 40
- 3- 50
- 4- 80
- 5- 100

Answer & Comments

Answer: 3- 50

The absolute risk of MI in the treatment group is $10\% \times 0.8 = 8\%$ (as they have a relative risk of 0.8 compared to the placebo group).

Number needed to treat (NNT) = $1 / \text{absolute risk reduction (ARR)}$.

ARR is the risk in control group - risk in treated group.

Therefore the ARR is $10\% - 8\%$ and the NNT for that period is $1 / 0.02 = 50$.

[Q: 3208] OnExamination 2012 - Statistics

Which of the following statements is correct regarding standard error of the mean (SEM) and standard deviation (SD)?

- 1- Standard deviation invariably falls with increasing sample size
- 2- Standard deviation may be greater than the mean even if all values are positive numbers
- 3- Standard error of mean increases with sample size
- 4- Standard error of mean is calculated by taking the square root of the standard deviation of the sample means
- 5- Student's t test is a non-parametric test

Answer & Comments

Answer: 2- Standard deviation may be greater than the mean even if all values are positive numbers

The standard error of the mean = SD / \sqrt{n} .

SD does not necessarily fall with sample size, as the distribution of values may increase and hence SD increase. SEM would decrease with sample size as can be seen in the above calculation.

The SD is greater than the mean if the sample values are negative. Even if none of the values are negative, the standard deviation may be greater than the mean. For example: 4 numbers: 0, 0, 2, 3. The mean is 1.25, the population standard deviation is 1.3 and the sample standard deviation is 1.5.

This is not the same as 'negatively skewed' where the distribution of data about the mean tails off to the left with the majority of points being greater (the median and the mode are greater than the mean).

This question is a trick - and quite a trivial one at that. A negative distribution's mean would

be, of course, negative but the standard deviation would still be a positive number.

Student's t test is a parametric test comparing normally distributed data.

[Q: 3209] OnExamination 2012 - Statistics

Adequate randomisation can be assumed in which of the following circumstances?

- 1- All consecutive patients attending a tertiary referral centre
- 2- A sample based on a family cluster
- 3- A sample of those judged to be appropriate for inclusion in the study
- 4- A sample using healthy volunteers
- 5- A stratified random sample

Answer & Comments

Answer: 5- A stratified random sample

The actual patients included in the study often differ substantially from what was initially intended. This dramatically alters one's interpretation of a study.

The target population includes all those with a given disease, and is seldom fully accessible. The accessible population available for study may be biased in time or place.

It is important to randomise when selecting a sample which is supposed to represent the target population. In simple randomisation, every member of the population is numbered, and a random sample is selected.

In a stratified random sample, groups of interest are identified, and then randomisation occurs within those groups.

In systematic sampling a "periodic" approach is used. This is not really random and is open to alteration and bias.

In a cluster sample, a natural grouping of population is used (such as a family), but this

may well be unrepresentative of the whole population.

Classic errors in randomisation are:

Consecutive sampling, which may well not be representative if the study time is short.

Convenience sampling: strong potential for bias, with volunteers generally healthier than others.

Judgmental sample: including those that you want only. The potential for systematic error is enormous.

[Q: 3210] OnExamination 2012 - Statistics

A clinical trial assessing a new lipid-lowering therapy for stroke allocates 1000 patients to active treatment and another 1000 patients to placebo.

Results demonstrate that number needed to treat (NNT) is 20 for the prevention of the primary end-point.

Which of the following best describes the results?

- 1- 20 patients in the treatment group were protected from stroke.
- 2- 20 extra patients in the placebo group had a stroke
- 3- For 1000 patients treated with active therapy, there would be 20 fewer strokes
- 4- For 1000 patients treated with active therapy, there would be 50 fewer strokes.
- 5- For every 1000 patients treated with active therapy there would be 100 fewer strokes

Answer & Comments

Answer: 4- For 1000 patients treated with active therapy, there would be 50 fewer strokes.

This prevention study for stroke reveals that 20 patients need to be treated to prevent one event.

Thus if you treat a 1000 patients then you will expect to have 50 fewer strokes.

Confidence Intervals for the Number Needed to Treat

[Q: 3211] OnExamination 2012 - Statistics

A new rapid test is developed for the screening of malaria.

Blood from 200 patients was analysed by the gold standard laboratory technique and by the new method. There were 100 positive results with the gold standard technique but there were only 50 positive results using the new technique.

Approximately which of the following values reflects the negative predictive value of the new technique?

- 1- 33%
- 2- 50%
- 3- 66%
- 4- 90%
- 5- It cannot be determined

Answer & Comments

Answer: 5- It cannot be determined

The negative predictive value is the number of true negatives / (number of true negatives + false negatives). It reflects the proportion of patients with negative test results who are correctly diagnosed.

100 patients do not have disease by the gold standard. But we don't know how many of these were tested negative using the new technique among the 150 who tested negative. Therefore, we don't know the number of true negatives and false negatives

[Q: 3212] OnExamination 2012 - Statistics

A new rapid test is developed for the

screening of leptospirosis.

Blood from 100 patients was analysed by the gold standard laboratory technique and by the new method. There were 20 positive results with the gold standard technique but there were 40 positive results using the new technique. The new technique correctly identified all cases that were later confirmed with the gold standard technique.

Approximately which of the following values reflects the positive predictive value of the new technique?

- 1- 33%
- 2- 50%
- 3- 66%
- 4- 75%
- 5- 90%

Answer & Comments

Answer: 2- 50%

The positive predictive value is number of true positives / (number of true positives + false positives).

In the new technique there were 20 true positives and 20 false positives.

Thus the positive predictive value is $20 / (20 + 20) = 50\%$.

[Q: 3213] OnExamination 2012 - Statistics

In a double blind controlled trial assessing the impact of a new antihypertensive in the treatment of stroke versus conventional antihypertensive therapy in the secondary prevention of stroke, the authors report an absolute annual risk reduction in the incidence of stroke of 0.5% and a relative risk reduction of 20% ($p = 0.032$).

The cost of the new treatment is £100 more expensive per year than conventional therapy.

What would be the cost of implementing the new therapy for each stroke prevented?

- 1- £2000
- 2- £4000
- 3- £10,000
- 4- £20,000
- 5- £50,000

Answer & Comments

Answer: 4- £20,000

In this case, the annual incidence of stroke is reduced by 0.5% and treatment is £100 more than conventional therapy.

The relative risk reduction of 20% means that the annual risk of stroke is 2.5% (0.5% is 1/5 of 2.5%) in the conventionally treated group.

Thus for every 200 patients treated one less stroke would occur with the new drug versus the conventional therapy.

Number needed to treat (NNT) is therefore 200 per year to prevent one stroke.

Thus the annual cost of this treatment associated with preventing one stroke, despite its significant reduction in stroke reduction ($p = 0.032$) would be:

$200 \text{ patients} \times £100 = £20,000.$

[Q: 3214] OnExamination 2012 - Statistics

A study was performed to assess the usefulness of a new autoantibody test for the detection of suspected Hashimoto's disease.

The test was undertaken in 1000 subjects who complained of tiredness and all test results were compared with FNA biopsy results which provided a gold standard for the diagnosis of Hashimoto's disease.

The following table lists the results:

	Antibody +ve	Antibody -ve	Total
Hashimoto's disease confirmed at FNA	35	15	50
No evidence of disease at FNA	30	920	950

Approximately, what is the sensitivity of the antibody test for the detection of Hashimoto's disease?

- 1- 50%
- 2- 60%
- 3- 70%
- 4- 80%
- 5- 90%

Answer & Comments

Answer: 3- 70%

The sensitivity of a test is the ability of a test to identify those with the condition.

In this example, 50 individuals had Hashimoto's disease according to the gold standard test of biopsy, with 35 of these being identified by the antibody test.

$35/50 \times 100 = 70\%.$

[Q: 3215] OnExamination 2012 - Statistics

In a primary prevention study of stroke comparing a new antihypertensive with conventional antihypertensive therapy, the number of patients who had a stroke over the study period was 200 in group 1 with the new therapy ($n = 5200$) versus 250 with conventional therapy ($n = 4750$).

Which of the following is the approximate odds ratio for the new therapy?

- 1- 0.25
- 2- 0.5

3- 0.75

4- 1

5- 1.5

Answer & Comments

Answer: 3- 0.75

An odds ratio is calculated by dividing the odds in the treated or exposed group by the odds in the control group. Studies generally try to identify factors that cause harm - those with odds ratios greater than one.

The new therapy odds of an event is 200/5000 (patients without an event 5200-200) = 0.04.

Group 2's odds event rate is 250/4500 (4750-250) = 0.055. The odds ratio is therefore:

$$0.04/0.055 = 0.73$$

This odds ratio is less than 1, indicating an overall benefit of therapy.

For calculations on odds ratio see this article.

[Q: 3216] OnExamination 2012 - Statistics

A clinical investigation examined the effectiveness of a new test for diagnosing pancreatic carcinoma.

The sensitivity was reported as 70%.

Which one of the following statements is correct?

- 1- 70% of people will be correctly classified as having or not having the disease
- 2- 70% of people with a normal test result will not have the disease
- 3- 70% of people with an abnormal test result will have the disease
- 4- 70% of people with the disease will have a normal test result
- 5- 70% of people with the disease will have an abnormal test result

Answer & Comments

Answer: 5- 70% of people with the disease will have an abnormal test result

Sensitivity is the conditional probability that the test will be positive if the condition is present.

Specificity is the conditional probability that the test will be negative if the condition is absent.

Therefore interpreting the data there is a 70% probability of the test being positive when tested in a group of patients with the disease.

[Q: 3217] OnExamination 2012 - Statistics

A randomised double-blind placebo controlled study of a cholesterol-lowering drug for the primary prevention of coronary heart disease was conducted. It had a five-year follow up period.

The results showed an absolute risk of myocardial infarction (MI), in the group receiving placebo, was 10 per cent. The relative risk reduction of those given the cholesterol lowering medication was 0.8.

Approximately what number of patients will need to be treated with the drug for five years to prevent one myocardial infarction?

- 1- 10
- 2- 12.5
- 3- 15
- 4- 20
- 5- 25

Answer & Comments

Answer: 2- 12.5

This is a question concerning number needed to treat (NNT). The calculation involves a little arithmetic.

The absolute risk of MI in the group is a pretty high 10%, that is, of 1000 patients on placebo 100 will have MI over five years.

The relative risk reduction is stated as 0.8, that is, 80%.

Therefore, if you treat 1000 patients for five years with the cholesterol lowering agent you will get only 20 MIs.

Thus, for 1000 patients treated you will get 80 fewer MIs.

Thus number needed to treat to get one fewer MI is $1000/80 = 12.5$.

Or, if you are any good at remembering formulae you can remember the following:

1. Relative risk reduction (RRR) = Absolute risk reduction (ARR) / Control event rate (CER)
2. Numbers needed to treat (NNT) = $1 / \text{Absolute risk reduction (ARR)}$

You can then just insert the figures into these formulae.

The control (or placebo) event rate (CER) is 10% or 0.10. The relative risk reduction is 0.80.

Inserting these figures into the above formulae.... $RRR = ARR / CER$ $0.80 = ARR / 0.10$
 $ARR = 0.80 * 0.10 = 0.08$. Then the NNT can be calculated by $NNT = 1 / ARR = 1 / 0.08 = 12.5$.

However, if algebra is not your thing you could try working with real numbers.

Imagine a group of 100 patients (it makes the maths easier). In the control (or placebo group) 10% (or 10 patients) suffered an MI. The relative risk reduction is 0.8 or 80%.

Therefore, in the treatment group, there would be a reduction in events by 80% (of 10 patients) = 8 patients. The number of patients suffering an MI in the treatment would therefore be $10 - 8 = 2$ patients.

It can therefore be said that treating 100 patients with the new drug would result in eight fewer MIs.

The number needed to treat to prevent one MI would be $100/8 = 12.5$ patients.

[Q: 3218] OnExamination 2012 - Statistics

Which of the following statements is true regarding statistical interpretation of data?

- 1- The cumulative incidence rate is usually given over a 10 year period.
- 2- The incidence equals the number of newly affected individuals divided by the number of people at risk for the disease for a given duration.
- 3- The mortality rate is a kind of cumulative prevalence rate.
- 4- The prevalence rate is defined as the total number of cases divided by the total number in the population.
- 5- Prevalence is always higher than incidence.

Answer & Comments

Answer: 2- The incidence equals the number of newly affected individuals divided by the number of people at risk for the disease for a given duration.

The incidence can be thought of as the number of new cases occurring in a given time.

The cumulative incidence rate is usually reported over a year.

Prevalence equals the total number of cases divided by the total number of at risk.

In diseases for which the exact onset cannot be determined such as cancers, it may be difficult to distinguish between incidence and prevalence.

Mortality rate is a special kind of cumulative incidence rate, with deaths in the numerator and population in the denominator.

Case fatality rate has deaths in the numerator and the number of people with a specific disease in the denominator.

Prevalence may be lower than incidence if the condition has high fatality or cure rate.

[Q: 3219] OnExamination 2012 - Statistics

In a trial of a new drug, 13/28 treated improved over a one month period, compared with 3/28 on placebo.

For Chi² testing which of the following is correct?

- 1- A value of Chi² of 4.6 would imply that the result would have been obtained by chance in 46/100 trials.
- 2- The figures should first be converted to percentages.
- 3- The results would almost certainly suggest that more cases were needed to obtain a significant result.
- 4- There is one degree of freedom.
- 5- The results would be invalidated if a disproportionate number of cases treated with the new drug had developed side effects.

Answer & Comments

Answer: 4- There is one degree of freedom.

Chi² testing refers to count data (categorical). It therefore refers to 2 by 2 tables or larger. The test statistic is defined by:

$$\text{Chi}^2 = \frac{E (\text{observed} - \text{expected})^2}{\text{expected}}$$

The degrees of freedom equal (rows -1) x (columns -1). Significance can be looked up using the Chi² distribution according to the appropriate number of degrees of freedom.

Side effects of the new drug will affect interpretation of the conclusion of the trial but not invalidate the results.

[Q: 3220] OnExamination 2012 - Statistics

A letter published in a medical journal suggests that an established antidepressant may cause photosensitivity. The manufacturer wishes to set up a study to determine rapidly and efficiently whether this is a true association.

Which one of the following techniques is most appropriate?

- 1- Case-control study
- 2- Dose ranging study
- 3- Double blind, randomised, placebo controlled study
- 4- Meta-analysis
- 5- Sequential trial

Answer & Comments

Answer: 4- Meta-analysis

The drug is an established one and the correct answer can be found by elimination.

A 'double-blind, randomised, placebo controlled study' would be time consuming, expensive and unlikely to be powered enough to detect what may be a rare toxic effect. Remember the drug is established so there have been many patients taking it already and only lately a letter is published in a medical journal.

A 'dose ranging study' is really for another purpose - to decide the correct dose in early clinical trials so it is hardly going to be of any use here.

A 'sequential' trial would be comparing one therapy to another sequentially (usually with wash out periods in between). Again there are

unlikely to be enough subjects in the trial for this small risk.

A case-control study would look at cases of photosensitivity (perhaps in subjects taking any antidepressant medication) and compare them to age matched (or other criteria matched) control subjects to see if they were more / less / equally likely to be on the antidepressant in question. It would produce a lower level of evidence than a meta-analysis, and would require getting more raw data (which is less rapid and efficient than meta-analysis).

A 'meta-analysis' would look at combining all previous data, hoping there had been some trials that looked at photosensitivity for it to be of any use in this case. This is likely to be the quickest option to complete, and also produces the highest level of evidence.

[Q: 3221] OnExamination 2012 - Statistics

In a study assessing two different antiplatelet agents in the prevention of stroke, 10,000 subjects were randomised to receive either the standard therapy or the new therapy.

Over the study period of five years, the side effect of major gastrointestinal (GI) bleeding was 3% in the standard therapy group compared with 2% in the new therapy group.

Which of the following is the absolute risk reduction associated with the new therapy in major GI bleeds?

- 1- 1%
- 2- 3%
- 3- 10%
- 4- 15%
- 5- 33%

Answer & Comments

Answer: 1- 1%

We are not told whether there is a significant difference between the two groups yet in the standard antiplatelet therapy group there is a risk of GI bleed of 3% vs 2% with the new therapy.

This is a 1% absolute risk reduction and a 33% relative risk reduction (1/3).

The number of people that would need to be treated with the new drug to avert the major effect of bleeding would be 100.

[Q: 3222] OnExamination 2012 - Statistics

A clinical trial is published demonstrating an absolute risk reduction of 2.5% on treatment with a new pharmaceutical agent.

Which of the following statements best describes absolute risk reduction?

- 1- Number of patients who need to be treated to prevent one event
- 2- The odds of an event in the control group divided by the odds of an event in the treatment group
- 3- The risk of an event in the control group minus the risk of an event in the treatment group
- 4- The risk of an event in the treated group divided by the risk of an event in the control group
- 5- The risk reduction divided by the initial risk in the control group

Answer & Comments

Answer: 3- The risk of an event in the control group minus the risk of an event in the treatment group

The number of patients who need to be treated to prevent one event is the number needed to treat (NNT).

The odds of an event in the control group divided by the odds of an event in the treatment group is the odds ratio.

The risk of an event in the treated group divided by the risk of an event in the control group is the relative risk.

The risk reduction divided by the initial risk in the control group is the relative risk reduction.

The absolute risk reduction is the proportion of the risk removed by treatment, and is calculated by the risk of an event in the control group minus the risk of an event in the treatment group. It is usually expressed as a percentage.

[Q: 3223] OnExamination 2012 - Statistics

A researcher compared the mean scores for nausea on a rating scale between standard therapy and a new drug in the treatment of chemotherapy induced nausea.

Which one of the following is the most appropriate statistical test?

- 1- Chi-square test
- 2- Life table analysis (log rank test)
- 3- Paired t test
- 4- Pearson correlation
- 5- Unpaired t test

Answer & Comments

Answer: 5- Unpaired t test

The two sample unpaired t test is used to test the null hypothesis that the two populations corresponding to the two random samples are equal.

For a paired t test, the data are dependent, that is, there is a one-to-one correspondence between the values in the two samples; for example, the same subject measured before and after a process change, or the same subject measured at different times.

[Q: 3224] OnExamination 2012 - Statistics

An experienced group of surgeons report on a randomised placebo-controlled trial comparing a particular carotid surgery technique to a sham operation.

Their study concludes that 'using this advanced surgical technique reduces the risk of stroke from 4.3% to 3.8% ($p < 0.05$)'.

What has this study proved about the surgical procedure?

- 1- Acceptability
- 2- Effectiveness
- 3- Efficacy
- 4- Safety
- 5- Usefulness

Answer & Comments

Answer: 3- Efficacy

This is an experienced group of vascular surgeons working in ideal conditions. Similar studies have been reported for carotid surgery but it has been difficult to prove their usefulness outside areas of expertise.

It is often difficult to generalise the findings in a study group to everyday practice.

Efficacy = the effect of something under ideal or laboratory conditions.

Effectiveness = the effect of something in the real world.

[Q: 3225] OnExamination 2012 - Statistics

In a chronic disease which has no known effective treatment, a new treatment is known to be effective in animal models and shows promise in short term studies in patients.

There are some theoretical concerns about toxicity involving liver and bone marrow

although no cases have been observed in studies so far.

What is the most appropriate next step in the drug's development?

- 1- Case-control study
- 2- No further studies should be done and drug development should be stopped
- 3- Open study
- 4- Randomised double blind placebo controlled study
- 5- Randomised single blind placebo controlled study

Answer & Comments

Answer: 4- Randomised double blind placebo controlled study

The story that is described is of an early drug development that has gone through phase I trials (normal volunteers) and phase II studies (more normal volunteers but it also mentions 'studies in patients').

The next step in the development of this drug is a phase III study - where the drug's efficacy and safety should be tested against a placebo.

Broadly, the development of a new drug can be divided into pre-clinical and clinical trials.

Pre-clinical development first involves identifying the target thought to be important in disease. Drug candidates are then identified, and their properties optimised. Pre-clinical safety studies are then conducted to determine dosage, ensure safety and study pharmacokinetic properties. These involve both computer and animal models. All information gathered from pre-clinical testing is submitted to the regulatory authorities, prior to moving to the clinical phase of drug development.

Clinical trials have a number of phases:

In phase I the drug is usually given to healthy volunteers to determine its safety and pharmacokinetic properties in humans.

In phase II a small group of patients (typically 100-250) are given the drug to evaluate its efficacy, optimum dose, safety and side effects (as these may be different in patients compared to healthy volunteers). If these trials are successful larger clinical trials can be planned.

Phase III trials typically involve more than 1000 patients, and are used to determine efficacy and side effects. If successful the drug must be registered by the authorities prior to being released to the market.

It is important to note the majority of drugs identified in early pre-clinical trials will never make it to market, as they are not shown to have a significant effect or they are associated with significant toxicity.

Post-marketing studies then continue to determine the long term and chronic toxicities. UK practitioners are requested to report any side effects via the yellow card scheme.

[Q: 3226] OnExamination 2012 - Statistics

A study is designed to test the accuracy of faecal occult blood (FOB) testing in excluding a certain type of bowel cancer. Faecal occult bloods are compared to a gold standard which consists of a battery of tests and pathological diagnoses. In the study 200 prospective patients undergo faecal occult blood testing and are followed up with the gold standard investigations.

The gold standard results test demonstrated that malignancy was present in 100 of the 200 patients tested. Of these 100 patients with proven malignancy, faecal occult blood testing was positive in 90 patients. Of those testing negative, FOBs were negative in 80 patients.

Approximately which of the following values reflects the negative predictive value of the faecal occult blood testing in this study?

- 1- 33%
- 2- 50%
- 3- 66%
- 4- 75%
- 5- 89%

Answer & Comments

Answer: 5- 89%

The negative predictive value is the number of true negatives/(number of true negatives + false negatives). It reflects the proportion of patients with negative test results who are correctly diagnosed.

In the new technique there were 100 true positives who had the disease (that is, 100 true negatives) and 10 false negatives (where the faecal occult blood test missed the diagnosis).

Thus the negative predictive value is $80/(80+10) = 88.9\%$.

[Q: 3227] OnExamination 2012 - Rheumatology

A 30-year-old man with longstanding psoriasis has a six week history of persistently swollen, painful, and tender right knee. The early morning stiffness lasts for over an hour, and he has partial relief from the use of NSAIDs.

He is negative for rheumatoid factor. A knee x ray is normal.

What is the next step in his long term management?

- 1- Alternative NSAID
- 2- Anti-TNF α agents
- 3- Disease modifying antirheumatic drugs (DMARDs)
- 4- Intra-articular corticosteroids
- 5- Oral corticosteroids

Answer & Comments

Answer: 3- Disease modifying antirheumatic drugs (DMARDs)

This patient has psoriatic arthritis and should be treated with a DMARD to prevent joint damage from proliferative/ erosive changes in psoriatic arthritis.

In the United Kingdom, anti-TNF agents are used for the treatment of psoriatic arthritis only if the patient fails to respond to an adequate trial of two DMARDs (for example, leflunomide, methotrexate, sulfasalazine). Hydroxychloroquine has been shown to exacerbate psoriatic skin lesions in certain situations, and is therefore used with caution if at all.

Nonsteroidal anti-inflammatory drugs (NSAIDs) provide partial symptom relief and do not prevent progressive joint damage.

In patients with cutaneous psoriasis, systemic corticosteroids predispose to pustular psoriasis, and may result in a flare of skin psoriasis when they are stopped.

Intra-articular corticosteroid injections may be considered for symptom control during a mono- or oligo-articular flare of psoriatic arthritis. This is a useful adjunct to therapy but is not appropriate long term management in itself.

[Q: 3228] OnExamination 2012 - Rheumatology

A 70-year-old man developed acute monoarthritis of his right ankle on the second postoperative day following an elective inguinal hernia repair. He was on a diuretic for hypertension.

On examination his temperature was 38°C.

What is the most likely diagnosis?

- 1- Acute rheumatoid arthritis
- 2- Gout
- 3- Pseudogout
- 4- Septic arthritis
- 5- Traumatic synovitis

Answer & Comments

Answer: 2- Gout

The most likely diagnosis is gout, given the history of recent surgery and diuretic use.

Gout is the most prevalent form of inflammatory arthropathy. It is caused by the deposition of monosodium urate crystals with resultant inflammation in the involved joint. It typically presents with acute monoarticular pain. Current EULAR guidelines state that the rapid development of severe pain, swelling, and tenderness that reaches its maximum within 6-12 hours, especially with overlying erythema, is highly suggestive of crystal arthropathy. Involvement of the first metatarsophalangeal joint is more specific for gout, but a variety of different joints can be involved. 50% of all attacks and 70% of first attacks of gout affect the first metatarsophalangeal joint.

In addition to joint symptoms, fever and malaise are common presenting features of an acute attack of gout. Acute gout can be a cause of systemic inflammatory response syndrome (SIRS) which is two or more changes of body temperature, heart rate, respiratory function, and peripheral leukocyte count.

There is a florid synovitis, with swelling and overlying erythema. Palpation is exquisitely painful. Untreated, the attack resolves spontaneously over 5-15 days with itching and desquamation of the overlying skin.

The EULAR guidelines conclude that for typical presentations of gout a clinical diagnosis alone is reasonably accurate but not definitive without visualisation of crystals on microscopy.

Pyrophosphate arthropathy is less common, associated with deposition of calcium pyrophosphate crystals chiefly in the knees, second and third metacarpophalangeal joints. There may be a history of haemochromatosis or osteoarthritis.

Rheumatoid arthritis most commonly manifests as a chronic polyarthritis and synovitis.

Septicaemia following an elective hernia repair would be uncommon as would traumatic synovitis. Examination of joint aspirate is always important however, to exclude septic arthritis as missing this diagnosis is associated with significant morbidity and mortality.

Although not needed to answer this question, it is important you also understand how to manage an acute episode of gout. The principles are:

- commence anti-inflammatory medication immediately, and continue for two weeks - NSAIDs are first line in conjunction with gastro-protective medication where indicated; colchicine is an alternative but is

slower to work and can be associated with significant diarrhoea

- rest the affected joints
- allopurinol should not be started during an acute attack but in patients already established on allopurinol it should be continued
- if diuretics are being used to treat hypertension an alternative antihypertensive should be considered, but they should not be stopped in the presence of heart failure
- corticosteroids are highly effective, and can be used where NSAIDs are not tolerated, or in refractory disease (intra-articular, oral, intramuscular, intravenous)

Reference:

EULAR evidence based recommendations for gout. Part 1: Diagnosis. Report of a task force of the Standing Committee for International Clinical Studies Including Therapeutics (ESCISIT). Zhang W et al. Ann Rheum Dis. 2006 Oct;65(10):1301-1311

British Society for Rheumatology and British Health Professionals in Rheumatology Guideline for the Management of Gout. Jordan KM et al. Rheumatology 2007;46:1372-1374.

[Q: 3229] OnExamination 2012 - Rheumatology

A 65-year-old male is referred due to inadequate pain relief for his hip osteoarthritis.

His GP has prescribed paracetamol and codeine 30 mg four times daily but he has found little improvement in his pain relief.

He has a past history of asthma for which he occasionally takes an inhaler.

What is the most likely explanation for the lack of clinical efficacy associated with this medication?

- 1- Fast acetylase status
- 2- Impaired absorption of codeine
- 3- Inadequate dose of codeine

- 4- Interaction of paracetamol with codeine
 5- Ipratropium accelerates the metabolism of codeine

Answer & Comments

Answer: 3- Inadequate dose of codeine

The most likely explanation is that the codeine dose is inadequate.

Studies have shown that paracetamol 1 g combined with codeine at dose of 60 mg have the best analgesic outcomes.

Ipratropium does not increase the metabolism of codeine.

[Q: 3230] OnExamination 2012 - Rheumatology

A 79-year-old woman presents with mild dyspnoea and confusion. Of note in her past medical history is a one year history of Raynaud's phenomenon.

On examination her pulse is 118 beats per minute, she has a blood pressure of 122/88 mmHg and she has a small ulcer on her right big toe.

Auscultation of her chest reveals bibasal crackles and she has mild ankle oedema.

Her investigations show:

Haemoglobin 9.5 g/dl (11.5-16.5)

White cell count $3.5 \times 10^9/L$ (4-11)

Platelet count $110 \times 10^9/L$ (150-400)

Serum total protein 120 g/l (61-76)

Serum immunoglobulins:

IgA 0.8 g/l (0.8-3.0)

IgG 15 g/l (6.0-13.0)

IgM 70 g/l (0.4-2.5)

Which of the following complications is she likely to develop?

- 1- Acute renal failure
 2- Atypical pneumonia

- 3- Erythema repens gyratum
 4- Hyperviscosity syndrome
 5- Pathological bone fracture

Answer & Comments

Answer: 4- Hyperviscosity syndrome

This elderly woman has a very raised IgM level, pancytopenia, Raynaud's phenomenon and a foot ulcer.

The most likely diagnosis here is Waldenström's macroglobulinaemia (WM). WM refers to a condition that presents in the seventh or eighth decade of life.

It is characterised by the presence of a high level of a macroglobulin (immunoglobulin M [IgM]), elevated serum viscosity and the presence of a lymphoplasmacytic infiltrate in the bone marrow, resulting in pancytopenias.

Raynaud's phenomenon may herald the onset of this condition and is due to cryoglobulinaemia.

The monoclonal IgM causes:

- Hyperviscosity syndrome
- Cryoglobulinaemia types 1 and 2
- Coagulation abnormalities
- Polyneuropathies
- Cold agglutinin disease and anaemia
- Primary amyloidosis

Tissue deposition of amorphous IgM in skin, the gastrointestinal tract, kidneys, and other organs.

The other conditions described here are not commonly associated with WM, and are more often seen in combination with myeloma. Erythema repens gyratum is a skin rash thought to be a paraneoplastic process.

[Q: 3231] OnExamination 2012 - Rheumatology

A 45-year-old male attends for an insurance

medical and is in good health.

Examination was normal but investigations reveal that he has a serum urate concentration of 0.55 mmol/L (0.25-0.45).

Which of the following is the most appropriate management for this patient?

- 1- Lifestyle advice
- 2- Start allopurinol
- 3- Start colchicine
- 4- Start diclofenac
- 5- Start prednisolone

Answer & Comments

Answer: 1- Lifestyle advice

The most appropriate treatment for this asymptomatic man with an isolated slightly elevated urate is lifestyle advice with an appropriately reduced purine diet, increased exercise and reduced alcohol consumption.

[Q: 3232] OnExamination 2012 - Rheumatology

A 42-year-old female with a recent diagnosis of systemic sclerosis, is referred to hospital with a complaint of headaches and blurred vision. She has a medical history of asthma.

On examination, her blood pressure is 230/120 mmHg and there is bilateral papilloedema.

Which of the following medications should be prescribed immediately?

- 1- IV furosemide
- 2- IV labetalol
- 3- IV sodium nitroprusside
- 4- Oral enalapril
- 5- Sublingual nimodipine

Answer & Comments

Answer: 4- Oral enalapril

Systemic sclerosis is a systemic disorder characterised by skin thickening due to the deposition of collagen in the dermis. Adverse prognostic features are renal, cardiac or pulmonary involvement.

A major complication is the development of scleroderma renal crisis. This is characterised by the abrupt onset of severe hypertension, usually with retinopathy, together with rapid deterioration of renal function and heart failure.

In addition patients may present with headaches, fever and malaise. It develops in 5-10% of patients with diffuse systemic sclerosis especially associated with diffuse cutaneous or rapidly progressive forms of systemic sclerosis, and patients in whom a high dose of corticosteroid has been started.

Renal crisis is linked with a positive ANA speckled pattern, anti-RNA polymerase I and II antibodies and absence of anti-centromere antibodies¹.

It usually presents early, within four years of diagnosis. The pathogenic mechanisms leading to renal damage are not completely understood but they involve endothelial cell damage and intimal thickening of the renal arteries, resulting in hyperplasia of the juxtaglomerular apparatus and increased renin release¹. Renal biopsy is not necessary in patients presenting with classical features of renal crisis².

The clinical presentation is typically with the symptoms of malignant hypertension:

Headaches

Hypertensive retinopathy associated with visual disturbances

Seizures

Heart failure and pulmonary oedema.

Renal function is impaired and usually rapidly deteriorates. The hypertension is almost always severe with a diastolic BP over 100

mmHg in 90% of patients. There is hypertensive retinopathy in about 85% of patients with exudates and haemorrhages and if severe, papilloedema. There may also be microangiopathic haemolytic anaemia, thrombocytopenia and raised renin levels.

Scleroderma renal crisis is a medical emergency. Aggressive treatment is required to prevent the occurrence of irreversible vascular injury. First line treatment is a gradual reduction in blood pressure (10-15 mmHg per day) with an ACE inhibitor until the diastolic pressure reaches 85-90 mmHg. This approach leads to a response in 90% of patients by reversing the angiotensin-II mediated vasoconstriction.

An abrupt fall in blood pressure should be avoided as it can further diminish renal perfusion and increase the risk of acute tubular necrosis. Therefore, parenteral antihypertensive agents (for example, intravenous nitroprusside or labetalol) should be avoided.

Calcium channel blockers, usually nifedipine, may be added where there is inadequate reduction of blood pressure with ACE inhibitors alone. Additional oral hypotensive agents (for example, labetalol) can be used if required, and if pulmonary oedema is present a nitrate infusion may be indicated. There is anecdotal evidence that intravenous prostacyclin helps the microvascular lesion without precipitating hypotension, and this is used in some UK centres.

Deterioration in renal function can be rapid, with gross pulmonary oedema; therefore patients with scleroderma renal crisis should be managed in hospitals with facilities for dialysis.

Early aggressive treatment with ACE inhibitors has improved prognosis in renal crisis, although 40% of patients will require dialysis and mortality at five years is 30-40%. Median time to recovery is one year, and

typically occurs within three years¹. Prognosis is worse for males¹. Patients who need dialysis for more than two years can be considered for renal transplantation². The recurrence rate has been estimated to be approximately 20%.

Care should be taken not to confuse scleroderma renal crisis with malignant hypertension. Malignant hypertension is a clinical syndrome characterised by marked elevation of blood pressure, with widespread acute arteriolar injury⁴. It has a number of different causes and treatment differs depending on the underlying condition. The pathogenesis overlaps, but idiopathic malignant hypertension tends to involve the smaller vessels than in scleroderma renal crisis⁵.

[Q: 3233] OnExamination 2012 - Rheumatology

A 62-year-old female presents with deteriorating arthralgia associated with longstanding rheumatoid arthritis. She was prescribed celecoxib in place of naproxen.

Which of the following concerning celecoxib is correct?

- 1- Anti-inflammatory effects of celecoxib are superior to those of naproxen
- 2- Celecoxib acts by inhibiting a different enzyme than naproxen
- 3- Celecoxib has a lower level of anti-platelet activity than naproxen
- 4- Celecoxib is associated with reduced hepatotoxicity compared with naproxen
- 5- Co-treatment with diuretic can be given more safely than with naproxen

Answer & Comments

Answer: 3- Celecoxib has a lower level of anti-platelet activity than naproxen

Celecoxib is a selective cyclo-oxygenase (COX)-2 inhibitor differing from the other non-

steroidal anti-inflammatory drugs (NSAIDs) such as naproxen which affects both COX-1 and COX-2.

COX-1 is involved in platelet aggregation and inhibition of this by the NSAIDs produces its beneficial cardiovascular effects. However platelet aggregation is not affected by COX-2.

Naproxen and celecoxib have been shown to be as effective at reducing inflammation. One of the benefits of celecoxib is its reduced incidence of upper gastrointestinal side effects.

As with the non-specific NSAIDs, hepatotoxicity may occur with the COX-2 specific inhibitors resulting in cholestatic, hepatocellular or mixed liver injury. Rates seem to be comparable between the traditional NSAIDs and the COX-2 selective inhibitors.

Co-administration of diuretics and COX-2 inhibitors should be avoided if possible, as COX-2 inhibitors may reduce the antihypertensive and diuretic effects of diuretics. This may be due to impaired prostaglandin synthesis, which results in salt and water retention. In addition, COX-2 inhibitors have nephrotoxic effects which can be exacerbated by diuretics.

Rofecoxib (Vioxx) has been withdrawn due to its increased cardiovascular events compared with naproxen. The cardiovascular effects of the COX-2 inhibitors remains under study, and care should be taken before prescribing them to patients with a past medical history of significant cardiovascular disease.

[Q: 3234] OnExamination 2012 - Rheumatology

A 78-year-old man presents with an acute onset of severe pain and swelling of the left wrist which had developed since he had a chest infection two weeks previously.

On examination he had a temperature of 38°C and the left wrist was red, swollen and painful.

What is the most appropriate investigation for this patient?

- 1- Erythrocyte sedimentation rate
- 2- Full blood count
- 3- Joint aspiration
- 4- Serum urate concentration
- 5- x Ray of the joint

Answer & Comments

Answer: 3- Joint aspiration

This gentleman has presented with an acute onset monoarthritis.

A destructive septic arthritis is a potential diagnosis, and must be excluded as a matter of urgency. An aspirate is the most crucial step to exclude this and allow the timely commencement of appropriate antibiotics. Differential diagnoses include gout and pseudogout, which can also be diagnosed on joint aspiration.

ESR will be raised in many causes of joint inflammation or infection, and is therefore not helpful in establishing a diagnosis in the acute situation. It can be used to guide treatment in inflammatory arthropathies after a diagnosis is made.

Full blood count is also non-specific and often does not assist in making a diagnosis.

Hyperuricaemia is a pre-requisite for gout, but normal serum urate levels at presentation does not exclude an acute gouty attack. It is therefore not the most appropriate investigation in this case.

In the acute stages of septic arthritis there may be no signs of damage to the joint seen on a radiograph. It may show typical changes of calcium pyrophosphate dehydrate deposition or gout, which may help in his long

term management, but would not change management in the acute situation.

[Q: 3235] OnExamination 2012 - Rheumatology

A young woman has acne and is taking oral medication. She develops polyarthrititis and has raised liver enzyme tests.

Investigations show:

AST 95 U/l (1-31)

ALT 170 U/l (5-35)

Bilirubin 16 µmol/l (1-22)

Antinuclear antibodies Strongly positive at 1/20

Negative at 1/640

Which of the following drugs is she most likely to have been prescribed?

- 1- Erythromycin
- 2- Isotretinoin
- 3- Minocycline
- 4- Oxytetracycline
- 5- Trimethoprim

Answer & Comments

Answer: 3- Minocycline

Except trimethoprim, all other drugs listed above are used in the treatment of acne. All of these can cause hepatotoxicity, and therefore raised alanine aminotransferase (ALT) and aspartate aminotransferase (AST).

Minocycline is the only drug listed which can account for the polyarthrititis and antinuclear antibody (ANA), due to its ability to cause drug-induced lupus erythematosus.

Classically, drug-induced lupus erythematosus is characterised by

Systemic disease with a lower incidence of nephritis

Lack of cutaneous involvement and

The presence of antihistone antibodies¹.

The most commonly associated drugs have historically been procainamide and hydralazine ², although their use is now decreasing. Medications associated more recently include the anti-TNF alpha agents, statins and minocycline.

Minocycline is unusual in that it seems to be associated with the development of long term immunological memory, and therefore exacerbation of symptoms within 12-24 hours of rechallenge².

Minocycline has been well documented as a cause of drug-induced systemic lupus erythematosus (SLE). Characteristically, the erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) are both markedly elevated, the ANA is strongly positive and there is a hypergammaglobulinaemia.

Anti-dsDNA antibodies are usually negative; antihistone antibodies are positive in 95% of drug-induced lupus (but also 50-80% of idiopathic SLE³).

A strongly positive ANA is a risk factor for developing drug-induced lupus, but a negative ANA would not exclude the diagnosis².

Drug-induced lupus is defined as a lupus-like syndrome temporally related to continuous drug exposure which resolves after discontinuation of the offending drug⁴.

There are several features which distinguish drug-induced lupus from idiopathic SLE:

Males and females are equally affected in drug-induced lupus, whereas idiopathic SLE affects females nine times more frequently³.

Caucasians are affected by drug-induced lupus more commonly than Afro-Caribbeans, whereas the inverse is true of idiopathic SLE.

In addition, the age of onset is typically older in drug-induced lupus, but this depends on the age at drug exposure.

Fever, arthralgia, serositis and ANA occur at least as frequently in drug-induced lupus as idiopathic SLE.

Haematological, renal and central nervous system (CNS) involvement, and double-stranded DNA autoantibodies are rare³.

The pathogenesis of drug-induced lupus is unclear. Factors that influence drug metabolism, such as acetylator status, have been implicated. In addition, lupus-inducing drugs have been shown to generate a variety of cytotoxic products on exposure to MPO released from activated neutrophils².

The time taken for symptoms to resolve after stopping minocycline is highly variable, from a few days to two years³. Typically, no further treatment is required but there are situations where corticosteroids or disease modifying antirheumatic drugs (DMARDs) are required to aid resolution³.

[Q: 3236] OnExamination 2012 - Rheumatology

A 74-year-old man has had increasingly severe, throbbing headaches for several weeks, centered on the right.

There is a palpable tender cord-like area over his right temple. His heart rate is regular with no murmurs, gallops, or rubs. Pulses are equal and full in all extremities, BP is 110/85 mmHg.

A biopsy of this lesion is obtained, and histologic examination reveals a muscular artery with luminal narrowing and medial inflammation with lymphocytes, macrophages, and occasional giant cells.

He improves with a course of high-dose corticosteroid therapy.

Which of the following laboratory test findings is most likely to be present with this disease?

1- Anti-double stranded DNA titre of 1:1024

2- Erythrocyte sedimentation rate of 110 mm/hr

3- HDL cholesterol of 0.6 mmol/L

4- pANCA titre of 1:160

5- Rheumatoid factor titre of 80 IU/mL

Answer & Comments

Answer: 2- Erythrocyte sedimentation rate of 110 mm/hr

The features described here are classical for giant cell arteritis (GCA).

GCA affects large and medium sized arteries, with a predilection for the external carotid, ciliary and retinal arteries.

Endovascular damage and cytokine-mediated inflammation causes local ischaemia. There is considerable overlap with polymyalgia rheumatica, and symptoms of both should be sought. Twenty per cent of patients develop loss of vision, which can be prevented with timely recognition and treatment.

The classically described jaw claudication occurs in a minority of cases, but does indicate a high risk of ischaemic complications.

The typical presentation of GCA is a temporal headache, with myalgia, malaise and fever. Erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) are usually raised.

Once the diagnosis is suspected, high dose corticosteroids should be given. If visual symptoms are present, intravenous methylprednisolone should be given. Once symptoms and laboratory abnormalities resolve, the dose of corticosteroid can be reduced and usually stopped within two years.

Anti-double stranded DNA antibodies are associated with systemic lupus erythematosus.

Reduced high-density lipoprotein (HDL) contributes to increased cardiovascular risk, and can be caused by a number of inherited metabolic conditions or may be secondary to other factors such as smoking. It is not commonly associated with rheumatological disease.

Perinuclear antineutrophil cytoplasmic antibody (pANCA) is associated with microscopic polyangiitis and Churg-Strauss syndrome, neither of which present as described above.

Rheumatoid factor is non-specific, and may be seen in patients with GCA but this is less likely than a raised ESR.

[Q: 3237] OnExamination 2012 - Rheumatology

A 75-year-old man has persistent back pain for several months that is unrelated to physical activity. He has lost 12 kg in weight during this time.

Laboratory findings include a white cell count of $6.7 \times 10^9/L$ with a differential of 5.4 neutrophils, 1.2 lymphocytes and 0.2 monocytes. Haemoglobin is 11.2 g/dl, haematocrit 33.3%, MCV 88 fl, and platelet count $89 \times 10^9/L$.

The biochemistry shows a sodium concentration of 144 mmol/l, potassium 4.5 mmol/l, chloride 100 mmol/l, bicarbonate 26 mmol/l, urea 14 mmol/l, creatinine 90 $\mu\text{mol/l}$, and a glucose of 5.4 mmol/l.

A CT scan of the spine reveals scattered 0.4 to 1.2 cm bright lesions in the vertebral bodies.

Which of the following additional laboratory test findings is he most likely to have?

- 1- Blood culture positive for *Neisseria gonorrhoeae*
- 2- Parathyroid hormone, intact, of 100 pg/ml (normal <65)
- 3- Positive serology for *Borrelia burgdorferi*
- 4- Serum calcium of 1.4 mmol/l

- 5- Serum prostate specific antigen of 35 microgram/l

Answer & Comments

Answer: 5- Serum prostate specific antigen of 35 microgram/l

The combination of back pain, weight loss and osteosclerotic lesions makes prostatic adenocarcinoma the most likely diagnosis in this case.

Several malignancies, including those originating in the prostate, exhibit a propensity to metastasise to the bone. The sequelae include severe pain, pathological fractures, hypercalcaemia and spinal cord compression. Osteoclast-mediated bone degradation and subsequent bone loss are the hallmarks of secondary bone metastases from most solid tumours. In prostate carcinoma, the majority of lesions are osteosclerotic due to inappropriate bone production.

The mainstay of treatment of metastatic bone disease is usually with intravenous bisphosphonates, which reduces bone pain in addition to treating hypercalcaemia. Current evidence indicates that the nitrogen-containing bisphosphonates, especially zoledronic acid, are potent inhibitors of bone resorption. Radiotherapy can also be used to reduce symptoms from localised bone lesions, and taxane-based chemotherapy can be effective for widespread disease. Increased understanding of the pathogenesis of bone metastases has resulted in the development of targeted therapies including RANKL inhibitors, and inhibitors of SRC and cABL kinases.

Gonorrhoea, caused by *Neisseria gonorrhoeae* is the second most common sexually transmitted infection in the UK. It typically affects a younger age group than described here, and septicaemia is uncommon. Whilst it can be associated with

septic and reactive arthritis, these CT findings are not typical.

Hyperparathyroidism is a disease of increased bone resorption and bone formation. Radiographic findings differ in primary and secondary hyperparathyroidism, but neither would explain the weight loss and the pain is typically more generalised.

Borrelia burgdorferi causes Lyme disease, which classically presents with fever and erythema migrans following a tick bite in an endemic area (e.g. the New Forest). Without treatment, it can progress to disseminated disease with a polyarticular arthritis but isolated persistent back pain is not typical.

Hypocalcaemia can be seen in patients with bone metastases, but this is rare and at levels this low you would expect symptoms of neuromuscular irritability (e.g. paraesthesia and carpopedal spasm).

[Q: 3238] OnExamination 2012 - Rheumatology

A 68-year-old woman presents with pain at the base of her right thumb. There is tenderness and swelling of the right first carpometacarpal joint.

What is the most likely diagnosis?

- 1- Avascular necrosis of the scaphoid
- 2- De Quervain's tenosynovitis
- 3- Osteoarthritis
- 4- Psoriatic arthritis
- 5- Rheumatoid

Answer & Comments

Answer: 3- Osteoarthritis

The first carpometacarpal joint is a frequent site of osteoarthritis in postmenopausal women. Clinical features include tenderness, stiffness, crepitus, swelling and pain on abduction of the thumb. Squaring of the

hand, caused by swelling, radial subluxation of the metacarpal and atrophy of the thenar muscles, is a characteristic clinical sign.

Scaphoid fractures are relatively common, typically occurring following a fall onto outstretched hand. The proximal portion lacks its own blood supply, so avascular necrosis can occur if a fracture leaves it isolated from the remainder of the scaphoid. This produces pain and tenderness of the radial side of the wrist, classically in the anatomical snuffbox rather than the base of the thumb, exacerbated by wrist movement.

De Quervain's tenosynovitis disease is a common pathology which consists of a stenosing tenosynovitis of the first dorsal compartment of the wrist. It typically presents with pain on the radial aspect of the wrist, with associated swelling and tenderness. Treatment is with splinting, with or without corticosteroid injection.

The first carpometacarpal joint can be affected in rheumatoid arthritis and psoriatic arthritis but rarely in isolation.

[Q: 3239] OnExamination 2012 - Rheumatology

A 41-year-old African man has a history of multiple episodes of sudden onset of severe abdominal pain and back pain lasting for hours. Each time this happens, his peripheral blood smear demonstrates numerous sickled erythrocytes.

A haemoglobin electrophoresis shows 94% Hgb S, 5% Hgb F, and 1% Hgb A2.

He now has increasing pain in his right groin radiating to the anterior aspect of the thigh and to the knee. His temperature was 38°C and examination of his hip revealed pain on internal rotation. A radiograph reveals irregular bony destruction of the femoral head.

What is the organism most likely to be responsible for these findings?

- 1- Candida albicans
- 2- Clostridium perfringens
- 3- Group B Streptococcus
- 4- Salmonella species
- 5- Yersinia pestis

Answer & Comments

Answer: 4- Salmonella species

Salmonella osteomyelitis is seen in patients with sickle cell anaemia.

Other organisms that are frequent causes for osteomyelitis with sickle cell anaemia include Staphylococcus aureus and Gram negatives such as Klebsiella.

Why Salmonella species predominate in patients with sickle cell disease instead of Staphylococcus aureus is a matter of debate.

Etiology of Osteomyelitis Complicating Sickle Cell Disease. Pediatrics 1998;101;296-297

[Q: 3240] OnExamination 2012 - Rheumatology

A 50-year-old man presents with a two month history of progressive painless weakness affecting the proximal arms and legs.

He has noticed difficulty getting out of a low chair and some difficulty swallowing but denies any rashes or visual symptoms.

Investigations shows a CK of 5000 IU/l.

Which of the following is the most likely diagnosis?

- 1- Guillain-Barre syndrome
- 2- Hypothyroidism
- 3- Myasthenia gravis
- 4- Polymyalgia rheumatica (PMR)
- 5- Polymyositis

Answer & Comments

Answer: 5- Polymyositis

Polymyositis classically presents with relatively painless progressive proximal muscle weakness. Dysphagia is common but the ocular muscles are very rarely involved unlike myasthenia gravis where this is a predominant feature.

Diagnosis of polymyositis confirmed by elevated muscle enzymes (creatinine kinase) and typical EMG and muscle biopsy findings.

PMR is characterised by marked proximal stiffness and pain but rarely weakness and the muscle enzymes are typically normal.

Although hypothyroidism can present with a proximal myopathy and elevated creatine kinase (CK) levels the latter are rarely elevated above 500IU/l and dysphagia would not be typical.

Guillain-Barre syndrome causes demyelination and axonal degeneration, which results in acute, ascending and progressive neuropathy. 75% of patients have a history of preceding infection, usually of the respiratory and gastrointestinal tract. Mild rises in CK can be seen but they are not as marked as in polymyositis, and the progression of disease is much quicker.

[Q: 3241] OnExamination 2012 - Rheumatology

A study has been designed to investigate whether a certain drug plus physiotherapy treatment is better than drug treatment alone in the management of rheumatoid arthritis.

After randomising the patients a small proportion of the drug plus physiotherapy group decide to drop out of the study or omit some treatment sessions specified in the research protocol.

What is the correct way of analysing the subsequent data?

- 1- Assume the patients have withdrawn their consent

- 2- Exclude these patients from all analysis
- 3- Extend the trial recruitment to make up the numbers
- 4- Include these patient outcomes in the drug plus physiotherapy group
- 5- Interview the patients and report their group separately

Answer & Comments

Answer: 4- Include these patient outcomes in the drug plus physiotherapy group

This is the principle of 'intention to treat'.

It is possible that the physiotherapy intervention was harmful to the patients and this is why they left.

Intention to treat helps to reduce bias by sticking to the original allocation of treatment and analysing the patient in that treatment group even (and concentrate for this bit), even if they don't get it!

[Q: 3242] OnExamination 2012 - Rheumatology

A 55-year-old lady returns for her three month follow up in your inflammatory arthropathy clinic. She reports satisfactory symptom relief with 10 mg prednisolone daily after failing several other disease modifying agents. Her past medical history includes coeliac disease and Smith's fracture. You advise that this may be her long term treatment of choice.

Regarding preservation of bone mineral density, which further measures are necessary before proceeding?

- 1- Alendronate 70 mg weekly
- 2- Calcichew D3 forte
- 3- DXA scan and treat at T-score -1.5
- 4- DXA scan and treat at T-score -2.5
- 5- None of the above

Answer & Comments

Answer: 1- Alendronate 70 mg weekly

Learning points:

Bone mineral density measurement

Indications for bisphosphonate prophylaxis with glucocorticoid therapy

Specific bisphosphonate pharmacotherapy.

This lady has three independent risk factors for the development of osteoporosis (coeliac disease, previous fragility fracture, long term glucocorticoid therapy).

In the context (long term glucocorticoid therapy), due to her previous fragility fracture and irrespective of her age, this patient should be commenced on bisphosphonate therapy without the need for bone mineral density quantification with DEXA scanning.

Indications for bisphosphonate prophylaxis in glucocorticoid use for a period > 3 months

<65 years>65 year

+ fragility fracture*All patients

+ T score > -1.5

NB: if T score 0 to -1.5 repeat in 1-3 years.

* fragility fracture - defined by The World Health Organisation as resulting from a mechanical force equivalent to a fall from standing height or less which should not ordinarily cause a fracture.

[Q: 3243] OnExamination 2012 - Rheumatology

A 28-year-old lady presents to clinic with a one year history of intermittently painful fingers. The pain occurs commonly in low ambient temperatures and there is commensurate skin colour change from white to blue to red. Each episode lasts approximately 15 - 20 minutes.

She tells you that her mother suffered from rheumatoid arthritis and Raynaud's.

Which bedside test could you perform that may indicate an underlying connective tissue disorder as the probable diagnosis?

- 1- Capnography
- 2- Cold water challenge
- 3- Digital artery closing temperature
- 4- Finger systolic pressure
- 5- Nailfold capillaroscopy

Answer & Comments

Answer: 5- Nailfold capillaroscopy

Learning points:

Presentation and triggers of Raynaud's phenomenon (RP)

Clinical evaluation of RP

Characteristics suggestive of secondary RP

Connective tissue disease causes of RP.

This young woman gives a history consistent with Raynaud's phenomenon and has a positive family history of rheumatological disease.

Nailfold capillaroscopy is performed by applying a drop of oil onto the periungual region of the nail and using an ophthalmoscope set to 40 diopter to examine.

Observation of a relative paucity of capillary loops or enlarged and distorted loops is positively predictive of an underlying connective tissue disorder (for example, rheumatoid arthritis, mixed connective tissue disease, polymyositis, dermatomyositis, Sjögren's syndrome).

Finger systolic pressure and digital artery closing temperature are laboratory investigations for other potential secondary causes.

Cold water challenge is a provocation test that is no longer recommended as responses are inconsistent even in those with established RP.

[Q: 3244] OnExamination 2012 - Rheumatology

A 55-year-old homeless man presents with a six month history of periodic knee pains and aching legs. These have been occurring monthly and episodes last up to two weeks. He has noticed a 'bumpy' rash to his lower legs and complains of feeling more tired than usual. He has no significant past medical history.

He is currently reporting to a pharmacy daily for methadone.

Clinical examination demonstrated; pulse 88 (regular), normal heart sounds and chest sounds, painful but full active range of knee motion and palpable purpura to the lower extremities.

Blood tests revealed;

Hb 11.9 g/dL(13-18)

MCV 93fL(80 - 96)

WCC $9.8 \times 10^9/L$ (4 - 11)

ALT 150 iu/L(5 - 35)

AST 90 iu/L(1 - 31)

Complement C₄ 64 mg/dL(75-135)

Which test is most likely to assist you in the management of this man's illness?

- 1- ANA
- 2- Anti-CCP
- 3- Cryoglobulin serology
- 4- Hepatitis C serology
- 5- Rheumatoid factor

Answer & Comments

Answer: 4- Hepatitis C serology

Learning points:

Presentation of mixed cryoglobulinaemia (MCG)

Risk factors for (MCG)

Haematological profile of MCG.

This patient presents with palpable purpura, arthralgia and myalgia (that is, Meltzer's triad) seen in cryoglobulinaemia (types II/III).

The diagnosis is made using historical accounts, skin purpura, hypocomplementaemia and demonstration of circulating cryoglobulins.

Type II (mixed essential) cryoglobulinaemia is closely associated with persistent hepatic infection (transaminitis, inferred IVDU) most commonly hepatitis C and to a lesser extent hepatitis B.

Management involves treating the underlying cause in the absence of any immediate life, organ or limb threatening complications. In this case with pegylated interferon alpha and ribavirin.

[Q: 3245] OnExamination 2012 - Rheumatology

A 65-year-old woman is referred by her GP for a six month history of acute onset, progressively worsening shoulder pain, occurring bilaterally and associated with morning stiffness lasting approximately one hour.

The GP's letter states that basic bloods demonstrated:

Westergren ESR 55 mm/Hr - 30

CRP 1mg/L < 10

Rheumatoid factor titre 1:80 > 1:40

Which one of the following increases the probability of a diagnosis other than polymyalgia rheumatica?

1- Advanced age

2- Duration of morning stiffness

3- ESR 55 mm/Hr

4- Rheumatoid factor titre 1:80 mg/L

5- Symmetry of shoulder pain

Answer & Comments

Answer: 4- Rheumatoid factor titre 1:80 mg/L

Learning points:

Core inclusion criteria for polymyalgia rheumatica (PMR)

Exclusion criteria for PMR

Common differentials of PMR.

The other four answers form part of The British Society for Rheumatology core inclusion criteria for diagnosing polymyalgia rheumatica (PMR).

The core exclusion criteria include any evidence of activity in the following;

Infection

Cancer or

Giant cell arteritis.

Factors which reduce the probability of PMR include:

Other inflammatory rheumatic disease

Drug-induced myalgia

Chronic pain syndrome

Endocrine disease and

Neurological conditions, for example, Parkinson's.

[Q: 3246] OnExamination 2012 - Rheumatology

A 44-year-old woman has a three month history of progressive pain, swelling and stiffness in both wrists, and the majority of her metacarpophalangeal joints (MCPJs). The symptoms are worse in morning, and it takes an hour to loosen up her joints.

There have been no recent illness and there is no personal or family history of chronic skin conditions. She drinks alcohol occasionally.

On examination there is synovitis in both wrists, and MCPJs. Examination of skin, nails and other joints is normal.

These are results of recent blood tests:

Haemoglobin 13.1gm/dl(11.5 - 16.5 g/L)

WBC $8.2 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils $5.1 \times 10^9/L$ (1.5 - $7 \times 10^9/L$)

Platelets $280 \times 10^9/L$ (150 - $400 \times 10^9/L$)

ESR 48 mm/hr(0 - 20 mm/1st hr)

Rheumatoid factor: positive (1:256)(<30 k IU/L)

Urea, electrolytes and creatinine: Normal

What most appropriate first step in her long term management?

- 1- Anti-TNF α agents
- 2- Disease modifying antirheumatic drugs
- 3- Intra-articular corticosteroids
- 4- NSAIDs
- 5- Oral corticosteroids

Answer & Comments

Answer: 2- Disease modifying antirheumatic drugs

The symptoms, signs and blood results described above suggest a diagnosis of (RA).

Rheumatoid arthritis (RA) is a complex disease which has many manifestations, and management should attempt to address all aspects. The British Society of Rheumatology has published guidelines on the management of RA within the first two years.

These state that a diagnosis of RA should be made as early as possible, on the basis of persistent joint inflammation affecting at least three joints with early morning stiffness of at least 30 minutes. Such patients should have rapid access to a specialist team who

can help to plan care, including training patients to self-manage some aspects of their disease. Specialist rheumatology nurses have a critical role to play within this team, as do physiotherapists, podiatrists, occupational therapists, and occasionally psychologists.

If treatment is warranted, the first step is DMARD therapy (disease modifying anti-rheumatic drugs). All patients should have their disease and its impact assessed and documented at onset, prior to starting DMARD therapy. Treatment should then be started as soon as possible after the diagnosis is made, ideally within three months of the onset of persistent symptoms. The most commonly used DMARD is methotrexate. Such treatment should be part of an aggressive package of care, including escalating doses, intra-articular steroids, parenteral methotrexate and combination therapy. Once established on DMARD therapy, all patients should have a formal assessment of treatment response, or lack of it, in order to justify continuing therapy or changing it. These assessments can include measurement of CRP and disease activity scores such as DAS28. Remission should be documented prior to reducing therapy.

In addition to managing the musculoskeletal aspects of disease, it must not be forgotten that RA is a significant independent risk factor for ischaemic heart disease, and other risk factors should also be aggressively controlled.

Systemic steroids can have an important role in establishing disease control, or bridging gaps between different DMARD therapies, but long-term use is not justified. Intra-articular corticosteroid injections may be considered for symptom control during a mono- or oligo-articular flare of RA. This is a useful adjunct to therapy but is not appropriate long term management in itself.

Long-term use of NSAIDs should be at the lowest effective dose, and should be avoided in those with high cardiovascular risk.

Surgery may be indicated if any of the following persist, despite optimum medical therapy:

- Persistent pain as a result of joint or soft tissue damage
- Worsening joint function
- Progressive deformity
- Persistent localised synovitis
- Imminent or actual tendon rupture
- Nerve compression
- Stress fracture

There is little evidence for the long term efficacy of dietary change, or complementary therapies, although a Mediterranean diet should be recommended. Patients should be helped to contact support organisations. The role of fatigue should be recognised and managed. Aerobic exercise should be encouraged.

Over recent years, biological agents (especially inhibitors of tumour necrosis factor) have been developed. In the United Kingdom, anti-tumour necrosis factor (TNF) agents are used for the treatment of RA only if the patient fails to respond to an adequate trial of two DMARDs (for example, lefunomide, methotrexate, sulfasalazine, etc). However, even with these the frequency and degree of responses are restricted. Newer agents are therefore being introduced, including rituximab (anti-CD20), abatacept (cytotoxic T-lymphocyte antigen 4 immunoglobulin) and tocilizumab (anti-interleukin 6 receptor).

[Q: 3247] OnExamination 2012 - Rheumatology

A 66-year-old man has a painful, swollen right knee and difficulty in walking for three days.

He had two self-limiting episodes of severe pain and swelling in the right big toe last year. He drinks 26 cans of beer/week.

On examination, his temperature is 36.8°. The right knee is red, swollen, warm and tender and has restricted movement.

The knee aspirate shows no organisms on Gram stain, plenty of leucocytes, and negatively birefringent crystals on polarised light microscopy.

The results of recent blood tests are:

Hb 12.3 g/dl (13.0 - 18.0 g/dL)

WBC $14.3 \times 10^9/\mu\text{l}$ ($4 - 11 \times 10^9/\text{L}$)

Neutrophils 88% (40-75%)

Platelet $340 \times 10^9/\text{L}$ ($150 - 400 \times 10^9/\text{L}$)

Urea, electrolytes and creatinine: Normal

ESR 79 mm/hr (0 - 15 mm/1st hr)

Urate $521 \mu\text{mol/l}$ ($210-415 \mu\text{mol/l}$)

What is the most likely diagnosis?

- 1- Gout
- 2- Osteoarthritis
- 3- Pseudogout
- 4- Reactive arthritis
- 5- Septic arthritis

Answer & Comments

Answer: 1- Gout

Monosodium urate crystals are needle shaped and are negatively birefringent. Therefore, this patient has acute gout.

He has several risk factors for gout including

Age more than 40 years

Male gender

High alcohol consumption (more than 21 units for men, more than 14 units for women).

Pseudogout is caused by intra-articular shedding of calcium pyrophosphate dihydrate

(CPPD) crystals. CPPD crystals are rhomboid and show a weak positive birefringence on polarised light microscopy. Pseudogout is common at the knee but rarely leads to podagra.

There is no history of recent infections to suggest reactive arthritis.

Septic arthritis of the knee is less likely as the Gram stain is negative.

Osteoarthritis of the knee usually presents as chronic mechanical joint pain.

[Q: 3248] OnExamination 2012 - Rheumatology

A 65-year-old woman with chronic hepatitis C presents with a six week history of extensive non-blanching rash on her legs. She has also developed swelling and stiffness in the MCP and IP joints.

On examination, there is pitting oedema, her BP is 130/90 mm Hg, and urine dipstick shows 3+ proteins.

Recent blood tests are as follows:

Haemoglobin 13.1g/dl(11.5 - 16.5 g/dL)

WBC $8.2 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils $5.1 \times 10^9/L$ (1.5 - $7 \times 10^9/L$)

Platelets $280 \times 10^9/L$ (150 - $400 \times 10^9/L$)

ESR 48 mm/hr(0 - 30 mm/1st hr)

Bilirubin 27 $\mu\text{mol/L}$ (1 - 22 $\mu\text{mol/L}$)

Albumin 25 g/L(37 - 49 g/L)

Alkaline phosphatase 160 U/L(45 - 105 U/L (over 14 years))

Rheumatoid factor positive (1:2048) (< 30 k IU/L)

ALT 58 IU/L

Urea, electrolytes and creatinine: Normal

What is the diagnosis?

1- Cryoglobulinaemia

2- Hepato-renal syndrome

3- Polyarteritis nodosa

4- Rheumatoid arthritis

5- Systemic lupus erythematosus

Answer & Comments

Answer: 1- Cryoglobulinaemia

Mixed cryoglobulinaemia manifests as

Purpura

Cutaneous ulcers

Polyneuropathy

Membranoproliferative glomerulonephritis

and non-erosive polyarthralgia associates with hepatitis C.

Laboratory investigations show positive rheumatoid factor, low C4, active urine sediments, and type II or III serum cryoglobulins. There may be axonal polyneuropathy.

Active urinary sediment suggests the presence of membranoproliferative glomerulonephritis.

Polyarteritis nodosa associates with hepatitis B.

[Q: 3249] OnExamination 2012 - Rheumatology

A 55-year-old woman on treatment for longstanding rheumatoid arthritis has recently become short of breath on mild exertion and developed a dry cough.

Oxygen saturation was found to be 87% on air, and chest x ray showed a diffuse bilateral interstitial infiltrate. An extensive infection screen was negative and her symptoms were thought to be drug-induced.

Which drug is most likely to have caused this adverse effect?

1- Azathioprine

2- Cyclosporin

- 3- Hydroxychloroquine
- 4- Methotrexate
- 5- Sulphasalazine

Answer & Comments

Answer: 4- Methotrexate

Methotrexate is widely used in the management of rheumatoid arthritis.

Pneumonitis is a well-recognised and potentially fatal hypersensitivity reaction associated with methotrexate. It is far less predictable than other side effects associated with the drug. Typical symptoms include progressive dyspnoea, cough and fever.

On examination, patients are typically hypoxic and tachypnoeic and there may be audible crackles on chest auscultation. Chest radiographs reveal interstitial or alveolar infiltrate, concentrated within the lower lung fields. Spirometry demonstrates a restrictive pattern with reduced diffusion capacity. Lung biopsy is not specific but often reveals cellular interstitial infiltrates, granulomas or diffuse alveolar damage with perivascular inflammation.

These features are common to many drug-induced toxicities.

It is important to educate patients regarding the possibility of developing this adverse reaction. If suspected, methotrexate should be stopped, other causes investigated and supportive measures initiated. Some units recommend a pre-treatment chest x ray, although it remains unclear as to whether pre-existing respiratory disease increases the risk of pneumonitis.

Additional adverse effects associated with methotrexate include hepatic toxicity and neutropenia. There are guidelines for close monitoring for the development of these, centred on regular blood tests.

Side effects of cytotoxic agents is a common topic of MRCP examination questions. Those of which it is important to be aware include:

Azathioprine: commonly associated with mild bone marrow suppression. Should be used with caution in patients receiving allopurinol due to the risk of life-threatening bone marrow failure.

Cyclosporin: common side effects include hirsutism, liver dysfunction, gum hypertrophy and hypertension.

Hydroxychloroquine: may cause hair loss and 'bull's eye maculopathy'. Visual acuity should be monitored every six to 12 months.

Sulphasalazine: associated with pancytopenia.

[Q: 3250] OnExamination 2012 - Rheumatology

A 38-year-old publican with a two month history of bloody diarrhoea, abdominal pain, and weight loss presents with a three week history of painful and swollen left knee. There is no other significant past or family history.

Stool cultures done by her GP have been negative for C. difficile toxin, and have not grown any pathogenic organisms. On examination, the left knee is warm, tender, and there is a large effusion.

What is the most likely diagnosis?

- 1- Carcinomatous arthropathy
- 2- Gout
- 3- Inflammatory arthritis associated with inflammatory bowel disease
- 4- Reactive arthritis
- 5- Psoriatic arthritis

Answer & Comments

Answer: 3- Inflammatory arthritis associated with inflammatory bowel disease

This patient has chronic diarrhoea (more than two week duration), most likely to be due to inflammatory bowel disease (IBD).

IBD associates with asymmetric oligoarthritis. Knees and ankles are the most commonly affected joints.

The clinical course of peripheral joint (appendicular) inflammatory arthritis associated with IBD frequently follows the clinical course of gut disease. This form of enteropathic arthritis frequently remits after successful treatment of bowel disease.

IBD also associates with sacroiliitis (axial disease). There is no association between the clinical course of sacroiliitis and gut disease. It is worth bearing in mind that sacroiliitis may precede the onset of IBD by many years in some cases, and as outlined above may progress despite bowel resection.

Reactive arthritis is unlikely as the arthritis in reactive arthritis occurs a few weeks (4-6 weeks) after the resolution of infection. There is no risk factor of gout (age < 50 years, female gender, low alcohol intake), malignancy, and there is no personal or family history of psoriasis.

[Q: 3251] OnExamination 2012 - Rheumatology

A 55-year-old woman with longstanding well controlled seropositive RA, treated with methotrexate (20 mg/week) and folic acid 5 mg/day, presents with cough productive of green phlegm, fever (38.5°C), and severe sore throat.

On examination, the BP is 110/70 mmHg, SaO₂ is 98% on air, there is an occasional crackle at the right base. A chest x ray is normal. FBC, UEC, and LFTs are also normal. The CRP is 34 mg/L.

Which of the following is the most appropriate course of action?

1- IV antibiotics, continue methotrexate

2- IV antibiotics, stop methotrexate, and give folinic acid rescue

3- IV antibiotics, stop methotrexate temporarily

4- Oral antibiotics, continue methotrexate

5- Stop methotrexate

Answer & Comments

Answer: 3- IV antibiotics, stop methotrexate temporarily

The most likely diagnosis in this scenario is a lower respiratory tract infection.

In the setting of acute infection, most DMARDs (except hydroxychloroquine) should be discontinued until the infectious process has resolved. Whilst it is possible the infection could be successfully treated with oral antibiotics, there is not an option here which includes this with stopping methotrexate therefore .

Methotrexate is a folic acid antagonist. It can result in a pneumonitis that manifests with non-specific symptoms such as fever, fatigue, cough and dyspnoea. It is rare and the presence of a productive cough here makes the diagnosis less likely but if suspected methotrexate should be stopped immediately. Additional adverse effects include hepatotoxicity, alopecia, mouth ulcers and nausea. Folic acid should be given daily to reduce the incidence of these in patients treated with methotrexate.

Taken in overdose, methotrexate can cause multiple organ damage. Folinic acid is indicated and should be given intravenously as soon as it is suspected to limit toxicity. There is no suggestion of methotrexate overdose in this patient, and therefore folinic acid is not indicated.

[Q: 3252] OnExamination 2012 - Rheumatology

A 30-year-old man with longstanding psoriasis has a six week history of persistently swollen, painful, and tender right knee. The early morning stiffness lasts for over an hour, and he has partial relief from the use of NSAIDs.

He is negative for rheumatoid factor. A knee x ray is normal.

What is the next step in his long term management?

- 1- Alternative NSAID
- 2- Anti-TNF α agents
- 3- Disease modifying antirheumatic drugs (DMARDs)
- 4- Intra-articular corticosteroids
- 5- Oral corticosteroids

Answer & Comments

Answer: 3- Disease modifying antirheumatic drugs (DMARDs)

This patient has psoriatic arthritis and should be treated with a DMARD to prevent joint damage from proliferative/ erosive changes in psoriatic arthritis.

In the United Kingdom, anti-TNF agents are used for the treatment of psoriatic arthritis only if the patient fails to respond to an adequate trial of two DMARDs (for example, leflunomide, methotrexate, sulfasalazine).

Nonsteroidal anti-inflammatory drugs (NSAIDs) provide partial symptom relief and do not prevent progressive joint damage.

In patients with cutaneous psoriasis, systemic corticosteroids predispose to pustular psoriasis, and may result in a flare of skin psoriasis when they are stopped.

Intra-articular corticosteroid injections may be considered for symptom control during a mono- or oligo-articular flare of psoriatic arthritis. This is a useful adjunct to therapy

but is not appropriate long term management in itself.

[Q: 3253] OnExamination 2012 - Rheumatology

A 62-year-old woman presents with a one year history of worsening bilateral, anterior knee pain. The pain is increased by climbing stairs. Both knees are stiff for five to 10 minutes in morning. There is no history of knee swelling. The pain is partially controlled by paracetamol 1 g up to four times a day. She has a history of diabetes, and angina.

On examination, she is overweight. There is crepitus and during active and passive movement of both knees. There is no knee effusion. A recent knee x ray shows joint space narrowing in the medial tibio-femoral joint.

What is the next step in her management?

- 1- Acupuncture
- 2- Oral NSAIDs
- 3- Rest
- 4- Topical NSAIDs
- 5- Transcutaneous electrical nerve stimulation (TENS)

Answer & Comments

Answer: 4- Topical NSAIDs

This lady has osteoarthritis.

NICE guidelines recommend formulating individualised management plans for patients with osteoarthritis.

Behavioural change, such as exercise, weight loss and suitable footwear should be encouraged. Comorbidities which compound the effect of osteoarthritis symptoms should be identified and their treatment optimised.

Paracetamol and/or topical NSAIDs (for knee or hand OA) should be offered before considering oral NSAIDs.

If symptoms are not controlled with the above strategies, oral NSAIDs or COX-2 inhibitors (but not etoricoxib) can be used. A proton pump inhibitor should be co-prescribed. The lowest effective dose should be prescribed for the shortest period possible. If the patient is already taking low-dose aspirin, an alternative analgesic should be considered.

Treatments which are not recommended include rubefacients, intra-articular hyaluronan, electro-acupuncture and chondroitin or glucosamine products.

Adjuvants which can be used include opioid analgesics, topical capsaicin and intra-articular corticosteroids.

Application of heat or cold packs, or TENS, can be considered if other strategies are ineffective. Manipulation and stretching can be helpful, particularly for hip osteoarthritis. Bracing/joint supports can be used for patients with biomechanical joint pain or instability.

Patients should be referred for joint surgery if they have already been offered all of the core treatments or if they have refractory joint symptoms which have a substantial impact on their quality of life.

If there is a clear history of mechanical locking, referral for arthroscopic lavage and debridement should be considered.

[Q: 3254] OnExamination 2012 - Rheumatology

A 25-year-old lady with SLE (ANA positive, 1:1280), had a healthy term baby boy.

At the time of birth he was noted to have macular erythematous rash on his face, and trunk. He is otherwise well.

What is the most likely cause of his rash?

- 1- Discoid lupus erythematosus
- 2- Erythema toxicum

- 3- Neonatal lupus
- 4- Staphylococcus aureus
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 3- Neonatal lupus

This child has neonatal lupus.

Neonatal lupus is an uncommon condition associated with the transplacental passage of maternal anti-Ro and/or anti-La autoantibodies.

Findings may include

Cutaneous lupus lesions

Third-degree heart block

Cardiomyopathy

Hepatobiliary disease and

Cytopenias.

Typically only one organ is affected in each infant.

The most severe manifestation is the heart block, which usually begins during the second trimester of pregnancy. It is rare, occurring in only 2% of mothers with anti-Ro or anti-La antibodies. Once established this is permanent, unlike the other manifestations which are generally transient.

The rash is most frequently seen around the eyes, but also occurs in other parts of the body. Lupus presents as erythematous macular rash, on face or trunk, which may be photosensitive. Asymptomatic elevation of liver function tests is seen in 10-25% of cases. Overall, non-cardiac involvement is more common than cardiac.

A significant number of babies with neonatal lupus are born to mothers who are not known to have systemic lupus erythematosus.

Systemic lupus erythematosus does not occur in neonates.

Discoid lupus erythematosus presents with ulcers which heal with scarring.

The rash in erythema toxicum is papular, small, yellow-to-white coloured, and surrounded by red skin. This rash changes rapidly, appearing and disappearing in different areas over hours to days.

Staphylococcus aureus can cause impetigo and scalded skin syndrome, but these are not commonly seen in the immediate neonatal period.

[Q: 3255] OnExamination 2012 - Rheumatology

A 54-year-old man presents with a six day history of sharp shooting pain radiating from his back to the lateral aspect of his leg. The pain is associated with pins and needles.

On examination, he has sensory loss on the lateral aspect of leg, dorsum of foot, and there is a partial foot drop.

Which lumbar spine nerve root is affected?

- 1- L2
- 2- L3
- 3- L4
- 4- L5
- 5- S1

Answer & Comments

Answer: 4- L5

The L5 nerve root supplies sensation to the lateral aspect of leg and dorsum of foot (except for the lateral border which is supplied by S1). In addition, it supplies hip extensors, knee flexors (with S1), ankle dorsiflexors (with L4), and toe dorsiflexors.

RootDermatome distributionMyotome distributionTendon reflex

[Q: 3256] OnExamination 2012 - Rheumatology

A 52-year-old woman presents with increasing lower back pain for the last six months. The pain is increased by working as a floor-layer, and is worse in the evening.

There is no weight loss, night pain, or fever. Her back is stiff for 15 minutes in morning.

Over the last few months she has developed firm to hard swelling on several distal and proximal interphalangeal joints, and has anterior knee pain worsened by climbing stairs. A full blood count, ESR, and CRP done by the GP have been normal.

What is the diagnosis?

- 1- Ankylosing spondylitis
- 2- Discitis
- 3- Generalised osteoarthritis
- 4- Metastasis

5- Osteoporosis

Answer & Comments

Answer: 3- Generalised osteoarthritis

This patient has generalised osteoarthritis (GOA), as there are OA related symptoms in at least three joint areas, namely

Bony swellings at distal and proximal IPJs termed Heberden's and Bouchard's nodes respectively

Anterior knee pain, worse on climbing stairs, suggesting patella-femoral joint OA, and

Low back pain, suggesting spinal degenerative changes.

Ankylosing spondylitis typically occurs in young men, and associates with pronounced early morning stiffness and buttock pain.

Osteoporosis is not symptomatic, unless accompanied by a spinal fracture. Osteoporotic spinal fractures present with acute pain which improves over a period of few weeks to a couple of months.

There are no red-flag symptoms to raise the possibility of discitis or malignancy.

[Q: 3257] OnExamination 2012 - Rheumatology

A 25-year-old man complaining of low back pain and stiffness gradually increasing in severity for six months presents to the outpatient department.

He has no past medical history and the only medications he takes are anti-inflammatories that ease the pain.

On examination, his back movements are stiff with decreased range of movement due to pain, but the spine curvature is normal.

Which one of the options below is the most likely diagnosis?

1- Ankylosing spondylitis (AS)

2- Metastatic disease of the spine

3- Muscular strain

4- Reactive arthritis

5- Scheuermann's disease

Answer & Comments

Answer: 1- Ankylosing spondylitis (AS)

All of these can be causes of back pain. The key differentiators in this case are the age of the patient and the detailed history of the type of back pain.

A. Patients often present with AS in their 20s and 30s with a history of chronic back pain and stiffness. Key features of the pain include

Early morning stiffness of more than 30 minutes

Alternating buttock pain

Waking in the second half of the night

Pain easing with non-steroidal anti-inflammatory drugs (NSAIDs)

Pain which is worse with rest and eases with exercise.

B. Metastatic cancer can affect the spine and cause back pain. This is usually associated with 'red flag' signs suggesting malignancy. This diagnosis is less common in younger patients.

C. Muscular strain is the commonest cause of back pain in general practice but chronic pain for more than three months may indicate AS and should be investigated.

D. Reactive arthritis can cause inflammatory back pain with similar symptoms to AS but there is no history of preceding genitourinary or gastrointestinal infection.

E. Scheuermann's disease generally presents in teenagers with thoracic back pain and increased thoracic kyphosis, and therefore does not fit with this scenario.

[Q: 3258] OnExamination 2012 -
Rheumatology

A 42-year-old woman presents with a small joint polyarthritis and significant morning stiffness which has increased over the past few months.

On examination she has a symmetrical small joint polyarthritis affecting the proximal interphalangeal joints, metatarsophalangeal joints, wrists, elbows and knees; otherwise the physical examination is unremarkable.

Haemoglobin 12.0 g/dl(11.5-16)

White cell count $7.1 \times 10^9/L$ (4-10)

Platelets $201 \times 10^9/L$ (150-400)

Sodium 141 mmol/l (134-143)

Potassium 4.3 mmol/l (3.5-5)

Creatinine 82 $\mu\text{mol/l}$ (60-120)

Rheumatoid factor negative

Anti-CCP antibody Positive

Which of the following is the most likely diagnosis?

- 1- Polymyalgia rheumatica
- 2- Reactive arthritis
- 3- Rheumatoid arthritis
- 4- Seronegative arthritis
- 5- SLE

Answer & Comments

Answer: 3- Rheumatoid arthritis

Anticyclic citrullinated protein (CCP) antibodies were identified as early as the 1970s in patients with rheumatoid arthritis, but it is only recently that more specific assays have become available.

They are the most specific biomarker associated with the diagnosis of rheumatoid arthritis. It has been suggested that citrullination and the anticitrullinated peptide antibodies play a critical role in initiating the

inflammatory response within rheumatoid arthritis.

In patients with the clinical picture of rheumatoid arthritis who are rheumatoid factor negative, anti-CCP antibodies can aid in making the diagnosis between rheumatoid and other causes of arthritis.

Positive rheumatoid factor is associated with a worse prognosis in rheumatoid arthritis.

Polymyalgia rheumatica is associated with a markedly raised erythrocyte sedimentation rate (ESR) and is characterised by severe bilateral pain and morning stiffness of the shoulder, neck and pelvic girdle.

Reactive arthritis is the triad of arthritis, urethritis and conjunctivitis which is classically associated with sexually transmitted or gastrointestinal infection.

Seronegative arthritis is a heterogeneous group of inflammatory rheumatic disease with predominant involvement of axial and peripheral joints, and enthesitis.

There is a high incidence of HLA-B27, but rheumatoid factor is typically negative. Diseases belonging to this group include ankylosing spondylitis, reactive arthritis, psoriatic arthritis and Behcet's disease.

Systemic lupus erythematosus (SLE) is a heterogeneous, multisystem, inflammatory autoimmune condition which is characterised by positive antinuclear antibodies.

[Q: 3259] OnExamination 2012 -
Rheumatology

A 17-year-old girl who had completed treatment for acute lymphoblastic leukaemia six months previously presents with a short history of marked, right hip pain and associated limp.

What is the most likely diagnosis?

- 1- Avascular necrosis of the femoral head
- 2- Gout

- 3- Osteoarthritis
- 4- Pseudogout
- 5- Septic arthritis

Answer & Comments

Answer: 1- Avascular necrosis of the femoral head

Avascular necrosis of the femoral head can occur as a consequence of her treatment or the disorder itself.

At age 17 osteoarthritis is particularly unlikely.

Gout, too, is unlikely (considering she completed treatment six months ago) unless she had relapsed (high white cell count) or had some other risk factors.

She would be considered to be no more likely to get septic arthritis or pseudogout than anyone who had not previously had acute lymphoblastic leukaemia, if in remission.

[Q: 3260] OnExamination 2012 - Rheumatology

A 40-year-old man presents with acute monoarthritis of the right knee.

Gout is confirmed following joint aspiration and examination of the fluid under polarised light microscopy. He underwent endoscopy three weeks earlier because of dyspepsia and this confirmed a duodenal ulcer.

Which of the following would be the best initial treatment for him?

- 1- Allopurinol
- 2- Indomethacin alone
- 3- Indomethacin and lansoprazole
- 4- Indomethacin and misoprostol
- 5- Intra-articular corticosteroid injection

Answer & Comments

Answer: 5- Intra-articular corticosteroid injection

The principles of treating an acute episode of gout are:

Commence anti-inflammatory medication immediately, and continue for two weeks - non-steroidal anti-inflammatory drugs (NSAIDs) are first line in conjunction with gastro-protective medication where indicated; colchicine is an alternative but is slower to work and can be associated with significant diarrhoea

Rest the affected joints

Allopurinol should not be started during an acute attack but in patients already established on allopurinol it should be continued

If diuretics are being used to treat hypertension an alternative antihypertensive should be considered, but they should not be stopped in the presence of heart failure

Corticosteroids are highly effective, and can be used where NSAIDs are not tolerated, or in refractory disease (intra-articular, oral, intramuscular, intravenous).

In this scenario, NSAIDs are contraindicated due to the presence of active gastrointestinal ulceration. Even with coadministration of a gastroprotective medication (for example, lansoprazole or misoprostol) the risk of haemorrhage or perforation is too high to use NSAIDs in this case.

Initiation of allopurinol can prolong an acute attack of gout due to shifts in uric acid levels. It is therefore recommended only one to two weeks after the resolution of symptoms, usually with colchicine cover.

Intra-articular corticosteroids is therefore the most appropriate answer in this case. If available, colchicine would be a reasonable option but it can be associated with

significant gastrointestinal toxicity. The systemic absorption from intra-articular corticosteroids is extremely low, and as you are bypassing the intestine they do not carry risk of peptic ulceration associated with oral corticosteroid use.

Potential local side effects of corticosteroid injections include increased pain for the first couple of days, septic arthritis, subcutaneous atrophy (causing skin dimpling), skin depigmentation, accidental nerve injury and tendon rupture.

Reference:

British Society for Rheumatology and British Health Professionals in Rheumatology Guideline for the Management of Gout. Jordan KM et al. Rheumatology 2007;46:1372-1374.

[Q: 3261] OnExamination 2012 - Rheumatology

A 55-year-old gentleman has been taking methotrexate 7.5 mg weekly for seronegative erosive rheumatoid arthritis with considerable clinical and symptomatic improvement. He has been on this dose for three months.

His most recent investigations, performed two days ago, reveal the following:

Haemoglobin 12.9 g/dl (12-16.5)

White cell count $5.3 \times 10^9/L$ (4-11)

Platelets $183 \times 10^9/L$ (150-400)

Urea 4.2 mmol/l (2.5-7.5)

Creatinine 88 $\mu\text{mol/l}$ (60-110)

Alkaline phosphatase 92 U/l (60-110)

AST 22 U/l (1-31)

ALT 15 U/l (5-35)

When should the next FBC be performed?

- 1- One week
- 2- Two weeks
- 3- One month
- 4- Six months

5- One year

Answer & Comments

Answer: 3- One month

His results are normal and he is receiving a stable dose of methotrexate.

The most appropriate time interval for monitoring his full blood count (FBC) according to current UK guidance would therefore be in one month.

Clinicians are recommended to check FBC fortnightly until 6 weeks after the last dose increase. Provided it is stable, it can be checked monthly thereafter until the dose and disease is stable for one year. Thereafter monitoring is guided by clinical judgement. If white cell count is less than 3.5, neutrophils less than 2 or platelets less than 150, methotrexate should be withheld pending discussion with the specialist team. An MCV greater than 105fL warrants checking B12, folate and TSH and treating any abnormality. If these are normal, discuss with the specialist team.

Liver function tests should be checked three monthly. If there is an unexplained decrease in albumin, or AST/ALT twice the upper limit of normal, the specialist team should be informed.

Urea, creatinine and electrolytes should be checked six monthly. If the estimated glomerular filtration rate falls below 50mL/minute, methotrexate should be withheld until the result has been discussed with the specialist team.

In addition to this monitoring, any clinical signs of toxicity should be monitored for. If the patient develops rash, oral ulceration, nausea, vomiting or diarrhoea, methotrexate should be withheld until discussed with the specialist team. Any new or increasing dyspnoea or dry cough should be urgently discussed with secondary care, and

methotrexate withheld. A sore throat or abnormal bruising should be investigated with an FBC, and methotrexate withheld until the results available.

[Q: 3262] OnExamination 2012 - Rheumatology

A 71-year-old man with a history of chronic renal impairment and atrial fibrillation for which he takes warfarin, presents with an acutely tender and red left big toe.

Investigations reveal:

Serum Creatinine 200 micromol/l (50-100)

Serum urate 0.5 mmol/l (0.12-0.42)

Which of the following is the most appropriate treatment for this man's presentation?

- 1- Allopurinol
- 2- Colchicine
- 3- Diclofenac
- 4- Paracetamol
- 5- Prednisolone

Answer & Comments

Answer: 5- Prednisolone

This man presents with acute gout, has chronic renal impairment, AF and takes warfarin.

Non-steroidal anti-inflammatory drugs (NSAIDs) would be the treatment of choice but may cause a deterioration in renal function and would be associated with an increased risk of bleeding in the elderly.

The adverse effects of colchicine (especially gastrointestinal symptoms) would be more likely in the elderly and should probably be avoided in those with renal impairment of this degree.

Thus steroids are probably the best option.

Allopurinol may well precipitate/exacerbate acute gout and is used once the acute attack has settled following adequate treatment.

This is a classic MRCP question since it is hard to answer this by just looking in textbooks. Steroids are the last resort choice where NSAIDs and colchicine are deemed too dangerous to use and that is a matter of judgement applied by physicians. There is plenty of evidence for their efficacy. Ann Emerg Med. 2007 May;49(5):670-7

[Q: 3263] OnExamination 2012 - Rheumatology

A 73-year-old female presents with difficulty opening jars and bottles.

On examination there is tenderness with crepitus and bony swelling over the base of the first metacarpal and wasting of the right thenar eminence.

Investigations reveal an ESR of 30 mm/1st hr (0-20), a C-reactive protein of 8mg/L (<10), a urate concentration of 0.40 mmol/L (0.19-0.36) and a rheumatoid factor was 60 IU/L (<30).

An x ray of the right hand showed a loss of the joint space with articular sclerosis and osteophytes of the first carpo-metacarpal joint.

What is the most likely diagnosis?

- 1- DeQuervain's tenosynovitis
- 2- Gouty arthritis
- 3- Osteoarthritis
- 4- Pyrophosphate arthritis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 3- Osteoarthritis

This woman has clinical and radiological features consistent with osteoarthritis (OA) of the first right carpometacarpal (CMC) joint. Osteoarthritis is one of the most common

joint disease, and its incidence is increasing with the age and weight of the population. It is characterised by joint pain, crepitus, stiffness after mobility, and limitation of motion, commonly affecting the knees, hips and small joints of the hand. The CMC joint is classically involved, and involved in gripping and twisting. Joint swelling is bony in nature, unlike the boggy swelling which occurs in inflammatory arthritis. Thenar wasting occurs in OA of the first CMC joint due to disuse.

Pathogenesis involves the localised loss of cartilage, with remodelling of adjacent bone. The associated pain is exacerbated by exercise and relieved by rest, although in advanced disease rest and night pain can develop. There may also be joint stiffness, typically in the morning or after rest. Diagnosis is often late, and treatment is usually aimed at reducing pain and improving function rather than targeting the disease process.

This woman's erythrocyte sedimentation rate (ESR) is not significantly raised and her C reactive protein (CRP) is within normal range making an inflammatory arthritis such as rheumatoid arthritis unlikely.

A positive rheumatoid factor does not make the diagnosis of rheumatoid arthritis. The frequency of positive rheumatoid factor in normal individuals of age over 70 is upto 10-20%.

The predominant feature of gouty arthritis is pain, and it rarely affects the hands. Pyrophosphate arthropathy can complicate osteoarthritis but it usually presents with acute onset large joint monoarthritis.

De Quervain's disease is a common pathology which consists of a stenosing tenosynovitis of the first dorsal compartment of the wrist. It typically presents with pain on the radial aspect of the wrist, with associated swelling and tenderness. Treatment is with splinting, with or without corticosteroid injection.

[Q: 3264] OnExamination 2012 - Rheumatology

A 30-year-old woman presents with Raynaud's phenomenon.

Which one of the following clinical features suggests an underlying connective tissue disease?

- 1- Episodes lasting in excess of one hour
- 2- Involvement of toes
- 3- One previous miscarriage in early pregnancy
- 4- Symmetrical involvement of fingers
- 5- Symptoms developed as a teenager

Answer & Comments

Answer: 1- Episodes lasting in excess of one hour

Raynaud's phenomenon is a common clinical presentation, which may be primary or secondary to underlying disease.

It can be diagnosed if there is a history of clearly demarcated pallor of the digit(s) followed by at least one other colour change (cyanosis and/or erythema). Symptoms are usually precipitated by cold (or less commonly emotion). Vasospasm without endothelial damage is thought to be the main cause for primary RP. The pathogenesis of secondary forms is probably initiated primarily by endothelial damage.

Physical examination, nailfold capillaroscopy and immunological tests can differentiate between primary and secondary Raynaud's.

You should suspect secondary Raynaud's phenomenon if any of the following are present:

Onset at more than 30 years of age

Intense, painful or asymmetrical episodes

Presence of additional clinical features suggestive of underlying disease

Positive anti-nuclear antibody

Abnormal nail-fold capillaries

Digital ulcers, gangrene or severe ischaemia of one or more digits.

Primary Raynaud's can be diagnosed if all the following are present:

No suspicion of underlying disease

Symmetrical episodes affecting both hands, but not necessarily all fingers

No tissue necrosis, ulceration, gangrene or severe ischaemia

Normal nail-fold capillaries

Normal ESR and negative anti-nuclear antibodies.

Treatment involves prevention so that permanent ischaemic damage can be avoided. Patients should avoid exposure to the cold.

The mild forms of primary RP can be controlled by non-pharmacological approaches alone. If insufficient, the first choice therapy is calcium channel blockers. In severe forms, intravenous prostaglandin, endothelin-1 receptor antagonists and phosphodiesterase-5 inhibitors are used.

Future treatment options may include selective alpha-2c adrenergic receptor blockers, tyrosine and Rho-kinase inhibitors and calcitonin gene-related peptide.

Differential diagnosis of Raynaud's phenomenon includes:

Chilblains (perniosis): erythematous itchy swellings on fingers and toes in response to cold

Acrocyanosis: continuous blueness of the extremities aggravated by cold

Erythromelalgia: painful erythema caused by paroxysmal dilatation of blood vessels

Vascular embolism

Livedo reticularis

Mottled, cyanotic discolouration of skin.

All the other features described here would be consistent with a diagnosis of primary Raynaud's disease.

Whilst miscarriage can be associated with connective tissue disease, in particular antiphospholipid syndrome, it is common in the population especially in early pregnancy.

[Q: 3265] OnExamination 2012 - Rheumatology

A 26-year-old male presents with a three month history of arthralgia, mouth ulceration and eye irritation.

On examination he was afebrile, had some ulceration of the mouth, bilaterally swollen wrists and effusions, with reduced range of movements of both knees.

Examination of the external genitalia revealed a scrotal ulcer.

His investigations showed:

White cell count $12 \times 10^9/L$ (4-11)

C reactive protein 120 mg/l (<10)

Rheumatoid factor negative

What is the most likely diagnosis?

1- Behçet's syndrome

2- Inflammatory bowel disease

3- Psoriatic arthritis

4- Reiter's syndrome

5- Sjögren's syndrome

Answer & Comments

Answer: 1- Behçet's syndrome

This man has Behçet's on the basis of his orogenital ulceration and oligoarthritis.

Behçet's syndrome is a multisystem disorder characterised by:

Recurrent oral and genital ulceration

Eye lesions (anterior or posterior uveitis or retinal vasculitis)

Skin lesions (erythema nodosum, papulopustular lesions or folliculitis)

A positive pathergy test (although this is rarely done in clinical practice).

Other features include

Musculoskeletal involvement with a mono- or oligoarthropathy

Venous thromboembolism

Neurological and

Gastrointestinal features.

Reiter's syndrome is a clinical triad of urethritis, conjunctivitis and arthritis after an infective dysentery. It is now referred to as reactive arthritis.

Genital ulceration is not a feature of systemic lupus erythematosus, rheumatoid arthritis or Sjögren's syndrome.

Inflammatory bowel disease can be associated with an oligoarthropathy, occasionally with uveitis, but you would expect a strong history of gastrointestinal symptoms.

[Q: 3266] OnExamination 2012 - Rheumatology

A 68-year-old woman presents to the casualty department with a two day history of pain and swelling of the right ankle. She could not recall any history of recent trauma.

On examination she was febrile, temperature 38.1°C. The right ankle was swollen and very tender with a reduced range of movement.

Which of the following investigations would be of most help in establishing the diagnosis?

- 1- Aspiration of the right ankle
- 2- Blood cultures
- 3- Erythrocyte sedimentation rate
- 4- Serum urate level
- 5- x Ray of the right ankle

Answer & Comments

Answer: 1- Aspiration of the right ankle

Septic arthritis is a medical emergency and this is the most likely diagnosis in this case. It is essential that the joint is aspirated in order to establish a microbiological diagnosis that will guide appropriate treatment.

All of the other investigations listed would be of value in managing this patient, but in this setting joint aspiration is critical.

[Q: 3267] OnExamination 2012 - Rheumatology

A 29-year-old professional singer presents with a prolonged history of epistaxis and rapidly progressive shortness of breath.

The KCO and eosinophil count are raised.

Which of the following is the most likely diagnosis?

- 1- Alveolar proteinosis
- 2- Churg-Strauss syndrome
- 3- Goodpasture's syndrome
- 4- Microscopic polyangiitis
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 5- Wegener's granulomatosis

This patient has shortness of breath and a raised KCO, which leads to you to a diagnosis of alveolar haemorrhage. The condition which links epistaxis and alveolar haemorrhage in the list above is Wegener's granulomatosis. KCO measures the uptake of carbon

monoxide by the lungs, and is equivalent to the transfer factor.

Wegener's granulomatosis is a multi-organ autoimmune disease, which can be fatal. The classical triad consists of necrotising granulomatous inflammation of the respiratory tract, glomerulonephritis and a small-vessel vasculitis. A prolonged history of epistaxis or sinusitis is commonly found in Wegener's granulomatosis, which in some patients is also associated with an eosinophilia. The detection of antineutrophil cytoplasmic antibodies directed against proteinase-3 is highly specific, but is found in only 50% of patients with disease localised to the respiratory tract and 95% with generalised Wegener's.

Standard therapy is with cyclophosphamide and corticosteroids. TNF-alpha blocking agents, anti-thymocyte globulin and monoclonal anti T-cell antibodies can be used in disease refractory to these agents.

Systemic inflammation and vasculitis contribute to accelerated atherosclerosis in patients with Wegener's and there is therefore a significantly increased incidence of stroke, myocardial infarction and occlusive artery disease.

Alveolar proteinosis is a rare diffuse lung condition, characterised by alveolar and interstitial accumulation of phospholipid protein derived from surfactant. It can be congenital, secondary or acquired, and patients often present with recurrent respiratory infections. Transfer factor (KCO) is typically reduced.

Churg-Strauss syndrome is a rare systemic vasculitis which affects small and medium sized vessels, in association with asthma. Patients initially present with allergic rhinitis and asthma, followed by eosinophilia and associated infiltrative disease (e.g. gastroenteritis) and then granulomatous inflammation classically within 3 years.

Goodpasture's syndrome is an important, and potentially rapidly fatal, cause of alveolar haemorrhage. It is caused by circulating antiglomerular basement membrane antibodies, and typically causes an acute glomerulonephritis. Epistaxis is not as common an association.

Microscopic polyangiitis is a small vessel vasculitis which classically spares the upper respiratory tract.

[Q: 3268] OnExamination 2012 - Rheumatology

A 40-year-old woman presents with a year history of Raynaud's phenomenon, dyspepsia and arthralgia.

On examination she has sclerodactyly and synovitis of the small joints of the hands. Her ESR is 40 mm/hr (<20, antinuclear antibody (ANA) is positive and rheumatoid factor is negative.

Which one of the following is most likely to develop as a further complication of this disorder?

- 1- Anterior uveitis
- 2- Butterfly rash
- 3- Erosive joint disease
- 4- Erythema nodosum
- 5- Malabsorption

Answer & Comments

Answer: 5- Malabsorption

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. 90-95% of patients have positive antinuclear antibodies. There are two major subtypes: limited cutaneous and diffuse cutaneous. CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynauds' phenomenon, oesophageal dysmotility, sclerodactyly,

telangiectasia). Patients with systemic sclerosis can present with skin abnormalities, musculoskeletal changes, gastrointestinal complications, pulmonary disease, renal crisis and dry eyes and mouth.

Involvement of the gastrointestinal tract can occur from mouth to anus with varying degrees of severity. It can be present in those with both the diffuse and limited cutaneous forms. Most GIT manifestations result from dysmotility secondary to infiltration of the intestinal wall with fibrous tissue, and can cause life-threatening malabsorption and malnutrition.

Gastric emptying is delayed in 10-75% of patients and causes symptoms of early satiety, bloating and emesis. Treatments include metoclopramide and erythromycin. The small bowel is also involved in 20-60% of patients, due to reduced or absent migrating motor complexes predisposing to bacterial overgrowth. This contributes to malabsorption, as does associated pancreatic insufficiency. In the colon there is often development of diverticuli involving all layers of the intestinal wall, or constipation due to reduced motility.

Anterior uveitis can be associated with ankylosing spondylitis, reactive arthritis, inflammatory bowel disease, sarcoidosis and Behcet's disease. None of these have clinical features which fit with the description above.

A malar, or butterfly rash, is classically associated with systemic lupus erythematosus. It involves the bridge of the nose, but spares the naso-labial folds. It is usually well demarcated and macular. It is not pathognomonic of SLE, and can be seen in pellagra and dermatomyositis, but again none of these would account for the symptoms described above.

Erosive arthritis and erythema nodosum have a variety of different causes, but neither are commonly associated with systemic sclerosis.

[Q: 3269] OnExamination 2012 - Rheumatology

Bone densitometry performed on a 48-year-old woman demonstrates bone mass decreased more than 2 standard deviations below the mean for her age in her left femoral head, wrist, and lumbar vertebral region.

Six months later the amount of bone loss is seen to be increased by repeat densitometry examination.

These findings are most likely to be associated with which of the following serum laboratory test abnormalities?

- 1- Cortisol of 2060 mmol/l (110 - 607)
- 2- Intact parathormone of 5 pmol/l (1.2 - 5.8)
- 3- Total cholesterol of 10 mmol/l (< 5.17)
- 4- Total serum globulin of 35 g/l
- 5- Uric acid of 930 µmol/l (149 - 446)

Answer & Comments

Answer: 1- Cortisol of 2060 mmol/l (110 - 607)

She has osteoporosis with decreased bone mass. Most cases do not have a specific aetiology, but Cushing's syndrome with hypercortisolism can promote osteoporosis. Her age should make you suspicious.

Hypoparathyroidism is not going to accelerate bone loss. The bone resorption that accompanies hyperparathyroidism can cause osteoporosis.

Over 95% of cases of osteoporosis are 'primary' with unknown cause. Elevated serum globulin should make you suspect a monoclonal gammopathy, but myeloma leads to focal bone lytic lesions.

Hyperuricaemia can be associated with gout that can cause focal bone destruction near affected joints, the bone mass overall is not decreased.

[Q: 3270] OnExamination 2012 -
Rheumatology

A 52-year-old woman presents with a two week history of malaise and lower limb joint pain, associated with a vasculitic rash over her shins, thighs and buttocks.

Investigations revealed:

Haemoglobin 9.8 g/dL (11.5-16.5)

Platelet count $275 \times 10^9/L$ (150-400 $\times 10^9$)

Serum creatinine 452 $\mu\text{mol/L}$ (60-110)

Antinuclear antibodies negative

Antineutrophil cytoplasmic antibodies negative

Antiglomerular basement membrane antibodies negative

Dipstick urinalysis Blood +++, protein +

What is the most likely diagnosis?

- 1- Amyloidosis
- 2- Haemolytic uraemic syndrome (HUS)
- 3- Henoch-Schönlein purpura
- 4- Membranous nephropathy
- 5- Myeloma

Answer & Comments

Answer: 3- Henoch-Schönlein purpura

The distribution of the rash together with lower limb joint pains and renal involvement are most suggestive of Henoch-Schönlein purpura (HSP).

HSP is a small vessel vasculitis mediated by IgA-immune complex deposition. It is characterised by the tetrad of purpura, abdominal pain, arthritis, and renal involvement (haematuria and proteinuria). The diagnosis can be easily missed, and a high degree of suspicion is required. Skin biopsy and immunofluorescence demonstrate leukocytoclastic vasculitis with IgA deposition, which is pathognomonic for HSP.

90% of cases of HSP occur in children aged 2-10 years but can occur in any age group. It is typically commoner in males, and may follow an infectious agent. An important risk factor for the development of HSP in adults is thought to be chronic alcohol intake. A variety of disorders have been associated with HSP in adults, including *Helicobacter pylori*, hepatitis B and malignancy. In some cases, overlap with polyangiitis or polyarteritis-like disease is seen.

Management of HSP in adults often involves the use of immunomodulatory or immune-suppressive regimens (in contrast to children where the majority of cases resolve spontaneously). There is often a more complicated course in adults, and 50% of patients who present with renal involvement develop renal insufficiency. In addition to renal disease, cardiac, pulmonary, ocular, gastrointestinal and neurological complications have been described.

Amyloidosis is a clinical disorder caused by extracellular and/or intracellular deposition of insoluble abnormal amyloid fibrils, which alter normal tissue function. It is classified chemically and is associated with a number of different conditions. There is typically a combination of symptoms which affect more than one system, including massive proteinuria, peripheral neuropathy, hepatomegaly and heart failure. A vasculitic rash affecting the lower limbs is not typical.

Haemolytic uraemic syndrome (HUS) is a triad of microangiopathic haemolytic anaemia, thrombocytopenia and acute renal failure. It is most commonly associated with *Escherichia coli* O157:H7. The classical presentation is profuse diarrhoea with blood, and the absence of this in the above scenario makes HUS unlikely.

Membranous nephropathy is a histological diagnosis and usually presents with proteinuria without haematuria. 85% of cases are idiopathic, and the remainder are

secondary to autoimmune conditions (SLE), infection (hepatitis B), drugs (captopril, NSAIDs) and malignancy.

In myeloma there is malignant proliferation of plasma cells, which produces marrow infiltration and overproduction of a monoclonal antibody detectable in serum and/or urine (Bence Jones protein). Common presenting features include pathological fractures, anaemia, anorexia, bruising and infection. Myeloma can rarely cause vasculitis which is antineutrophil cytoplasmic antibody (ANCA) negative but this is rare and less likely than HSP in this scenario.

[Q: 3271] OnExamination 2012 - Rheumatology

A 50-year-old woman presents with dry eyes, a dry mouth, an erythematous rash and polyarthralgia.

Investigations show:

Anti-nuclear antibody Strongly positive (1:1600)

Anti-Ro/SSA antibodies Strongly positive

Rheumatoid factor Positive

IgG 45 g/L (<15)

IgM Normal

IgA Normal

Kappa/lambda ratio Normal

What is the most likely diagnosis?

- 1- Hyperviscosity syndrome
- 2- Myeloma associated vasculitis
- 3- Primary Sjogren's syndrome
- 4- Rheumatoid arthritis with secondary Sjogren's syndrome
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 3- Primary Sjogren's syndrome

The clinical features and the serology are typical of primary Sjögren's syndrome (occurs alone and more likely to have positive anti-Ro SSA antibodies than secondary Sjogren's).

Hypergammaglobulinaemia is present in 80% of individuals.

ANA and anti-Ro/SSA antibodies are present in approximately 90% of individuals as is a weakly positive rheumatoid factor.

The normal kappa/lambda ratio confirms the hypergammaglobulinaemia is polyclonal.

Typically secondary Sjogren's has pre-existent rheumatoid or SLE before the development of Sjogren's symptoms.

[Q: 3272] OnExamination 2012 - Rheumatology

A 20-year-old woman presents with typical erythema nodosum. She has a low grade fever and bilateral ankle arthritis but no other symptoms and has no medical history. There is no history of travel abroad and she is on no medication.

Which of the following would be the most appropriate investigation for this patient?

- 1- Barium enema
- 2- Chest x ray
- 3- Erythrocyte sedimentation rate (ESR)
- 4- Upper gastrointestinal (GI) endoscopy
- 5- Viral titres

Answer & Comments

Answer: 2- Chest x ray

Erythema nodosum is commonly idiopathic.

It can also be related to streptococcal infections, acute sarcoidosis or related to drugs such as the oral contraceptive pill, sulphonamides and penicillins.

Rarer causes include inflammatory bowel disease, tuberculosis, Behçet's disease and other connective tissue disorders.

In this case, a chest x ray would be the most helpful investigation as this may identify bilateral hilar lymphadenopathy which together with a bilateral ankle arthropathy would strongly support a diagnosis of acute sarcoidosis.

Investigation of the bowel is unlikely to help in the absence of any bowel symptoms.

Viral titres and ESR are non-specific.

[Q: 3273] OnExamination 2012 - Rheumatology

Which of the following auto-antibodies may have a role in monitoring disease activity?

- 1- Anti-ds DNA antibodies in systemic lupus erythematosus (SLE)
- 2- Antinuclear antibodies in systemic lupus erythematosus
- 3- Anti-Ro (SSA) antibodies in Sjogren's syndrome
- 4- Anti-Sm antibodies in systemic lupus erythematosus
- 5- Rheumatoid factor in rheumatoid arthritis

Answer & Comments

Answer: 1- Anti-ds DNA antibodies in systemic lupus erythematosus (SLE)

The serum levels of anti-dsDNA antibodies appear to correlate with disease activity in many patients and often levels will rise just before a flare of disease.

The relationship is not close enough to be able to alter treatment based on a rising titre of antibodies but patients should be followed more closely in this situation.

Anti-Sm antibodies are very specific for SLE but not sensitive and there is no evidence that levels change with disease activity.

The only other autoantibody where there may be some correlation between levels and disease activity is circulating anti-neutrophil cytoplasmic antibody (cANCA) in Wegener's granulomatosis.

[Q: 3274] OnExamination 2012 - Rheumatology

A 50-year-old man presents with lethargy, polyuria, polydipsia and pain and stiffness of the hands.

He has evidence of an arthropathy affecting the second and third metacarpo-phalangeal (MCP) joints of both hands with radiographic evidence of degenerative disease at these sites. He also has 5 cm hepatomegaly.

Which of the following is the most likely diagnosis?

- 1- Gout
- 2- Haemochromatosis
- 3- Osteoarthritis
- 4- Pyrophosphate arthropathy
- 5- Rheumatoid arthritis with amyloidosis

Answer & Comments

Answer: 2- Haemochromatosis

This gentleman has haemochromatosis. The typical presenting features are diabetes, bronzing of the skin, hepatomegaly (due to iron deposition) and arthropathy (especially of the second and third metacarpophalangeal joints, with hook-like osteophytes on x-ray). Occasionally the arthropathy affects larger joints such as the hips, knees and shoulders and can resemble rheumatoid arthritis. Other rheumatic manifestations include acute pyrophosphate arthropathy, asymptomatic chondrocalcinosis and osteoporosis.

Hereditary haemochromatosis is an autosomal recessive disorder, so taking a family history is helpful in these cases. Affected patients are at increased risk of

cirrhosis and hepatocellular carcinoma. Regular phlebotomy is the main treatment, although iron chelation and therapeutic erythrocytapheresis may become more widely used in the future.

The second and third metacarpophalangeal joints are rarely affected in isolation in osteoarthritis, and this would not explain the hepatomegaly and symptoms of diabetes.

The distribution of the arthropathy, and associated polyuria and polydipsias are not typical for gout or pseudogout (pyrophosphate arthropathy).

Amyloidosis secondary to rheumatoid arthritis would account for the hepatomegaly and small joint arthropathy, but diabetes is very rarely a consequence. Typically there is a combination of symptoms such as fatigue, weight loss, peripheral oedema and polyneuropathy.

Reference:

Diagnosis and management of hereditary haemochromatosis. Bokhoven et al. BMJ 2011 Jan 19;342:c7251

[Q: 3275] OnExamination 2012 - Rheumatology

A 21-year-old woman presents with a six month history of bilateral wrist pain, generalised aching, morning stiffness and an intermittent subjective fever.

She has a medical history of grade 4 acne, which she states has become worse over her nasal bridge and cheeks despite being commenced on minocycline one year ago. She tells you that her mother has rheumatoid arthritis.

An autoimmune screen demonstrated positivity for ANA, P-ANCA and anti-DNA histone; negative anti-ds DNA antibody; normal complement C3, C4 levels.

Which of the following should your first management step?

- 1- 15 mg methotrexate
- 2- 80 mg methylprednisolone
- 3- 400 mg hydroxychloroquine
- 4- 500 mg naproxen BD
- 5- Stop minocycline

Answer & Comments

Answer: 5- Stop minocycline

Learning points:

Presentation of drug-induced lupus

Common drug culprits

Autoantibody profile

Management of drug-induced lupus.

Drug-induced lupus can occur in susceptible patients or those with underlying lupus, secondary to drugs which induce the development of ANA antibodies.

It usually occurs in the sixth decade (except in young patients being treated for acne with minocycline).

Common drug culprits are

Procainamide

Hydralazine

Isoniazid and

Anti-TNF medications (infliximab and etanercept).

In contrast to idiopathic systemic lupus erythematosus (SLE), it is almost never seen in Afro-Caribbeans.

Antihistone antibodies are present in 90% of cases (cf. idiopathic SLE 80%).

In contrast to idiopathic SLE, anti-Smith and anti-ds DNA antibodies are rare, complement levels are normal and there is a M:F ratio of 1:1.

Resolution of symptoms usually occurs within one to seven months of withdrawing the offending drug.

[Q: 3276] OnExamination 2012 - Rheumatology

A 42-year-old lady presents with fatigue and tiredness.

Recently, she has noted that her eyes feel dry and gritty, and she requires water to swallow her food. On examination, there is salivary gland enlargement in her neck.

Recent blood tests are:

Hb 12.1g/dl(11.5 - 16.5 g/dL)

WBC $7.8 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils 70%(40-75%)

Platelet $270 \times 10^9/L$ (150 - $400 \times 10^9/L$)

ESR 36 mm/hr (0 - 20 mm/1st hr)

Anti-nuclear antibody positive (1:80)
(Negative at 1:20 Dil)

Anti-centromere antibody negative (Negative at 1:40 Dil)

Anti-Scl70 antibody negative (Negative)

Anti-U1RNP negative (Negative)

Anti-Ro/La antibody positive (Negative)

Urea, electrolytes and creatinine normal

What is the diagnosis?

- 1- Discoid lupus erythematosus
- 2- Mixed connective tissue disease
- 3- Sjogren's syndrome
- 4- Systemic lupus erythematosus
- 5- Systemic sclerosis

Answer & Comments

Answer: 3- Sjogren's syndrome

This patient has Sjogren's syndrome.

Other causes of dry eyes, and/or dry mouth include

Past head and neck radiation

Hepatitis C infection

Acquired immunodeficiency disease

Pre-existing lymphoma

Sarcoidosis

Graft versus host disease or

The use of an anticholinergic drugs.

Patients are at a higher risk of developing lymphoma (non-Hodgkin's lymphoma [NHL] B cell), and should be monitored for this.

[Q: 3277] OnExamination 2012 - Rheumatology

A 29-year-old lady presents with recurrent troublesome acne, episodes of palmo-plantar pustules, and painful swelling of the acromioclavicular joint.

Recent blood tests are:

Hb 12.1g/dl(11.5 - 16.5 g/L)

WBC $7.8 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils 70%(40-75%)

Platelet $270 \times 10^9/L$ (150 - $400 \times 10^9/L$)

ESR 36 mm/hr(0 - 20 mm/1st hr)

Bilirubin 17 $\mu\text{mol/L}$ (1 - 22 $\mu\text{mol/L}$)

ALT 34 IU/L(5 - 35 U/L)

AST 36 IU/L(1 - 31 U/L)

Alkaline phosphatase 215 U/L(45 - 105 U/L (over 14 years)

Urea, electrolytes and creatinine Normal

What is the diagnosis?

- 1- Multicentric reticulohistiocytosis
- 2- Osteomyelitis
- 3- Reactive arthritis
- 4- Reiter's syndrome
- 5- SAPHO syndrome

Answer & Comments

Answer: 5- SAPHO syndrome

This patient has SAPHO syndrome. SAPHO is an acronym for synovitis, acne, pustulosis, hyperostosis, and osteitis. It is characterised by osteosclerotic bone lesions, sterile osteomyelitis, and a variety of skin lesions.

Synovitis - may be present rarely, and associates with erosions.

Acne - may be severe (conglobate or fulminans) and recur with new bony involvement.

Pustulosis - palmo-plantar pustulosis occurs in approximately 50% of patients, other skin lesions may include psoriasis, hidradenitis suppurativa, acne, and rarely Sweet's syndrome.

Hyperostosis (increase in bone substance) and osteitis (inflammation of the bones) - the bony lesions typically involve the acromioclavicular, and sternoclavicular joints. Other sites include anterior chest wall, sternum, clavicle, pubic symphysis, spine, and mandible. These lesions are visualised on 99m technetium bone scan or MRI.

The cause of the SAPHO syndrome is unknown. The skin lesions are characterised by neutrophilic pseudoabscesses. Bone biopsy can reveal sterile osteomyelitis.

Diagnosis should be suspected when there is an association of rheumatic pain with a pustular skin disease.

SAPHO has no specific treatment, and some cases remit spontaneously. Typical treatment can be used for the arthritic symptoms (i.e. non-steroidal anti-inflammatories and disease modifying anti-rheumatic agents). Isotretinoin and aciretin can be used to treat the skin disease. In the more severe cases corticosteroids, calcitonin, bisphosphonates and TNF-inhibitors can be used.

[Q: 3278] OnExamination 2012 - Rheumatology

A 30-year-old architect presents with a three month history of low back pain, and stiffness. This is worse in the morning and improves with activity.

There are no other symptoms. There is no significant past or family history. He has tried over the counter ibuprofen (400 mg up to three times a day), which led to a significant improvement in his symptoms.

A lumbar spine and pelvic radiograph done by his GP is reported as normal. Blood tests show a normal FBC, UEC and liver function tests. The CRP is 23 mg/L and the ESR is 32 mm/hr.

What is the most likely diagnosis?

- 1- Ankylosing spondylitis
- 2- Discitis
- 3- Mechanical back pain
- 4- Osteoarthritis
- 5- Spondylolisthesis

Answer & Comments

Answer: 1- Ankylosing spondylitis

The combination of lower back pain and stiffness makes ankylosing spondylitis (AS) the most likely diagnosis in this scenario.

Ankylosing spondylitis is a chronic, potentially disabling, form of seronegative spondyloarthropathy which primarily involves the axial skeleton. The aetiology is not clearly understood, but it involves the interaction of genetic and environmental factors. The pathology mainly affects the entheses, where ligaments, tendons and capsules are attached to the bone.

Current British Society for Rheumatology recommendations state that the modified New York criteria should be used to diagnose ankylosing spondylitis:

Clinical criteria

Low back pain, present for more than three months, improved by exercise but not relieved by rest

Limitation of lumbar spine motion in both the sagittal and frontal planes

Limitation of chest expansion relative to normal values for age and sex

Radiological criteria

Sacroiliitis on x ray

Diagnose

Definite AS if the radiological criterion is present plus at least one clinical criterion

Probable AS if three clinical criteria are present alone or if the radiological criterion is present but no clinical criteria are present.

It is widely accepted that making the diagnosis early is difficult because the onset is insidious, and there is no definitive diagnostic test. One study has stated that the average time from onset to diagnosis ranges from three to 11 years. Timely diagnosis therefore requires a high index of suspicion.

HLA-B27 is found in 90% patients with AS but also 8% of the general population and therefore should not be relied upon in making a diagnosis.

MRI can visualise sacroiliitis in patients with typical symptoms of AS but normal radiographs and it is evolving as the most important diagnostic imaging tool in early disease.

However, as yet a diagnosis of ankylosing spondylitis cannot be made on MRI findings alone and these cases are currently termed non-radiographic axial spondyloarthritis (SpA).

Both HLA-B27 and sacroiliitis on MRI play a major role in the recently proposed Assessment of SpondyloArthritis International

Society (ASAS) diagnostic algorithm. This may replace the modified New York criteria in the future.

An x ray of the lumbar spine may show bridging syndesmophytes between the vertebral bodies in keeping with ankylosing spondylitis but this is not part of the diagnostic criteria, and it is a late sign.

Radiographic sacroiliitis is a requirement for patients to be eligible for anti-TNF treatment for AS. The sacroiliitis is usually bilateral and symmetrical. It progresses from blurring of the subchondral bone plate to irregular erosions of the margins of the sacroiliac joints to sclerosis, narrowing, and finally fusion.

Erosions of the sacroiliac joint are generally seen earlier in the lower portion due to its synovial lining, and on the iliac side due to the thinner cartilage covering this side of the joint.

Discitis is inflammation of the vertebral disc space, often related to infection. It typically presents with an insidious onset of pain and localised tenderness, which is worsens with activity (unlike the stiffness described here).

Mechanical back pain and osteoarthritis pain also improve with NSAIDs. However, they cause low back pain that is worse with activity, and relieved with rest.

Spondylolisthesis is the movement of one vertebra due to instability. It presents with pain which is worse with activity, and may be associated with nerve root compression.

[Q: 3279] OnExamination 2012 - Rheumatology

A 45-year-old man presents with a six month history of gradually worsening right knee pain, swelling, and restricted movements. There is no history of injury, or recent infections. He does not take any long term medications, and there is no significant past or family history of note.

On examination, the knee is grossly swollen, warm, non-tender, and there is restricted flexion and extension. The synovial fluid aspirated is brown stained.

What is the diagnosis?

- 1- Acute CPP crystal arthritis (pseudogout)
- 2- Gout
- 3- Meniscal tear
- 4- Pigmented villonodular synovitis
- 5- Reactive arthritis

Answer & Comments

Answer: 4- Pigmented villonodular synovitis

Haemophilia

Haemosiderosis from recurrent haemarthrosis

Haemochromatosis and

Pigmented villonodular synovitis (PVNS)

are differential diagnoses of arthropathies associated with iron deposition in the joints. Iron deposition causes a brown stained synovial fluid.

They can therefore lead to brown-stained synovial fluid.

Calcium pyrophosphate crystal arthritis (pseudogout), typically occurs in elderly patients who have a history of osteoarthritis. It presents with acute onset of joint swelling and pain.

This patient also has no risk factors for gout (young age, no history of excessive alcohol intake), meniscal tears (no injury), or reactive arthritis (no preceding infections).

PVNS is a rare proliferative disorder that affects the synovium in young and middle aged adults. Current thinking is that it is an inflammatory process, although some believe it is a benign neoplasm.

Monoarticular involvement, the most common manifestation, occurs in two forms: localised and diffuse. The localised form is characterised by focal synovial involvement, with either nodular or pedunculated masses. The diffuse form, in contrast, affects virtually the entire synovium. Although any joint can be involved, the knee is the most common.

Symptoms are usually non-specific (pain, warmth, swelling). On examination there is tenderness, effusion and restricted joint mobility. Radiographs are often unremarkable, but MRI can show intra-articular masses with signal dropout on T2 weighted images. Joint aspiration yields xanthochromic or serosanguineous fluid.

The optimal treatment of PVNS is surgery. The local recurrence after marginal excision for localised disease is low. However, recurrence after open synovectomy for diffuse PVNS is relatively high (up to 46%, higher with arthroscopic resection). Synovectomy, in addition to disease control, can prevent secondary osteoarthritis. Complications include arthrofibrosis and wound breakdown.

Intra-articular radioactive isotopes or external beam radiotherapy may be beneficial adjunct therapy for extensive diffuse and recurrent PVNS.

In some patients total joint arthroscopy may be the only effective treatment.

PVNS can be aggressive, with marked extra-articular extension.

[Q: 3280] OnExamination 2012 - Rheumatology

A 67-year-old man with Wegener's granulomatosis, previously treated with cyclophosphamide, is currently on azathioprine.

His vasculitis is well controlled. He was found to have microscopic haematuria on two

occasions a month apart. Urine culture showed no growth. There is no proteinuria, abdominal pain, and a renal ultrasound is normal.

He has normal inflammatory markers and stable urea electrolytes and creatinine over the last year.

What is the next step in his management?

- 1- Cystoscopy
- 2- Prolonged urinary culture
- 3- Renal angiogram
- 4- Renal biopsy
- 5- Urine culture for TB

Answer & Comments

Answer: 1- Cystoscopy

Cyclophosphamide causes haemorrhagic cystitis, and increases the risk of developing bladder cancer in the future. The risk increases with increasing doses of cyclophosphamide.

Renal biopsy is not indicated as there is no evidence of active renal vasculitis - normal inflammatory markers, stable creatinine.

Renal angiogram is used to investigate renal artery stenosis.

Renal tract TB is unlikely in the absence of proteinuria.

[Q: 3281] OnExamination 2012 - Rheumatology

A 50-year-old man presented with a six week history of general malaise and a two day history of a right foot drop, a left ulnar nerve palsy and a widespread purpuric rash.

He complained of arthralgia but had no clinical evidence of inflammatory joint disease.

Investigations revealed:

ESR 100 mm/hr (0-20)

ANCA Negative

ANA Negative

Rheumatoid factor Strongly positive

C₃ 0.8 g/L (0.75-1.6)

C₄ 0.02 g/L (0.14-0.5)

Urine dipstick blood ++, No protein

An echocardiogram was normal and two sets of blood cultures were negative.

What is the most likely diagnosis?

- 1- ANA negative SLE
- 2- Cryoglobulinaemia
- 3- Infective endocarditis
- 4- Polyarteritis nodosa
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 2- Cryoglobulinaemia

The history is strongly suggestive of systemic vasculitis with mononeuritis multiplex, purpuric rash and haematuria.

It is important to exclude conditions which can mimic vasculitis such as infective endocarditis. The normal echocardiogram and negative blood cultures make this unlikely.

Whilst polyarteritis nodosa can present with exactly this clinical picture, the marked consumption of C₄ together with a strongly positive rheumatoid factor strongly suggests cryoglobulinaemia as the underlying cause.

Cryoglobulins are immunoglobulins which precipitate in the cold. They can be

Type I (monoclonal)

Type II (mixed monoclonal and polyclonal) or

Type III (polyclonal).

Type I cryoglobulinaemia is associated with haematological diseases such as myeloma and Waldenstrom's.

Type II and type III cryoglobulinaemia can be associated with many connective tissue disorders, chronic infections and most importantly, hepatitis C infection which should always be excluded.

Treatment of cryoglobulinaemia would include plasmapheresis, high dose steroids and cyclophosphamide.

[Q: 3282] OnExamination 2012 - Rheumatology

A 50-year-old man with insulin dependent diabetes presents with a two week history of an acutely painful, erythematous, swollen left mid-foot for the last two weeks. He does not drink alcohol, and has had no recent injuries to the foot.

On examination, the mid-foot is warm. Pedal pulses are intact. There is sensory loss in a glove and stocking distribution bilaterally. Recent blood tests show a normal FBC, CRP, urea and electrolytes and creatinine.

What is the most likely diagnosis?

- 1- Cellulitis
- 2- Charcot joint
- 3- Deep venous thrombosis
- 4- Fragility fracture
- 5- Gout

Answer & Comments

Answer: 2- Charcot joint

In patients with longstanding diabetes and peripheral neuropathy, a red hot swollen foot should raise suspicion of Charcot neuroarthropathy.

Charcot neuropathy presents as a warm, swollen, erythematous foot and ankle, and infection is important to exclude. The majority of patients are in their 50-60s, and they often present in the latter stages of the disease.

It can occur in association with a variety of conditions, including leprosy, poliomyelitis, rheumatoid arthritis, although today the most common cause is diabetes mellitus.

The pathophysiology of Charcot neuroarthropathy is not completely understood, but is thought to start with peripheral neuropathy. The lack of pain sensation may mean that patients subject the foot joints (commonly the midfoot) to stress injuries that lead to the Charcot process. It is important to note however that about half of patients present with pain.

Four stages of Charcot neuropathy are recognised:

Stage 0 (inflammation): characterised by erythema and oedema, but no structural changes

Stage 1 (development): bone resorption, fragmentation and joint dislocation. Swelling, warmth and erythema persist but there are also radiographic changes such as debris formation at the articular margins, osseous fragmentation and joint disruption

Stage 2 (coalescence): bony consolidation, osteosclerosis and fusion are all seen on plain radiographs

Stage 3 (reconstruction): osteogenesis, decreased osteosclerosis, progressive fusion. Healing and new bone formation occur, and the deformity becomes permanent.

Radiographs are an important part of investigating a patient with possible Charcot arthropathy. All radiographs should be taken in the weight-bearing position.

MRI can demonstrate changes in the earlier stages of the condition, and is therefore important in allowing treatment to be instigated earlier.

In stages 0 and 1 the treatment is immediate immobilisation and avoidance of weight-bearing. A total-contact cast is worn until the

redness, swelling and heat subside (generally 8-12 weeks, changed every 1-2 weeks to minimise skin damage). After this the patient should use a removable brace for a total of four to six months.

Bisphosphonates can be used, but evidence of clinical benefit is lacking. Surgery is reserved for severe deformities that are susceptible to ulceration, and where braces and orthotic devices are difficult to use.

A normal FBC and CRP in this case make cellulitis unlikely. There is no swelling of the calf to suggest a deep vein thrombosis.

Fragility fractures are those which are caused by a force equivalent to a fall from the height of a chair or less. They are typically seen on a background of osteoporosis and there is usually a history of trauma.

Gout classically causes an acute monoarthritis and the presentation is typically more acute than described here.

[Q: 3283] OnExamination 2012 - Rheumatology

A 36-year-old woman presents with an acutely painful red eye and painful lumpy red-blue lesions on her shin.

On enquiry she gives a history of recurrent episodes of oral and genital ulcers in the last year. Some of these ulcers have been scarring.

Recent blood tests show a normocytic normochromic anaemia, normal LFTs, UE&C, and a raised ESR of 56 mm/hr.

What is the diagnosis?

- 1- Behcet's disease
- 2- Reactive arthritis
- 3- Sarcoidosis
- 4- Stevens-Johnson syndrome
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 1- Behcet's disease

This patient has Behcet's disease. This is a clinical diagnosis. Recurrent scarring oro-genital ulcers are pathognomonic of Behcet's disease. Recurrent oral ulcers occur in SLE but they are generally non-scarring.

Reactive arthritis and sarcoidosis do not associate with recurrent scarring oro-genital ulcers.

Uveitis does not occur in Steven-Johnson's syndrome.

The International Study Group criteria for classification of Behcet's disease require the presence of recurrent oral ulceration (minor aphthous, major aphthous or herpetiform ulceration observed by physician or patient, which have recurred at least three times in a 12 month period), and two of the following:

Recurrent genital ulceration: aphthous ulceration or scarring, observed by physician or patient

Eye lesions: anterior uveitis, posterior uveitis, or cells in vitreous on slit lamp examination; or retinal vasculitis observed by ophthalmologist

Skin lesions: erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; or acneiform nodules observed by the physician in post-adolescent patients not on corticosteroid treatment

Positive pathergy test: read by physician at 24-48 hours.

Pathergy is the non-specific hyperreactivity of the skin following minor trauma, and is specific to Behcet's disease. It involves intradermal injection of skin with a 20-gauge needle under sterile conditions. It is considered positive if an erythematous sterile papule develops within 48 hours.

[Q: 3284] OnExamination 2012 -
Rheumatology

A 75-year-old woman presents with a three week history of new-onset headache.

She had an episode of transient visual loss one week ago but ocular examination is now normal. She reports that when she chews food, she gets aching in her jaw.

Blood tests reveal:

C reactive protein 90 mg/L (< 10 mg/L)

Erythrocyte sedimentation rate 120 mm/hour
(0 - 30 mm/1st hr)

Haemoglobin 9.5 g/dL (11.5 - 16.5 g/dL)

Platelet $528 \times 10^9/L$. 150 - $400 \times 10^9/L$

What treatment needs be given that day?

Select the single best answer.

- 1- Aspirin 300 mg by mouth
- 2- Nothing
- 3- Methylprednisolone 500 mg IV
- 4- Prednisolone 40 mg by mouth
- 5- Prednisolone 60 mg by mouth

Answer & Comments

Answer: 3- Methylprednisolone 500 mg IV

These symptoms and investigation findings are typical of giant cell arteritis (GCA).

GCA affects large and medium sized arteries, with a predilection for the external carotid, ciliary and retinal arteries. Endovascular damage and cytokine-mediated inflammation causes local ischaemia. There is considerable overlap with polymyalgia rheumatica, and symptoms of both should be sought. 20% of patients develop loss of vision, which can be prevented with timely recognition and treatment. Visual loss typically occurs early in the course of disease and, once established, rarely improves. The classically described jaw claudication occurs in a minority of cases, but

does indicate a high risk of ischaemic complications.

The typical presentation of GCA is a temporal headache, with myalgia, malaise and fever. ESR and CRP are usually raised.

As soon as the diagnosis is suspected, high dose corticosteroids should be given. Current BSR guidelines recommend:

- Uncomplicated GCA (no jaw or tongue claudication, or visual symptoms): prednisolone 40-60mg daily
- Complicated GCA:
 - Evolving visual loss or history of amaurosis fugax: IV methylprednisolone 500mg-1g daily for three days, followed by oral corticosteroids
 - Established visual loss: at least 60mg prednisolone daily

Bone protection and proton-pump inhibitors should be co-prescribed.

It is important to note that the pathological findings of giant cell arteritis persist for one to two weeks following initiation of corticosteroid, and therefore treatment should not be delayed to obtain a biopsy.

Aspirin 75mg once daily is sometimes given as an adjunct but higher doses are not recommended.

Symptoms usually resolve quickly, often with two or three days. Once they and laboratory abnormalities resolve, the dose of corticosteroid can be reduced and usually stopped within two years. The patient should be monitored for recurrence throughout the taper: ESR every 4 weeks for 2-3 months, then every 8-12 weeks until 12-18m after cessation of therapy.

Giant cell arteritis is a medical emergency and should be treated without delay. It is not acceptable to give no treatment.

[Q: 3285] OnExamination 2012 -
Rheumatology

A 30-year-old man is referred to the outpatient clinic complaining of persistent low back pain associated with prolonged morning stiffness. His father has a long history of back problems.

Which is the best option to confirm a diagnosis of ankylosing spondylitis?

- 1- Blood test for HLA-B27
- 2- Clinical examination showing reduced mobility of the spine
- 3- MRI of the sacroiliac joints and spine
- 4- x Ray of the lumbar spine
- 5- x Ray of the sacroiliac joints

Answer & Comments

Answer: 5- x Ray of the sacroiliac joints

Ankylosing spondylitis (AS) is a chronic, potentially disabling, form of seronegative spondyloarthropathy which primarily involves the axial skeleton. The aetiology is not clearly understood, but it involves the interaction of genetic and environmental factors. The pathology mainly affects the entheses, where ligaments, tendons and capsules are attached to the bone.

Current British Society for Rheumatology recommendations state that the modified New York criteria should be used to diagnose ankylosing spondylitis:

CLINICAL CRITERIA

Low back pain, present for more than 3 months, improved by exercise but not relieved by rest

Limitation of lumbar spine motion in both the sagittal and frontal planes

Limitation of chest expansion relative to normal values for age and sex

RADIOLOGICAL CRITERIA

Sacroiliitis on x ray

DIAGNOSE

Definite AS if the radiological criterion is present plus at least one clinical criterion

Probable AS if three clinical criteria are present alone or if the radiological criterion is present but no clinical criteria are present

It is widely accepted that making the diagnosis early is difficult because the onset is insidious, and there is no definitive diagnostic test. One study has stated that the average time from onset to diagnosis ranges from 3-11 years. Timely diagnosis therefore requires a high index of suspicion.

A. Blood test for HLA-B27:

This is found in 90% patients with AS but also 8% of the general population therefore should not be relied upon in making a diagnosis.

B. Clinical examination showing reduced mobility of the spine:

This should be performed and would likely show reduced range of movement of the spine but alone cannot confirm the diagnosis of ankylosing spondylitis.

C. MRI of the sacroiliac joints and spine:

MRI can visualise sacroiliitis in patients with typical symptoms of AS but normal radiographs, and it is evolving as the most important diagnostic imaging tool in early disease. However, as yet a diagnosis of ankylosing spondylitis cannot be made on MRI findings alone and these cases are currently termed non-radiographic axial spondyloarthritis (SpA). Both HLA-B27 and sacroiliitis on MRI play a major role in the recently proposed Assessment of SpondyloArthritis International Society (ASAS) diagnostic algorithm. This may replace the modified New York criteria in the future.

D. x Ray of the lumbar spine:

An x ray of the lumbar spine may show bridging syndesmophytes between the vertebral bodies in keeping with ankylosing spondylitis but this is not part of the diagnostic criteria, and it is a late sign.

E. x Ray of the sacroiliac joints:

This is the current gold standard for the diagnosis of ankylosing spondylitis as part of the modified New York criteria. Radiographic sacroiliitis is a requirement for patients to be eligible for anti-TNF treatment for AS. The sacroiliitis is usually bilateral and symmetrical. It progresses from blurring of the subchondral bone plate to irregular erosions of the margins of the sacroiliac joints to sclerosis, narrowing, and finally fusion. Erosions of the sacroiliac joint are generally seen earlier in the lower portion due to its synovial lining, and on the iliac side due to the thinner cartilage covering this side of the joint.

Reference:

New approaches to diagnosis and classification of axial and peripheral spondyloarthritis. Rudwaleit M. Curr Opin Rheumatol 2010 Jul;22(4):375-380.

[Q: 3286] OnExamination 2012 - Rheumatology

A 66-year-old man presented to the ophthalmologist with a two day history of sudden loss of vision in his left eye, with which he had awoken.

He also had left jaw claudication and tingling and numbness in his hands with difficulty in performing fine movements for the last 10 days. In addition he has had stiffness in his shoulders and neck with difficulty getting up from a chair for a few weeks. He has lost a stone in six weeks and has had night sweats. He has not travelled recently.

He is a non-smoker and does not drink alcohol. His past medical history includes late onset asthma, recurrent sinusitis and allergic rhinitis.

Examination revealed no perception of light in left eye, weak hand grip and power 4/5 in proximal muscles of the lower limbs with normal reflexes and down going plantars. He was pyrexial with a temperature of 38.9°C. Fundoscopy revealed a possible left retinal artery infarct. His temporal arteries were palpable and non-tender.

Full blood count revealed:

WCC 37(4 - 11 x 10⁹/L)

Eosinophils 14(0.04 - 0.4 x 10⁹/L)

Neutrophils 14(1.5 - 7 x 10⁹/L)

Platelets 574(150 - 400 x 10⁹/L)

Hb 12.9(13.0 - 18.0 g/dL)

Plasma viscosity 1.82(1.50 - 1.72 mPa/s)

CRP 211(< 10 mg/L)

CK 802(24 - 195 U/L)

CXR revealed a thickened right middle lobe fissure. CT head demonstrated fluid within the left maxillary sinus, and normal intracranial appearances. His immunology revealed a high titre of P-ANCA with MPO 82, and PR3 2. ANA was negative and immunoglobulins were normal. Total IgE was 233 (normal range 4.2-595U/ml).

Muscle biopsy showed no evidence of myositis.

What is the most probable diagnosis?

- 1- Allergic bronchopulmonary aspergillosis
- 2- Churg-Strauss syndrome
- 3- Giant cell arteritis
- 4- Hypereosinophilic syndrome
- 5- Wegener's granulomatosis

Answer & Comments

Answer: 2- Churg-Strauss syndrome

Churg-Strauss syndrome (CSS) is a rare form of small-vessel vasculitis, characterised by asthma, allergic rhinitis and prominent peripheral blood eosinophilia. Rarely, it can

cause either an anterior or a posterior ischaemic optic neuropathy, which presents with visual loss as is the case here. Whilst the history seems typical of giant cell arteritis the raised eosinophilia count and positive MPO antibodies should lead you to a diagnosis of Churg-Strauss.

The most commonly involved organ is the lung, followed by the skin. CSS, however, can affect any organ system, including the cardiovascular, gastrointestinal, renal, and central nervous systems. The unifying feature of patients presenting with CSS is asthma. Vasculitis involving the peripheral nervous system is also a characteristic feature, and mononeuritis multiplex occurs in 75% of patients.

Vasculitis of extrapulmonary organs is largely responsible for the morbidity and mortality associated with CSS. Forty to 60% are associated with positive ANCA, usually pANCA/MPO.

Intravenous glucocorticoid is used for initial therapy of acute multi-organ disease, followed by oral glucocorticoid therapy, often with azathioprine as a steroid-sparing agent..

Loss of vision must be treated aggressively.

Allergic bronchopulmonary aspergillosis is a hypersensitivity reaction to *Aspergillus*. Its clinical presentation varies from corticosteroid-dependent asthma to diffuse bronchiectasis with fibrosis. Visual loss is not an associated feature.

Wegener's granulomatosis is a multi-organ autoimmune disease, which can be fatal. The classical triad consists of necrotising granulomatous inflammation of the respiratory tract, glomerulonephritis and a small-vessel vasculitis. A prolonged history of epistaxis or sinusitis is commonly found in Wegener's granulomatosis, which in some patients is also associated with an eosinophilia.

Hypereosinophilic syndrome is characterised by a peripheral blood eosinophil count of >1.5 for more than six months. Generalised symptoms are fatigue, myalgia, fever, night sweats, diarrhoea and pruritis. Other symptoms depend on the organ involved: cardiac disease causes chest pain and dyspnoea, respiratory disease presents with a dry cough.

Reference:

Churg-Strauss syndrome presenting with visual loss. Carmichael J et al. Rheumatology 2000;39(12):1433-1434

[Q: 3287] OnExamination 2012 - Rheumatology

June, a 45-year-old woman has had arthritis for 16 weeks. She has morning stiffness lasting two hours. The hands, wrists, right elbow and knees are swollen. She also complains of painful feet.

The ESR is 41 mm/hr and C reactive protein is 34 mg/L. The full blood count is normal.

Which antibody test would you request if you suspected that she had early rheumatoid arthritis?

- 1- Antinuclear antibodies (ANA)
- 2- Anticyclic citrullinated peptide antibodies (anti-CCP antibodies)
- 3- Antiphospholipid antibodies
- 4- Complement
- 5- Antineutrophil cytoplasmic antibodies (ANCA)

Answer & Comments

Answer: 2- Anticyclic citrullinated peptide antibodies (anti-CCP antibodies)

A. High titres of ANA are associated with a large number of autoimmune diseases, most commonly systemic lupus erythematosus (SLE).

B. Anti-CCP antibodies are highly specific and sensitive for rheumatoid arthritis and their titre correlates with erosive disease.

Anticyclic citrullinated peptide antibodies should be used as one of the first line immunological investigations in suspected rheumatoid arthritis.

C. Antiphospholipid antibodies would be requested when the clinical presentation suggests a diagnosis of antiphospholipid syndrome.

D. Complement is not an antibody test. Levels are generally performed in specific cases, for example, cryoglobulinaemia and SLE.

E. Antineutrophil cytoplasmic antibodies (ANCA) are more commonly associated with vasculitides which the history does not suggest in this case.

[Q: 3288] OnExamination 2012 - Rheumatology

A 25-year-old female was started on minocycline for the treatment of acne.

Seven days later she presented with fever, myalgia, arthralgia and a fixed erythematous rash over the malar eminences that spared the nasolabial folds.

Which autoantibody test would confirm the diagnosis?

- 1- Anti ds-DNA
- 2- Antihistone
- 3- Anti-Jo-1
- 4- Anti-RNP
- 5- Anti-SCI70

Answer & Comments

Answer: 2- Antihistone

This patient has developed drug-induced lupus as a result of minocycline therapy.

This is a syndrome of positive antinuclear antibody (ANA) that appears during therapy with medications and biologic agents.

It

Has a less female predilection than systemic lupus erythematosus (SLE)

Rarely involves central nervous system (CNS) and kidneys

Is rarely associated with anti-ds-DNA

Is commonly (almost 100%) associated with antibodies to antihistones,

hence, option B is the correct answer.

It usually resolves over several weeks after discontinuation of the offending medication.

About 50 drugs have been listed. The important ones are penicillamine, procainamide, phenytoin, carbamazepine, isoniazid, minocycline, ACE inhibitors, beta blockers, hydralazine, propylthiouracil, hydrochlorthiazide, interferons and TNF inhibitors.

Reasons for the other options being incorrect:

Anti ds-DNA - Almost exclusive for SLE but rarely positive in drug-induced lupus

Anti Jo-1 - Associated with acute onset of poly/dermatomyositis

Anti RNP - Present in syndromes that have overlap features of several rheumatic syndromes

Anti SCI-70 - Associated with 40% cases of diffuse systemic sclerosis.

[Q: 3289] OnExamination 2012 - Rheumatology

A 40-year old lady presents to clinic complaining of an 18 month history of dorsoradial wrist pain. She is a keen tennis player.

On examination she has tenderness localised to the dorsoradial aspect of the wrist and passive motion of the thumb causes crepitus in the same region. Finkelstein's test is positive.

Which of the following is the likely diagnosis?

- 1- Carpal tunnel syndrome
- 2- De Quervain's tenosynovitis
- 3- Golfer's elbow
- 4- Tennis elbow
- 5- Ulnar tunnel syndrome

Answer & Comments

Answer: 2- De Quervain's tenosynovitis

De Quervain's tenosynovitis is thought to be related to overuse, and is common in golfers and racquet sport players.

Most affected are females 30-50 years old.

Finkelstein's test (flexion of the thumb into the palm, making a fist over the thumb and ulnar deviation of the wrist causes pain in the first dorsal extensor compartment) is diagnostic.

[Q: 3290] OnExamination 2012 - Rheumatology

A 60-year-old lady develops a fracture of the wrist following a fall; dual energy x ray absorptiometry (DEXA) scan reveals osteoporosis in lumbar spine and hip.

She has been commenced on once weekly alendronate 70 mg weekly and also takes a Calcichew tablet.

By what mechanism does the bisphosphonate function in the treatment of osteoporosis?

- 1- Enhancing the absorption and action of vitamin D
- 2- Enhancing the absorption of calcium from the gut

- 3- Enhancing the survival and function of osteoblasts
- 4- Enhancing the survival and function of osteoclasts
- 5- Reducing the survival and function of osteoclasts

Answer & Comments

Answer: 5- Reducing the survival and function of osteoclasts

The mechanism of action of bisphosphonates involves the inhibition of farnesyl diphosphate synthase within osteoclasts. In doing this they interfere with geranylgeranylation (attachment of the lipid to regulatory proteins), which causes osteoclast inactivation. This leads to reduced bone turnover, increased bone mass and improved mineralisation.

Bisphosphonates licensed for the prevention and treatment of osteoporosis include alendronate, risedronate and ibandronate.

The bisphosphonates zoledronate and pamidronate are used for the treatment of metastatic bone disease and short term management of hypercalcaemia.

[Q: 3291] OnExamination 2012 - Rheumatology

A 75-year-old female presents with hyperosmolar non-ketotic hyperglycaemia. She has a red, hot and swollen knee.

Which of the following is most useful in the diagnosis of the swollen knee joint?

- 1- ANA
- 2- CRP
- 3- Joint aspiration
- 4- Orthopaedic referral for joint washout
- 5- Rheumatoid factor

Answer & Comments

Answer: 3- Joint aspiration

Joint aspiration is the best option in this context. It is a simple procedure with a high diagnostic yield. A destructive septic arthritis is a potential diagnosis and it must be excluded as a matter of urgency. Joint aspirate is the most crucial step in excluding a septic arthritis, and allows the timely commencement of surgical management and appropriate antibiotics.

Sending the joint aspiration for M/C/S in a blood culture bottle may increase yield. Whilst joint washout is appropriate management of septic arthritis, a diagnosis must be made prior to this being considered.

The risk of introducing infection into the knee joint during simple aspiration by non-experts is 1 in 10,000 procedures, so the procedure is safe.

[Q: 3292] OnExamination 2012 - Rheumatology

A 62-year-old lady is followed up with a one year history of ultrasound positive, bilateral carpal tunnel syndrome. It is refractory to previous physiotherapy and two subcutaneous injections.

Her past medical history includes multiple myeloma. Her BMI is 33 kg/m².

You refer her for a carpal tunnel release and request that a biopsy sample is taken to refute amyloidosis.

Which of the following is a pathological feature of amyloidosis?

- 1- Congo red histological staining - negative birefringence
- 2- Crystallisation in water and buffers of low ionic strength
- 3- Electron micrography - fibrillar appearance
- 4- Haematoxylin and eosin staining - amorphous granulomatous appearance

- 5- x Ray diffraction pattern - alpha helical structure

Answer & Comments

Answer: 3- Electron micrography - fibrillar appearance

Learning points:

Define and recognise histological and radiological properties of amyloid

Understand the basic nomenclature of amyloidosis

Common clinical association of AL amyloid.

Amyloidosis, as a clinic-pathological descriptor is used to denote the in vivo, extracellular deposition of material (amyloid) characterised by the following properties:

Electron micrography - fibrillar appearance

x Ray diffraction pattern - beta pleated sheet structure

Haematoxylin and eosin staining - amorphous eosinophilic appearance

Congo red histological staining - apple-green birefringence

Solubility in water and buffers of low ionic strength.

All types of amyloid consist of an insoluble major fibrillar protein (more than 27 unrelated proteins in humans) that defines the type of amyloid.

This patient has probably developed AL (light chain; formerly primary amyloidosis) amyloid in association with her underlying multiple myeloma, where the precursor protein is a clonal immunoglobulin light chain or light chain fragment.

[Q: 3293] OnExamination 2012 - Rheumatology

A 24-year-old male has been receiving

sulfasalazine at a stable dose for six months as treatment for Reiter's disease. His most recent series of blood tests were normal.

When should he next be screened?

- 1- Two weeks
- 2- One month
- 3- Three months
- 4- Six months
- 5- One year

Answer & Comments

Answer: 3- Three months

Current United Kingdom guidance suggests that during the first three months of treatment with sulfasalazine, full blood count (FBC) should be monitored monthly for the first three months.

If

The white cell count is less than 3.5

Neutrophils less than 2 or

Platelets less than 150

sulfasalazine should be withheld until discussion with the specialist team.

If mean corpuscular volume (MCV) is more than 105 fl, Vitamin B₁₂, folate and thyroid-stimulating hormone (TSH) should be checked and treated if found to be abnormal. If these are all normal it should be discussed with the specialist team.

If counts remain normal within the first three months, full blood count can be checked three monthly.

Liver function tests (LFTs) should also be checked monthly for the first three months. If either the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) are more than twice the upper limit of normal sulfasalazine should be withheld until discussion with the specialist team. If the LFTs

remain normal for the first three months, monitoring can be decreased to three monthly.

If, following the first year, the dose has not been increased and blood results have been stable, the frequency of monitoring can be reduced to every six months for the second year of treatment. Thereafter monitoring is not required, although FBC and LFTs should be checked one month after any dose increase.

Side effects of sulfasalazine include myelosuppression, macrocytosis, hypersensitivity and azoospermia in males.

There are numerous signs of sulfasalazine toxicity. Rash and oral ulceration should be asked about and, if severe, the drug should be withheld until specialist advice has been sought. Nausea, dizziness and headache can be common and sometimes necessitate dose reduction. If patients present with abnormal bruising or sore throat an urgent FBC should be done, and sulfasalazine withheld until results are available.

[Q: 3294] OnExamination 2012 - Rheumatology

A general practice covers a population of 20,000 patients in the United Kingdom.

How many newly diagnosed patients with rheumatoid arthritis would be expected in this population each year?

- 1- 1000
- 2- 500
- 3- 5
- 4- 100
- 5- 50

Answer & Comments

Answer: 3- 5

The incidence of rheumatoid arthritis is approximately 2.5 per 10,000 per year (1.5 in men and 3.6 in women).

Thus in a practice of 20,000 there would be five patients with newly diagnosed rheumatoid arthritis per year.

Rheumatoid arthritis increases with age and the peak age for both genders is the 70s. The overall occurrence of RA is two to four times greater in women than men.

Reference:

<http://www.nice.org.uk/nicemedia/live/12131/43327/43327.pdf> (published feb 2009)

[Q: 3295] OnExamination 2012 - Rheumatology

A 35-year-old female presents with a six month history of joint pain and stiffness of hands and feet.

Examination reveals a synovitis of the distal interphalangeal joints of the left index finger and the right ring finger together with the right wrist and ankle joints. Her ESR was 35 mm/hr (0-10).

Which one of the following conditions is most likely to exhibit this pattern of joint involvement?

- 1- Osteoarthritis
- 2- Psoriatic arthritis
- 3- Reactive arthritis
- 4- Rheumatoid arthritis
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 2- Psoriatic arthritis

This woman is most likely to have psoriatic arthritis.

Psoriatic arthritis has been subclassified according to different patterns of arthritis.

The rash typically predates the arthropathy by a number of years, but the opposite can be true. Small plaques should be looked for on the elbows and scalp.

There are five patterns of disease:

Symmetrical polyarthritis ('rheumatoid pattern') - affects wrists, hands, feet and ankles. The distal interphalangeal joints are more commonly affected than the metacarpophalangeal joints, which helps to distinguish it from rheumatoid arthritis

Asymmetrical oligoarticular arthritis: dactylitis

Distal interphalangeal joint disease: typically in men

Arthritis mutilans (rare)

Spondylitic pattern with sacroileitis.

Osteoarthritis in this age group is unlikely.

Rheumatoid arthritis is a symmetrical arthritis typically affecting the metacarpophalangeal joints.

Arthritis does occur in systemic lupus erythematosus, however there are several other clinical features that form part of the diagnostic criteria, none of which are present here.

Reactive arthritis occurs following a gastrointestinal or genitourinary infection. It commonly affects the large joints.

[Q: 3296] OnExamination 2012 - Rheumatology

A 51-year-old female has rheumatoid arthritis.

She states that she is allergic to penicillin and co-trimoxazole.

Therefore, which of the following drugs is contraindicated?

- 1- Azathioprine
- 2- Ciclosporin

- 3- Gold therapy
- 4- Methotrexate
- 5- Sulphasalazine

Answer & Comments

Answer: 5- Sulphasalazine

Both co-trimoxazole and sulphasalazine contain sulphonamide groups and hence an allergy to co-trimoxazole would be a contraindication to the use of sulphasalazine.

Co-trimoxazole is a mixture of trimethoprim and sulfamethoxazole.

Sulphasalazine is a combination of 5-aminosalicylic acid and sulfapyridine. It is commonly used in the treatment of inflammatory bowel disease, and can also be used in rheumatoid and psoriatic arthritis.

Azathioprine is a purine analogue which is commonly used as a steroid-sparing agent.

Ciclosporin is a calcineurin inhibitor, used for the prevention of transplant rejection.

Gold therapy was previously used as a disease modifying agent in rheumatoid arthritis, but this has now been replaced by methotrexate which is a dihydrofolate reductase inhibitor.

[Q: 3297] OnExamination 2012 - Rheumatology

A 22-year-old female presents with a six month history of increasing fatigue and arthralgia of the wrists and ankles. More recently, she has also noted a symmetrical rash on her cheeks and some hair loss.

What is the most likely diagnosis?

- 1- Dermatomyositis
- 2- Hypothyroidism
- 3- Porphyria cutanea tarda
- 4- Scleroderma
- 5- Systemic lupus erythematosus (SLE)

Answer & Comments

Answer: 5- Systemic lupus erythematosus (SLE)

This woman has clinical features consistent with systemic lupus erythematosus.

She gives a history of fatigue which occurs commonly in SLE. Arthralgia and arthritis are the most common presenting manifestations of SLE typically affecting the small joints of the hands, wrists and knees. The symmetrical rash is the classical butterfly rash that occurs in a malar distribution. Alopecia is common and may be diffuse or patchy.

In dermatomyositis there is proximal, symmetrical muscle weakness that progresses over weeks to months. The typical lilac papular rash occurs over the dorsum of the metacarpophalangeal (Gottron's papules), eyelids, elbows and knees.

Hypothyroidism does not commonly result in a symmetrical facial rash.

The initial symptoms of scleroderma, now termed systemic sclerosis tend to be non-specific and may consist of fatigue, weakness and musculoskeletal complaints. Raynaud's phenomenon is an early symptom. Skin changes include telangiectasia, hyper- and hypo-pigmentation.

Porphyria cutanea tarda is either primary or secondary uroporphyrinogen decarboxylase deficiency. The commonest symptoms are cutaneous fragility and blistering of sun-exposed skin. There may also be urine discolouration.

[Q: 3298] OnExamination 2012 - Rheumatology

A 31-year-old female presents with red scaly plaques on her cheeks, forehead and sides of the neck.

On close inspection of the lesions there was plugging of some hair follicles with keratin and atrophy of the skin.

What is the most likely diagnosis?

- 1- Atopic eczema
- 2- Discoid lupus erythematosus
- 3- Polymorphic light eruption
- 4- Porphyria cutanea tarda
- 5- Psoriasis

Answer & Comments

Answer: 2- Discoid lupus erythematosus

This woman has discoid lupus erythematosus.

Lesions are discrete plaques, often erythematous, covered by scales that extend into dilated hair follicles. These lesions most typically occur on the face, scalp, in the pinnae, behind the ears and on the neck. They can exist in areas not exposed to the sun.

The lesions can progress, with active indurated erythema at the periphery. Central atrophic scarring is characteristic.

Without treatment, lesions can cause permanent scarring and alopecia. Patients with widespread disease are at increased risk of developing systemic lupus erythematosus and should be closely followed up. Fluocinonide cream, hydrocortisone and acitretin are topical treatment options.

In eczema dryness and lichenification are predominant features.

Psoriasis commonly appears as inflamed lesions covered with a silvery white scale.

Polymorphic light eruption is characterised by recurrent, abnormal, delayed reactions to sunlight, ranging from erythematous papules, papulovesicles, and plaques to erythema multiforme-like lesions on sunlight-exposed surfaces.

Porphyria cutanea tarda is either primary or secondary uroporphyrinogen decarboxylase deficiency. The commonest symptoms are cutaneous fragility and blistering of sun-exposed skin. There may also be urine discolouration.

[Q: 3299] OnExamination 2012 - Rheumatology

A 74-year-old woman with longstanding hypertension and rheumatoid arthritis present with dyspnoea.

On examination she is in atrial fibrillation and is normotensive. The jugular venous pressure (JVP) is elevated. She has bilateral pitting lower limb oedema and ascites. Her echocardiogram shows normal left ventricular systolic function and bi-atrial enlargement.

What is the most likely diagnosis?

- 1- Constrictive pericarditis
- 2- Hypertensive heart disease
- 3- Hypothyroidism
- 4- Lymphatic obstruction
- 5- Pulmonary fibrosis

Answer & Comments

Answer: 1- Constrictive pericarditis

The combination of:

Shortness of breath

Atrial fibrillation

Lower limb oedema

Ascites

Raised JVP

Bi-atrial enlargement with normal systolic ventricular function

is typical of constrictive pericarditis.

Further ECHO examination would reveal peak systolic and diastolic values decreasing with inspiration, and impaired diastolic function.

Constrictive pericarditis is the commonest cardiac complication of rheumatoid arthritis. It is found in 30-50% of patients at postmortem and up to 30% by echocardiography. It is commoner in males and seropositive patients with active joint disease. Histopathology shows chronic inflammation and fibrosis.

Pericardial fluid is usually an exudate with high protein and lactate dehydrogenase and low glucose. Infective pericarditis is an important differential diagnosis, which is also more common in rheumatoid arthritis.

Symptoms are present in only 24% patients and can be non-specific, which often delays the diagnosis. Fewer than 0.5% experience haemodynamic compromise. Presentations include pleuritic chest pain, dyspnoea, oedema and hepatic congestion. Signs are also non-specific and include pericardial rub, tachycardia and quiet heart sounds.

Echocardiography is the investigation of choice, but CT is also useful to confirm pericardial thickening. Cardiac catheterisation is used if pericardectomy is considered.

Pericarditis is usually treated only if it is symptomatic. First line treatment is with non-steroidal anti-inflammatories or steroids. Effusion or constriction is associated with a high mortality, and surgical treatment is associated with better long term outcome if patients can tolerate thoracotomy and pericardial resection.

Hypertension is another cause of diastolic dysfunction, and chronically elevated levels leads to changes in myocardial structure and the conduction system. Left ventricular hypertrophy is typically seen on echocardiography.

Hypothyroidism leads to a decrease in cardiac output and contractility, reduced heart rate and increased peripheral vascular resistance. Symptomatic cardiac disease is rare, and there is no history of thyroid disease in this patient.

Lymphatic obstruction causes lymphoedema, which is most obvious in the limbs.

Pulmonary fibrosis can be associated with rheumatoid arthritis, but would not commonly present with the combination of symptoms described here.

[Q: 3300] OnExamination 2012 - Rheumatology

A 25-year-old female with systemic lupus erythematosus (SLE) attends at 20 weeks into her pregnancy for her routine obstetric appointment.

The fetal heart rate is 50 beats per minute. Fetal echocardiography shows complete heart block.

Which one of the following maternal autoantibodies is likely to be present?

- 1- Anti-dsDNA
- 2- Anti-Jo 1
- 3- Anti-La (SSB)
- 4- Anti-mitochondrial
- 5- Anti-Ro (SSA)

Answer & Comments

Answer: 5- Anti-Ro (SSA)

Anti-Ro antibody is associated with congenital complete heart block (CHB) accounting for the vast majority of cases of CHB.

Anti-mitochondrial antibody is associated with primary biliary cirrhosis.

Anti-dsDNA is associated with SLE rather than specific of HB.

Anti-La is associated with Sjogren's.

Anti-Jo is associated with polymyositis.

[Q: 3301] OnExamination 2012 - Rheumatology

A 52-year-old man with a history of diabetes mellitus presented with hepatomegaly.

Investigations revealed:

Albumin 30 g/L (37-49)

Total bilirubin 22 µmol/L (1-22)

Alkaline Phosphatase 134 U/L (60-110)

ALT90 U/L (5-35)

Gamma-glutamyl transferase 125 U/L (<50)

Ferritin 1450 µg/L (15-300)

Which of the following features would be most suggestive of a diagnosis of haemochromatosis?

- 1- Chondrocalcinosis
- 2- Gynaecomastia
- 3- Migratory polyarthrititis
- 4- Myxoedema
- 5- Rash

Answer & Comments

Answer: 1- Chondrocalcinosis

This man with diabetes has evidence of liver disease with grossly elevated ferritin suggesting a diagnosis of haemochromatosis.

A non-migratory polyarthrititis would be suggestive particularly of the hands, in over 50% of patients there is involvement of the 2nd and 3rd MCPs, and large joints. The most commonly affected joints are MCPs, PIPs, knees, feet, wrists, back and neck.

Skin pigmentation rather than a rash is more typical.

Myxoedema is not a feature of haemochromatosis.

Gynaecomastia is a feature of liver disease/cirrhosis per se and not just haemochromatosis.

However, chondrocalcinosis together with the chronic arthropathy is well recognised in association with haemochromatosis.

[Q: 3302] OnExamination 2012 - Rheumatology

A 70-year-old man from Lancashire has noted increasing back and leg pain for several years.

x Rays reveal bony sclerosis of the sacroiliac, lower vertebral, and upper tibial regions with cortical thickening, but without mass effect or significant bony destruction.

He also says his hat does not fit him anymore. He has difficulty hearing on the left and has orthopnoea and pedal oedema.

Blood tests reveal an elevated serum alkaline phosphatase.

What is the most likely pathologic process that explains these findings?

- 1- Metastatic adenocarcinoma
- 2- Mineral density
- 3- Paget's disease of bone
- 4- Renal failure with renal osteodystrophy
- 5- Vitamin D deficiency

Answer & Comments

Answer: 3- Paget's disease of bone

This man has Paget's disease, with bone pain, cardiac failure and sensorineural deafness.

Paget's disease of bone is a localised disorder of bone remodelling. There are increased numbers of giant osteoclasts, which increase bone resorption with subsequent increase in new bone formation and altered bone architecture.

The structure of the new bone is disorganised and mechanically weaker, and therefore

liable to pathological fracture and deformity. It can affect any bone, but is commonest in the axial skeleton, long bones and skull. The hands and feet are rarely affected. Both genetic and environmental factors are implicated, and it has been suggested paramyxovirus is involved.

The majority of patients affected are over the age of 55, and men are more commonly affected. The UK has the highest prevalence of Paget's disease in the world.

The signs and symptoms of Paget's are varied, depending on the location of involved sites and the degree of increased bone turnover. It is commonly asymptomatic and is discovered by an elevated serum alkaline phosphatase or typical radiographic findings.

When symptoms do occur, the most common are bone pain and/or deformity. Deafness or tinnitus are not uncommon, due to compression of cranial nerve VIII. The most concerning complication is the development of osteosarcoma, which carries a poor prognosis.

Management concentrates on control of pain and the reduction of complications. In addition to analgesia, bisphosphonates are the mainstay of treatment. These reduce bone turnover, improve pain, promote healing of osteolytic lesions and restore normal bone histology. Serial monitoring of alkaline phosphatase can help to monitor treatment.

Decreased bone mineral density is seen in osteoporosis, which is not associated with a rise in alkaline phosphatase.

Bone metastases may be osteolytic, sclerotic or mixed on radiograph, but typically spread to destroy the medullary bone.

Renal osteodystrophy combines features of osteitis fibrosa cystica and osteomalacia, and is typically more focal than described in this scenario.

Vitamin D deficiency leads to osteomalacia, which does not present with the clinical features described above.

[Q: 3303] OnExamination 2012 - Rheumatology

A 37-year-old man presents with fever, dry cough, recurrent episodes of sinusitis, and weight loss for last three weeks. This has failed to respond to oral amoxicillin prescribed by his GP.

On admission, he is noted to have a temperature of 37.0°C, BP 128/70 mm Hg, and pedal oedema. He has blood-stained nasal discharge, and is noted to have a stridor.

Recent blood tests are:

Hb 11.1gm/dl(13.0 - 18.0 g/dL)

WBC $12.8 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils 88%(40-75%)

Lymphocytes 10%(20-45%)

Eosinophils 2%(1-6%)

Platelet $470 \times 10^9/\mu l$ (150 - $400 \times 10^9/L$)

ESR 86 mm/hr(0 - 15 mm/1st hr)

CRP 103 mg/L(< 10 mg/L)

Anti-proteinase 3 antibody Positive (Negative anti-nuclear antibody Negative (Negative at 1:20 Dil)

ANCA Positive (cytoplasmic pattern)

Urea, electrolytes & creatinine normal

What is the diagnosis?

1- Anti-GBM syndrome

2- Churg-Strauss syndrome

3- Microscopic polyangiitis

4- Polyarteritis nodosa

5- Wegener's granulomatosis

Answer & Comments

Answer: 5- Wegener's granulomatosis

Common manifestations of Wegener's granulomatosis include:

Constitutional symptoms like fevers, night sweats, fatigue, lethargy, weight loss, arthralgia

Ocular involvement including conjunctivitis, episcleritis, uveitis, optic nerve vasculitis, and proptosis

ENT symptoms like chronic sinusitis, rhinitis, otitis media and hearing loss, subglottic stenosis (leading to stridor and features of extrathoracic airway obstruction on flow-volume loop)

Pulmonary disease, for example, pulmonary infiltrates, cough, haemoptysis, chest discomfort, and dyspnoea

Renal disease manifests as crescentic necrotising glomerulonephritis

Nervous system involvement manifests as mononeuritis multiplex, sensorimotor polyneuropathy, cranial nerve palsies, vasculitis of small to medium-sized vessels of the brain or spinal cord, and granulomatous masses that involve the orbit, optic nerve, meninges or brain

Skin involvement can lead to palpable purpura or skin ulcers.

[Q: 3304] OnExamination 2012 - Rheumatology

Which of the following drugs is most likely to cause drug-induced lupus erythematosus (DILE) syndrome?

- 1- Baclofen
- 2- Isoniazid
- 3- Methotrexate
- 4- Procainamide
- 5- Sulfasalazine

Answer & Comments

Answer: 4- Procainamide

A recessive gene is responsible for the activity of hepatic N-acetyl transferase resulting in slow or fast (intermediate and fast groups get lumped together) acetylation.

Forty five per cent of the United Kingdom population are slow acetylators.

Drugs affected include:

Isoniazid

Hydralazine

Dapsone

Procainamide

Sulfasalazine.

Slow acetylators have increased risk of isoniazid-induced peripheral neuropathy, and hydralazine or procainamide-induced systemic lupus erythematosus (SLE).

At least 38 drugs currently in use can cause DILE. However, most cases have been associated with these three:

Procainamide

Hydralazine

Quinidine.

The risk for developing lupus-like disease from any of the other 35 drugs is low or very low; with some drugs only one or two cases have been reported.

Isoniazid (INH) - low risk.

Sulfasalazine - low risk.

[Q: 3305] OnExamination 2012 - Rheumatology

A 73-year-old male presented with an acute attack of gout in his left knee.

What is the most likely underlying metabolic cause?

- 1- Decreased renal excretion of uric acid
- 2- Endogenous overproduction of uric acid
- 3- Excessive dietary purine intake
- 4- Lactic acidosis
- 5- Starvation

Answer & Comments

Answer: 1- Decreased renal excretion of uric acid

Gout is the most prevalent form of inflammatory arthropathy. It is caused by the deposition of monosodium urate crystals with resultant inflammation in the involved joint. Serum urate concentrations exceeding 7 mg/dl are associated with increased risk of gout.

The aetiology of gout can broadly be divided into cases where there is

Underexcretion of uric acid via the kidney (90%) or

Endogenous overproduction of uric acid (10%)

although in practical terms the distinction is rarely made as allopurinol is the mainstay of long term treatment (not during the acute attack!) in both groups.

Uric acid is the end product of purine metabolism. Its production and excretion are tightly regulated and, in normal circumstances, uric acid excretion is two thirds renal and one third via intestinal bacterial uricolysis. Where renal elimination is impaired, the amount of extra-renal excretion can be increased.

In a 73-year-old man it is almost certainly reduced renal excretion due to deteriorating renal function and possibly diuretic use.

Excessive dietary intake of purines is rarely a cause of sustained hyperuricaemia, although patients should be advised to follow

a low purine diet to reduce the risk of recurrent attacks.

Starvation leads to an increase in lactic acid, which impairs the kidneys' ability to excrete uric acid and therefore increases the risk of developing gout. This is however a rare underlying cause, and decreased renal excretion is more likely in this case.

Gout can also be caused by inborn errors of metabolism which alter uric acid homeostasis. These are mainly inherited enzyme defects, and present in younger patients.

As a final point, it is also important to note that gout appears to be an independent risk factor for cardiovascular mortality and morbidity, additional to the risk conferred by its association with more traditional risk factors.

[Q: 3306] OnExamination 2012 - Rheumatology

A 25-year-old lady gives birth to a baby with complete heart block who subsequently requires pacemaker insertion.

Which of the following antibodies is most likely to be detected in the maternal serum?

- 1- Anti-dsDNA antibodies
- 2- Anti-endothelial antibodies
- 3- Anti-Ro/SSA antibodies
- 4- Anti-SCL70 antibodies
- 5- Rheumatoid factor

Answer & Comments

Answer: 3- Anti-Ro/SSA antibodies

The majority of cases of congenital heart block are due to the presence of anti-Ro/SSA antibodies in the maternal serum.

The mother may have no evidence of a connective tissue disorder.

The risks of congenital heart block in mothers with anti-Ro/SSA antibodies remains very small (<3%) but the correlation between the presence of anti-Ro/SSA antibodies and congenital heart block is very strong.

The heart block is generally permanent (unlike other features of neonatal lupus) and insertion of a permanent pacemaker is frequently required.

[Q: 3307] OnExamination 2012 - Rheumatology

A 64-year-old lady is referred to your connective tissue disease clinic by her GP.

She has been complaining of four months of progressively worsening lower mandibular pain and gum swelling to the premolar region. This was commensurate with a dental extraction for an ipsilateral cavity thought to be the culprit. The residual wound has failed to heal.

Her past medical history includes multiple myeloma, and she takes zoledronic acid once monthly.

A CT scan of her mandible demonstrates disruption to cortical bone, a pathological fracture line and a large region of central bone loss.

What is the pathological process underlying this presentation?

- 1- Actinomyces induced osteonecrosis
- 2- Bisphosphonate induced osteonecrosis of the jaw
- 3- Osteolysis secondary to multiple myeloma
- 4- Osteoradionecrosis secondary to radiation therapy
- 5- Primary (AL) amyloidosis

Answer & Comments

Answer: 2- Bisphosphonate induced osteonecrosis of the jaw

Learning points:

Bone mineral density measurement in postmenopausal women

Indications for bisphosphonate prophylaxis with glucocorticoid therapy

Specific bisphosphonate pharmacotherapy.

The salient features of this case are;

The underlying history of multiple myeloma

Long term use of zoledronic acid

Dental extraction surgery

A non-healing lesion which has persisted for greater than eight weeks despite investigation and radiological evidence of pathological fractures.

Zoledronic acid has been linked to the development of osteonecrosis of the jaw, with a statistically significant association to dental extraction surgery as a precipitant. There is an increased incidence of this complication amongst patients with underlying malignancy, especially multiple myeloma.

A putative role for homozygosity of the T allele polymorphism for cytochrome P450 CYP2C8 conferring a significantly increased likelihood of developing ONJ is still under investigation.

[Q: 3308] OnExamination 2012 - Rheumatology

A 62-year-old man presents with a six month history of a painless lesion to his left subcostal region. The lesion was noticed by his wife and he is asymptomatic.

He has no significant past medical history and takes no regular medication.

The lesion (pictured below) was non tender, dry, indurated and slightly coarse to palpation.

Basic bloods demonstrate;

Hb 12.7g/dL(13-18)

MCV 88fL(80 - 96)

WCC $6.5 \times 10^9/L$ (4 - 11)

Westergren ESR 10/hr(0 - 20)

CRP 5mg/L(<10)

IgM 5.2g/dL(0.05-3.2g/dL)

IgG 2.1g/dL(0.6-1.7g/dL)

ANA - positive, anti-histone - positive, anti-Cu/Zn superoxide dismutase - positive.

What is the diagnosis?

- 1- Diffuse systemic sclerosis
- 2- Discoid lupus erythematosus
- 3- Eosinophilic fasciitis
- 4- Limited systemic sclerosis
- 5- Morphea (localised scleroderma)

Answer & Comments

Answer: 5- Morphea (localised scleroderma)

Learning points:

Clinical appearance of early morphea

Pathophysiology of morphea

Immunological profile of morphea.

This gentleman has developed localised scleroderma, an idiopathic inflammatory skin condition which causes excessive collagen deposition and fibrosis. This patient exhibits the commonest form, 'circumscribed/plaque' morphea.

This is a well defined oval to round plaque that fails to meet the criteria for generalised morphea. The pathogenesis is poorly defined. An autoimmune component is suggested by enhanced T helper 2 (Th2) dependent interleukin 4 (IL-4) activity, which in turn upregulates transforming growth factor beta (TGF- β). TGF- β stimulates fibroblast production of collagen and other extracellular matrix proteins.

Possible serum abnormalities include hypergammaglobulinaemia, peripheral eosinophilia and an elevated erythrocyte sedimentation rate (ESR) and C reactive protein (CRP). Anti-Cu/Zn superoxide dismutase antibodies have been found in up to 90% of some patient samples.

[Q: 3309] OnExamination 2012 - Rheumatology

A 50-year-old man is brought in by ambulance complaining of a two day history of malaise, subjective fever, sweating, nausea, abdominal pains and foul smelling diarrhoea.

He has a past medical history of Crohn's disease, which has been quiescent for three years following the initiation of immunosuppressive therapy. He was commenced on allopurinol three weeks ago, after suffering another flare of his gout.

Clinical examination demonstrated; he is confused, clinically dehydrated, GCS 14, temperature 35.1°C, pulse 101 + regular, BP 95/66 mmHg, normal chest sounds, generalised abdominal tenderness with hyperkinetic bowel sounds.

Blood tests revealed;

Hb 12.0g/dL(13.0 - 18.0)

MCV 90fL(80 - 96)

WCC $1.5 \times 10^9/L$ (4 - 11)

Neutrophils $1 \times 10^9/L$ (1.5 - 7)

Lymphocytes $0.8 \times 10^9/L$ (1.5 - 4)

Platelets $50 \times 10^9/L$ (150 - 400)

Creatinine 150 $\mu\text{mol/L}$ (60 - 110)

Urea 8.9 mmol/L(2.5 - 7.5)

Alanine aminotransferase 50 U/L(5 - 35)

Amylase 70 U/L(60 - 180)

CRP 10 mg/L(<10)

Westergren ESR 25 mm/hr(0 - 20)

Uric acid 200 mmol/L

What is the most likely underlying cause of his presentation?

- 1- Acute pancreatitis
- 2- Allopurinol toxicity
- 3- Azathioprine toxicity
- 4- Calcium pyrophosphate deposition disease (CPPD)
- 5- Crohn's flare

Answer & Comments

Answer: 3- Azathioprine toxicity

Learning points:

Basic mechanism of action and pharmacokinetics of allopurinol

Basic mechanism of action of azathioprine

Potential consequence of their interaction

Second line urate lowering therapy.

This patient has developed bowel sepsis (foul smelling diarrhoea, hypothermic, tachycardic, hypotensive) secondary to pancytopenia induced by the co-administration of allopurinol and azathioprine.

The prodrug azathioprine is metabolised to its active compound 6-mercaptopurine (6-MP). 6-MP undergoes catabolic oxidation to 6-thiouric acid by xanthine oxidase.

Allopurinol has a peak onset of action of one to two weeks and works by inhibiting xanthine oxidase.

Co-administration of these drugs may lead to accumulation of 6-MP and increases the risk of myelosuppression.

A second line urate-lowering agent such as febuxostat would be more appropriate.

A Crohn's flare would not typically cause pancytopenia.

Normal amylase refutes pancreatitis.

Reference:

<http://www.uptodate.com/contents/diagnosis-and-classification-of-osteoarthritis>

[Q: 3310] OnExamination 2012 - Rheumatology

A 30-year-old housewife with SLE had some blood tests.

Results of investigations are as follows:

Hb 12.1g/dl(11.5 - 16.5 g/dL)

WBC $8.9 \times 10^9/L$ (4 - $11 \times 10^9/L$)

Neutrophils 84%(40 - 75%)

Platelet $90 \times 10^9/L$ (150 - $400 \times 10^9/L$)

ESR 14 mm/hr(0 - 20 mm/1st hr)

INR 1.1(<1.4)

aPTT 48 seconds(30 - 40s) did not normalise after addition of normal plasma

Blood film thrombocytopenia, no schistocytes

Urea, electrolytes and creatinine: Normal

What is most likely explanation for the abnormal aPTT?

- 1- Antiphospholipid antibody syndrome
- 2- Disseminated intravascular coagulation
- 3- Idiopathic thrombocytopenic purpura
- 4- Thrombotic thrombocytopenic purpura
- 5- Haemolytic uraemic syndrome

Answer & Comments

Answer: 1- Antiphospholipid antibody syndrome

This patient has antiphospholipid antibody syndrome which is a non-inflammatory pro-thrombotic state in vivo, in the presence of laboratory tests suggesting an anticoagulant state.

The antiphospholipid antibodies (anticardiolipin and lupus anticoagulant) cause coagulation defect in-vitro (raised aPTT which fails to correct after the addition of

normal human plasma). However, despite the coagulation defects and thrombocytopenia, the lupus anticoagulant causes arterial and venous thromboses in vivo.

Disseminated intravascular clotting and thrombotic thrombocytopenic purpura are severe systemic illnesses, where bleeding may occur due to consumption of clotting factors, and platelets by an overactive clotting cascade.

Idiopathic thrombocytopenic purpura does not cause raised aPTT.

[Q: 3311] OnExamination 2012 - Rheumatology

A 58-year-old man has a one year history of anterior knee pain increased by climbing stairs, and walking. There is no rest or night pain. There is no history of joint swelling, alcohol use or chronic skin conditions.

On examination, there is crepitus on active and passive knee movements and knee flexion is painful beyond 110°. Hip and back movements are normal.

What is the most likely diagnosis?

- 1- Gout
- 2- Osteoarthritis
- 3- Osteonecrosis
- 4- Psoriatic arthritis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 2- Osteoarthritis

Osteoarthritis is likely as the joint pain is increased by activity.

Knee crepitus occurs with patella-femoral osteoarthritis.

Gout is unlikely, as there is no history of episodes of acute crystal synovitis. Also there are no risk factors for gout, for example,

excess alcohol intake, renal impairment, or diuretic use.

There is no symptom suggestive of inflammatory arthritis, for example, early morning stiffness, or synovitis.

The lack of a personal or family history of psoriasis makes psoriatic arthritis very unlikely.

Osteonecrosis is usually an acutely painful condition, presenting as acute exacerbation of knee pain in those with knee OA.

[Q: 3312] OnExamination 2012 - Rheumatology

A 28-year-old woman with a 15 year history of Raynaud's phenomenon and no other symptoms had some blood tests with her GP.

These show that she has a homogeneous pattern anti-nuclear antibody in a titre of 1:5120, and that she is negative for anti-dsDNA antibody using the Crithidia luciliae assay. A full blood count, urea electrolyte and creatinine, liver function tests, and C3 and C4 are normal.

What is the most likely diagnosis?

- 1- Discoid lupus erythematosus
- 2- Primary Raynaud's phenomenon
- 3- Scleroderma
- 4- Sjogren's syndrome
- 5- Systemic lupus erythematosus (SLE)

Answer & Comments

Answer: 2- Primary Raynaud's phenomenon

Diffuse staining ANA on immunofluorescence in high titre raises the possibility of systemic lupus erythematosus (SLE).

Further tests are required to ascertain if the diffuse staining ANA is due to anti-dsDNA (pathogenic in SLE) or due to anti ss-DNA antibody (not thought to play a pathogenic role in SLE).

Crithidia luciliae immunofluorescence is positive only in the presence of anti-dsDNA antibody. This is as Crithidia luciliae has a giant mitochondrion, with a circular dsDNA. It does not have ssDNA or any histones. In routine clinical practice, only anti-dsDNA are tested for. Diffuse staining ANA on immunofluorescence, in low titres (<1:160) is very common in the general population.

Although not mutually exclusive, different ANA immunofluorescence patterns suggest different diseases:

Anti-centromere pattern: limited cutaneous systemic sclerosis

Cytoplasmic pattern: Sjogren's syndrome, anti-synthetase syndrome

Nucleolar pattern: diffuse cutaneous systemic sclerosis

Speckled pattern: mixed connective tissue disease.

This patient has no symptoms to support the diagnoses of

Discoid lupus erythematosus (scarring photosensitive skin ulceration)

Sjogren's syndrome (dry eyes, dry mouth, fatigue)

Scleroderma (Raynaud's phenomenon, skin thickening, tightness, telangiectasia), and

SLE (photosensitive rash).

Anti-dsDNA antibodies are highly specific for diagnosis of SLE. However, they are neither necessary, nor sufficient in themselves for the diagnosis of SLE. At any one time only 50% patients with SLE have the anti-dsDNA antibody, while only 70% patients with SLE develop anti-dsDNA antibodies at any one time during the course of their illness.

Raynaud's phenomenon is a common clinical presentation, which may be primary or secondary to underlying disease. It can be diagnosed if there is a history of clearly

demarcated pallor of the digit(s) followed by at least one other colour change (cyanosis and/or erythema). Symptoms are usually precipitated by cold (or less commonly emotion). Vasospasm without endothelial damage is thought to be the main cause for primary RP. The pathogenesis of secondary forms is probably initiated primarily by endothelial damage.

Physical examination, nailfold capillaroscopy and immunological tests can differentiate between primary and secondary Raynaud's.

You should suspect secondary Raynaud's phenomenon if any of the following are present:

Onset at more than 30 years of age

Intense, painful or asymmetrical episodes

Presence of additional clinical features suggestive of underlying disease

Positive anti-nuclear antibody

Abnormal nailfold capillaries

Digital ulcers, gangrene or severe ischaemia of one or more digits.

Primary Raynaud's can be diagnosed if all the following are present:

No suspicion of underlying disease

Symmetrical episodes affecting both hands, but not necessarily all fingers

No tissue necrosis, ulceration, gangrene or severe ischaemia

Normal nailfold capillaries

Normal ESR and negative anti-nuclear antibodies.

Treatment involves prevention so that permanent ischaemic damage can be avoided. Patients should avoid exposure to the cold.

The mild forms of primary RP can be controlled by non-pharmacological approaches alone. If insufficient, the first choice therapy is calcium channel blockers. In severe forms, intravenous prostaglandin, endothelin-1 receptor antagonists and phosphodiesterase-5 inhibitors are used.

Future treatment options may include selective alpha-2c adrenergic receptor blockers, tyrosine and Rho-kinase inhibitors and calcitonin gene-related peptide.

Differential diagnosis of Raynaud's phenomenon includes:

Chilblains (perniosis): erythematous itchy swellings on fingers and toes in response to cold

Acrocyanosis: continuous blueness of the extremities aggravated by cold

Erythromelalgia: painful erythema caused by paroxysmal dilatation of blood vessels

Vascular embolism

Livedo reticularis: mottled, cyanotic discolouration of skin.

All the other features described here would be consistent with a diagnosis of primary Raynaud's disease.

Whilst miscarriage can be associated with connective tissue disease, in particular antiphospholipid syndrome, it is common in the population especially in early pregnancy.

[Q: 3313] OnExamination 2012 - Rheumatology

A 76-year-old lady with stable congestive cardiac failure presents to the Emergency department at 11 pm with a two day history of a painful hot swollen right knee. She is unable to weight bear. She lives alone. Her temperature is 37.4°.

Which of the following is the most crucial step in her management?

- 1- Aspirate the right knee for urgent Gram stain, microscopy, culture and sensitivity
- 2- Provide non-steroidal anti-inflammatory for pain relief
- 3- Prescribe paracetamol and discharge home with GP follow up
- 4- Take a full history from the patient, in particular, enquire into any previous episodes of joint pain
- 5- x Ray the right knee

Answer & Comments

Answer: 1- Aspirate the right knee for urgent Gram stain, microscopy, culture and sensitivity

This lady has presented with an acute onset monoarthritis. A destructive septic arthritis is a potential diagnosis, and must be excluded as a matter of urgency. An aspirate is the most crucial step to exclude this and allow the timely commencement of appropriate antibiotics. Differential diagnoses include gout and pseudogout, which can also be diagnosed on joint aspiration.

Regarding the options:

B. Although non-steroidal anti-inflammatories would be useful as pain relief they may exacerbate the congestive cardiac failure and should be used with caution. Also the renal function must be checked to ensure a non-steroidal anti-inflammatory can be used.

C. Discharging home with paracetamol is not an acceptable management plan as the lady lives alone and cannot weight bear. She is unlikely to cope and will be at risk of falls.

D. A full history is imperative in formulating a differential diagnosis. For example, previous similar episodes in her great toes and the use of diuretics may suggest a diagnosis of acute gout. However, this does not exclude a destructive septic arthritis. An aspirate is the most crucial step to exclude this and allow

the timely commencement of appropriate antibiotics.

E. In the acute stages of septic arthritis there may be no signs of damage to the joint seen on a radiograph. It may show typical changes of calcium pyrophosphate dihydrate deposition disease or gout, which may help in her long term management, but this would not change the management in this acute situation.

[Q: 3314] OnExamination 2012 - Rheumatology

A 75-year-old woman with polymyalgia rheumatica (PMR) presents with a two week history of sudden onset right temporal headache, pain whilst brushing her hair. There are no visual symptoms. She is currently on prednisolone 8 mg/day.

On examination, there is tenderness overlying the right temporal artery.

Recent blood tests show:

Hb 11.1g/dl(11.5 - 16.5 g/dL)

WBC $7.8 \times 10^9/L$ ($4 - 11 \times 10^9/L$)

Neutrophils 70%(40-75%)

Platelet $270 \times 10^9/L$ ($150 - 400 \times 10^9/L$)

ESR 76 mm/hr(0 - 30 mm/1st hr)

CRP 93 mg/L(< 10 mg/L)

Urea, electrolytes and creatinine Normal

What is the next step in her management?

- 1- Admit for intravenous methyl prednisolone.
- 2- Arrange temporal artery biopsy
- 3- Increase prednisolone to 15 mg/day.
- 4- Increase prednisolone to 40 mg/day
- 5- Increase prednisolone to 40 mg/day, and arrange a temporal artery biopsy

Answer & Comments

Answer: 5- Increase prednisolone to 40 mg/day, and arrange a temporal artery biopsy

These symptoms and investigation findings are typical of giant cell arteritis (GCA).

GCA affects large and medium sized arteries, with a predilection for the external carotid, ciliary and retinal arteries. Endovascular damage and cytokine-mediated inflammation causes local ischaemia. There is considerable overlap with polymyalgia rheumatica (PMR), and symptoms of both should be sought. About 50% of patients with GCA also have PMR, and about 10% of those with PMR also have GCA. 20% of patients develop loss of vision, which can be prevented with timely recognition and treatment. Visual loss typically occurs early in the course of disease and, once established, rarely improves. The classically described jaw claudication occurs in a minority of cases, but does indicate a high risk of ischaemic complications.

The typical presentation of GCA is a temporal headache, with myalgia, malaise and fever. ESR and CRP are usually raised.

As soon as the diagnosis is suspected, high dose corticosteroids should be given. Current BSR guidelines recommend:

- Uncomplicated GCA (no jaw or tongue claudication, or visual symptoms): prednisolone 40-60mg daily
- Complicated GCA:
 - Evolving visual loss or history of amaurosis fugax: IV methylprednisolone 500mg-1g daily for three days, followed by oral corticosteroids
 - Established visual loss: at least 60mg prednisolone daily

Bone protection and proton-pump inhibitors should be co-prescribed.

It is important to note that the pathological findings of giant cell arteritis persist for one to two weeks following initiation of corticosteroid, and therefore treatment should not be delayed to obtain a biopsy.

Aspirin 75mg once daily is sometimes given as an adjunct but higher doses are not recommended.

Symptoms usually resolve quickly, often with two or three days. Once they and laboratory abnormalities resolve, the dose of corticosteroid can be reduced and usually stopped within two years. The patient should be monitored for recurrence throughout the taper: ESR every 4 weeks for 2-3 months, then every 8-12 weeks until 12-18m after cessation of therapy.

Giant cell arteritis is a medical emergency and should be treated without delay. It is not acceptable to give no treatment.

[Q: 3315] OnExamination 2012 - Rheumatology

You see a 44-year-old woman with a three month history of progressive pain, swelling and stiffness in both knees. Her symptoms are worse in the morning, and it takes an hour or so to loosen up the joints. She has had no recent preceding illness and there is no personal or family history of any chronic skin conditions.

Since she was a teenager she has had painful fingers and toes when they are exposed to cold weather, but her digits do not change colour. She has also recently had pain and stiffness in her fingers and toes in the morning, and this fluctuates from day to day. She occasionally drinks alcohol.

On examination you find reduced flexion and extension and an effusion in both knees. She has bilateral metatarsalgia on squeezing her toes. Examination of her fingers is normal and there is no psoriasis of her skin or nails.

Recent blood tests showed:

Haemoglobin 13.1gm/dl(13.0 - 18.0 g/dL)

White cell count $8.2 \times 10^3/\mu\text{l}$ (4 - $11 \times 10^9/\text{L}$)

Neutrophil count $5.1 \times 10^3/\mu\text{l}$ (1.5 - $7 \times 10^9/\text{L}$)

Platelet count $280 \times 10^3/\mu\text{l}$ (150 - $400 \times 10^9/\text{L}$)

ESR 48 mm/hr(0 - 20 mm/1st hr)

Urea 5.0 mEq/L(2.5 - 7.5 mmol/L)

Creatinine 82 mEq/L(60 - 110 $\mu\text{mol/L}$)

Sodium 142 mEq/L(137 - 144 mmol/L)

Potassium 4.2 mEq/L(3.5 - 4.9 mmol/L)

Rheumatoid factor (RF): positive (1:256)

Antinuclear antibody (ANA): positive (1:40)

What is the most likely diagnosis?

- 1- Rheumatoid arthritis
- 2- Reactive arthritis
- 3- Systemic lupus erythematosus
- 4- Pseudogout
- 5- Psoriatic arthritis

Answer & Comments

Answer: 1- Rheumatoid arthritis

A. Rheumatoid arthritis

Patients with rheumatoid arthritis often present with synovitis which may affect a variety of joints before developing the classic features of a symmetrical, inflammatory polyarthritis affecting the small joints of the hands and feet.

This patient has symptoms suggestive of peripheral synovitis, even though her signs are limited on the day of examination. The working diagnosis has to be rheumatoid arthritis, in view of the clinical history, duration and distribution of symptoms and signs, and the fact that she is strongly positive for rheumatoid factor.

Learning bite: Diagnosing rheumatoid arthritis:

Rheumatoid arthritis is a clinical diagnosis. The classic features are:

Symmetrical inflammatory polyarthritis

Arthritis affecting the small joints of the hands and feet.

The most commonly used classification criteria are the American College of Rheumatology criteria. These criteria do not perform well in early disease.

Diagnostic tests are:

Rheumatoid factor: there are many false positive and negatives

Anticyclic citrullinated peptide antibody (anti CCP antibody): more specific for rheumatoid arthritis

Antinuclear antibody: present in 20-30% of patients with rheumatoid arthritis.

B. Reactive arthritis

The absence of any preceding infection and symmetry of her symptoms and signs makes the diagnosis of reactive arthritis unlikely.

C. Systemic lupus erythematosus

This patient does not have other features of systemic lupus erythematosus which one may expect. She only has a low titre of antinuclear antibody which makes the diagnosis of systemic lupus erythematosus unlikely, although it is important to note ANA is not specific for systemic lupus erythematosus.

Learning bite: Inflammatory arthritis in systemic lupus erythematosus:

The inflammatory arthritis of systemic lupus erythematosus typically affects the hands, wrists and knees, with often little in the way of signs, but significant symptoms. Swelling is mainly soft tissue with small joint effusions. Large knee effusions are unusual.

D. Pseudogout

Pseudogout is caused by deposition of calcium pyrophosphate dihydrate (CPPD) crystals, and can present as an acute monoarthritis. It commonly affects older individuals, over 70-years-old, or those with pre-existing osteoarthritis. Attacks of pseudogout begin over a period of a few hours and usually subside after two weeks.

Although knees are the most frequently involved joint in pseudogout, the age of this patient and length of symptoms make the diagnosis of pseudogout very unlikely.

E. Psoriatic arthritis

Lower limb oligoarthritis is one of the manifestations of psoriatic arthritis. However the absence of a family history of psoriasis or any psoriasis on examination makes this diagnosis unlikely.

[Q: 3316] OnExamination 2012 - Rheumatology

A 51-year-old man presents with increasing lethargy over the past few months. He has had to give up his job as a storeman, and it now takes him 15 minutes to get up one flight of stairs and he has difficulty getting up out of a chair.

On examination his BP is 135/82 mmHg, pulse is 85 and regular. His heart sounds are normal and his chest is clear. He has clear proximal muscle weakness, with sparing of distal muscle power. His CK is elevated at 1200.

Which of the following antibodies is most likely to be elevated?

- 1- Anti-Jo antibody
- 2- Anti-La antibody
- 3- Anti-nuclear antibody
- 4- Anti-Rho antibody
- 5- Anti-smooth muscle antibody

Answer & Comments

Answer: 1- Anti-Jo antibody

The proximal myopathy and raised creatine kinase (CK) in the absence of a violaceous rash suggests that polymyositis is the most likely diagnosis.

Polymyositis is associated with the presence of anti-Jo 1 antibodies. Corticosteroids are the mainstay of immunosuppression. Patients with anti-Jo 1 antibodies are at increased risk of lung fibrosis, and therefore immunosuppression is usually continued long term.

A steroid sparing agent, such as azathioprine, may well be added to reduce the corticosteroid dose.

Anti-Rho and -La antibodies are seen in systemic lupus erythematosus (SLE) and are associated with the development of neonatal lupus.

Antinuclear antibodies are seen in a variety of autoimmune disorders, and the pattern can be used to diagnose different conditions.

Some of the common patterns seen are:

Homogenous (diffuse) - SLE, mixed connective tissue disease

Speckled - SLE, Sjogren syndrome, systemic sclerosis, polymyositis, rheumatoid arthritis, mixed connective tissue disease

Nucleolar - systemic sclerosis, polymyositis

Centromere - systemic sclerosis, CREST syndrome.

Antismooth muscle antibodies are associated with autoimmune hepatitis.

[Q: 3317] OnExamination 2012 - Rheumatology

A 16-year-old girl comes to the surgery feeling under the weather. She has recently suffered from a streptococcal throat infection but feels that she has not really picked up since, although she did have a course of oral penicillin.

She complains of an extensive purpuric rash which is affecting her buttocks, the back of her legs, and the ulnar side of her arms. There is also a history of abdominal and joint pains.

On examination her BP is 105/70 mmHg, with a pulse of 75. She has a purpuric rash, mainly affecting her buttocks and the tops of her legs.

Investigations show

Haemoglobin 11.5 g/dl (11.5-16.0)

White cell count $11.2 \times 10^9/L$ (4-11)

Platelets $230 \times 10^9/L$ (150-400)

Serum Sodium 140 mmol/l (135-146)

Serum Potassium 4.2 mmol/l (3.5-5)

Creatinine 135 $\mu\text{mol/l}$ (79-118)

Urine Blood ++

Protein ++

Which of the following immunoglobulins is most likely to be raised?

1- IgA

2- IgD

3- IgE

4- IgG

5- IgM

Answer & Comments

Answer: 1- IgA

This patient has Henoch-Schönlein purpura (HSP). HSP is more commonly seen in infants, but may also be seen in older individuals.

The buttock rash seen here is characteristic as is the blood and proteinuria. Creatinine may be elevated, although progression to renal failure is rare. Platelet count can be low, normal or elevated. IgA levels are elevated and the patient may also have an eosinophilia.

HSP is usually managed with supportive measures only. There is no evidence that

steroid therapy impacts on progression to renal failure.

Non-steroidals may be of value in treating joint pain.

[Q: 3318] OnExamination 2012 - Rheumatology

A 57-year-old woman presents to the clinic with increasing shortness of breath. She has a history of hypertension for which she takes amlodipine, reflux oesophagitis, and Raynaud's phenomenon.

On examination you notice that her skin has a speckled appearance, and she has peripheral calcinosis on examination of her hands. Respiratory examination reveals inspiratory crackles consistent with pulmonary fibrosis.

Investigations reveal

Haemoglobin 10.4 g/dl(11.5-16)

White cell count $9.2 \times 10^9/L$ (4-10)

Platelets $190 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (134-143)

Potassium 4.9 mmol/l (3.5-5)

Creatinine 139 $\mu\text{mol/l}$ (60-120)

SaO₂ on air 94%(?96%)

CXR Interstitial shadowing consistent with fibrosis

Which of the following autoantibodies is most associated with her respiratory picture?

- 1- Anti-centromere antibodies
- 2- Anti-PM/Scl antibodies
- 3- Anti-Scl-70 antibodies
- 4- Anti-smooth muscle antibodies
- 5- Rheumatoid factor antibodies

Answer & Comments

Answer: 3- Anti-Scl-70 antibodies

This woman has a clinical picture which is consistent with systemic sclerosis.

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. Ninety to 95% of patients have positive antinuclear antibodies.

There are two major subtypes: limited cutaneous and diffuse cutaneous.

CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynauds' phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia).

Patients with systemic sclerosis can present with

Skin abnormalities

Musculoskeletal changes

Gastrointestinal complications

Pulmonary disease

Renal crisis and

Dry eyes and mouth.

Pulmonary fibrosis is associated with anti-Scl-70 antibodies in up to 70% of cases.

Pulmonary involvement is the second commonest organ involvement after oesophageal disease and is the leading cause of death.

Anticentromere antibodies are more commonly seen in patients without pulmonary fibrosis.

Anti-PM/Scl antibodies are a rarely encountered type of antinuclear antibodies. They are mainly seen in association with idiopathic myositis, systemic sclerosis overlap syndromes, polymyositis and dermatomyositis.

Anti-smooth muscle antibodies are associated with autoimmune hepatitis.

Rheumatoid factor is non-specific, but is seen at increased frequency in patients with rheumatoid arthritis.

[Q: 3319] OnExamination 2012 -
Rheumatology

A 50-year-old Asian lady with severe rheumatoid arthritis has failed on most traditional disease modifying anti-rheumatic drugs (DMARD) treatments.

She is currently on methotrexate 20 mg weekly and for the last six months has been receiving regular infusions of the anti-tumour necrosis factor (TNF)-alpha monoclonal antibody, infliximab. Her joint disease has dramatically improved.

She now presents with fevers, pleuritic chest pain and a large left sided pleural effusion, but little evidence of joint synovitis.

What is the most likely diagnosis?

- 1- Primary bronchial carcinoma
- 2- Pulmonary embolus
- 3- Pulmonary metastases
- 4- Rheumatoid related effusion
- 5- Tuberculosis

Answer & Comments

Answer: 5- Tuberculosis

The most likely answer is TB.

All of the other answers are possible and need to be excluded.

A rheumatoid effusion is unlikely when peripheral joint disease is so well controlled.

Treatment with anti-TNF-alpha increases the risk of opportunistic infections and in particular, there is a significant increase in the risk of TB reactivation in conjunction with infliximab.

[Q: 3320] OnExamination 2012 -
Rheumatology

A 55-year-old lady has recently commenced on 20 mg of leflunomide daily for sero-negative rheumatoid arthritis.

At baseline, prior to commencing the drug, her AST was 33 U/l (1-31) and her ALT was 40 U/l (5-35).

She attends for routine blood monitoring. Her FBC is normal but her liver function tests (LFTs) reveal:

AST 58 U/l (1-31)

ALT 71 U/l (5-35)

Alkaline phosphatase 100 U/l (45-105)

Bilirubin 12 µmol/l (1-22)

What is the most appropriate management option for this patient?

- 1- Continue leflunomide and monitor LFTs in one month
- 2- Continue leflunomide and monitor LFTs in two weeks
- 3- Reduce the dose and recheck LFTs in one week
- 4- Stop leflunomide and commence washout procedure
- 5- Stop the leflunomide and repeat tests in two weeks

Answer & Comments

Answer: 3- Reduce the dose and recheck LFTs in one week

Leflunomide is associated with serious hepatotoxicity.

Increased aminotransferases are commonly seen in association with therapy occurring in 15-20% of cases (less than a twofold rise).

However, more serious elevation (greater than threefold) is seen in less than 5%.

Generally, most hepatic events occur within the first six months of use. It is recommended liver function tests (LFTs) be checked monthly for six months and, if stable, two monthly thereafter.

If aspartate aminotransferase (AST) or alanine aminotransferase (ALT) is between two and

three times the upper limit of normal, and the leflunomide dose is more than 10 mg daily, the dose should be reduced to 10 mg and LFTs rechecked weekly until normalised. If the ALT and AST are returning to normal, the patient should be left on 10 mg per day. If the LFTs remain elevated, leflunomide should be stopped and discussed with the specialist team.

If the AST or ALT is more than three times the upper limit of normal, the LFTs should be rechecked within 72 hours. If they remain more than three times the reference range, leflunomide should be stopped and washout considered (cholestyramine and activated charcoal). It is important to note that the half life of leflunomide is usually two weeks (mean 1-4) therefore if a rapid response is required, washout should be considered.

Current UK guidance also recommends frequent monitoring for patients on leflunomide. Full blood count (FBC) should be checked monthly for six months and, if stable, two monthly thereafter.

White cell count less than 3.5, neutrophils less than 2 or platelets less than 150 should be discussed with the specialist team, and leflunomide withheld until this has taken place.

Monitoring should be continued at least monthly in the long term if leflunomide is co-prescribed with any other immunosuppressant or potentially hepatotoxic agent.

In addition, signs of leflunomide toxicity should be monitored. If the patient develops a rash or itch dose reduction should be considered, with or without the addition of antihistamines. If severe, leflunomide should be stopped and washout considered.

Hair loss, headaches and gastrointestinal upset may also warrant dose reduction or washout.

A blood pressure of greater than 140/90 mmHg should be treated as per NICE guidelines. If it remains elevated, stop leflunomide and consider washout.

Weight should be monitored, and a weight loss of greater than 10% should be identified. If no other cause can be found, consider dose reduction or washout.

If there is increasing shortness of breath, pneumonitis should be considered and leflunomide should be stopped.

[Q: 3321] OnExamination 2012 - Rheumatology

A 60-year-old lady with rheumatoid arthritis has been on long term therapy to control her disease.

She presents with increasing shortness of breath and a chest x ray shows 'bilateral interstitial shadowing'.

Which of the following medications is the most likely cause for her symptoms?

- 1- Azathioprine
- 2- Hydroxychloroquine
- 3- Infliximab
- 4- Methotrexate
- 5- Sulfasalazine

Answer & Comments

Answer: 4- Methotrexate

Methotrexate is a recognised cause of pulmonary fibrosis. However, it is sometimes used in the treatment of idiopathic pulmonary fibrosis as a steroid sparing agent.

"Pulmonary parenchymal or pleural reactions to chemotherapeutic agents used in the management of patients with malignant diseases are being recognized with increasing frequency. Alkylating agents, asparaginase, bleomycin, methotrexate and procarbazine

have all been implicated." West J Med. 1977 October; 127(4): 292-298

"Drug-related interstitial pneumonia should also be considered in rheumatoid arthritis patients on methotrexate or newer drugs such as leflunomide." Curr Opin Pulm Med. 2006 Sep;12(5):346-53

[Q: 3322] OnExamination 2012 - Rheumatology

A 33-year-old female presents with pain at the elbow which she has been aware of for the last two weeks.

Which of the following would be consistent with a diagnosis of tennis elbow?

- 1- Pain on extension of the elbow
- 2- Pain on flexion of the fingers against resistance
- 3- Pain on pressure over the medial epicondyle
- 4- Pain on pronation of the forearm
- 5- Pain on wrist extension against resistance

Answer & Comments

Answer: 5- Pain on wrist extension against resistance

Tennis elbow is due to lateral epicondylitis and is due to overuse/strain of the extensor muscles of the forearm. It is most common in the fourth decade.

On examination there is pain in the region of the lateral epicondyle during resisted extension of the fingers and wrist.

Management is initially with a reduction in strenuous activity for at least six weeks, with or without a wrist splint.

Local injection with corticosteroid and anaesthetic agents is also a possibility. Surgical treatment is reserved for those with refractory symptoms.

[Q: 3323] OnExamination 2012 - Rheumatology

A 34-year-old nulliparous woman attends clinic because she wants to start a family as soon as possible. She is currently receiving weekly methotrexate for rheumatoid arthritis, but her rheumatologist has suggested that she would be able to stop taking it soon.

Assuming that there are no other contraindications to her becoming pregnant, how long should she wait before stopping the oral contraceptive pill (OCP) and trying to conceive in relation to her discontinuing methotrexate treatment?

- 1- She can stop the OCP at the same time as she stops methotrexate
- 2- She should continue the OCP for at least two weeks after stopping methotrexate.
- 3- She should continue the OCP for at least one month after stopping methotrexate
- 4- She should continue the OCP for at least three months after stopping methotrexate
- 5- She should continue the OCP for at least one year after stopping methotrexate

Answer & Comments

Answer: 4- She should continue the OCP for at least three months after stopping methotrexate

Methotrexate is teratogenic and, according to the British National Formulary (BNF), the manufacturers advise effective contraception during and for at least three months after stopping methotrexate (both males and females).

Fertility may be reduced during treatment, but this usually reverses upon stopping.

The National Patient Safety Agency (NPSA) state on their patient held record that 'It is recommended that you wait six months after

finishing your treatment, before trying to become pregnant'.

[Q: 3324] OnExamination 2012 - Rheumatology

A 16-year-old girl developed pulmonary haemorrhage and acute renal failure requiring dialysis.

She has a history of recurrent epistaxis.

Investigations revealed:

Renal biopsy Crescentic glomerulonephritis

Which one of the following antibodies is most likely to be found in the blood?

- 1- Anticardiolipin
- 2- Anticentromere
- 3- Antimitochondrial
- 4- Antimyeloperoxidase
- 5- Antinuclear

Answer & Comments

Answer: 4- Antimyeloperoxidase

This patient manifests a pulmonary renal syndrome which is most commonly due to an antineutrophil cytoplasmic antibody test (ANCA) positive vasculitis and less commonly due to Goodpasture's syndrome (antiglomerular basement membrane [GBM] antibodies). The history of epistaxis makes Wegener's granulomatosis the more likely diagnosis.

ANCA antibodies are of two types:

cANCA which correlates with antiproteinase 3 antibodies (PR3)cANCA and specificity for the PR3 antigen is most specific for Wegener's granulomatosis. Proteinase-3 is a neutral serine proteinase present in azurophil granules of human neutrophils. Antibodies against it may be present in isolation without a cANCA. In Wegener's, the level of PR3 antibody and ANCA titre are related to

disease activity and the antibodies typically disappear when the disease is in remission.

pANCA and/or antibody to MPO are far less specific than cANCA and can be present in a range of inflammatory conditions such as microscopic polyangiitis, Churg-Strauss syndrome and Goodpasture's syndrome. MPO and pANCA may also be present in systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjogren syndrome and occasionally in chronic infections. They are positive in 10% of patients with Wegener's granulomatosis and are the most likely antibody to be present in this case, where proteinase-3 is not an option.

Wegener's granulomatosis is a multi-organ autoimmune disease which can be fatal.

The classical triad consists of

Necrotising granulomatous inflammation of the respiratory tract

Glomerulonephritis and

A small-vessel vasculitis.

A prolonged history of epistaxis or sinusitis is commonly found in Wegener's granulomatosis, which in some patients is also associated with an eosinophilia. The detection of antineutrophil cytoplasmic antibodies directed against proteinase-3 is highly specific, but is found in only 50% of patients with disease localised to the respiratory tract and 95% with generalised Wegener's.

Standard therapy is with cyclophosphamide and corticosteroids. TNF-alpha blocking agents, antithymocyte globulin and monoclonal anti-T cell antibodies can be used in disease refractory to these agents.

Systemic inflammation and vasculitis contribute to accelerated atherosclerosis in patients with Wegener's and there is therefore a significantly increased incidence

of stroke, myocardial infarction and occlusive artery disease.

Antimitochondrial antibodies are found in primary biliary cirrhosis.

Anticentromere antibodies are found in CREST/scleroderma syndrome.

Aniinuclear (ANA) and anticardiolipin antibodies are found in systemic lupus erythematosus (SLE) which is not a cause of pulmonary renal syndrome.

[Q: 3325] OnExamination 2012 - Rheumatology

A 34-year-old man with psoriasis has a three week history of painful swollen right knee and difficulty walking. He has early morning stiffness of over an hour.

He drinks six units of alcohol/week and has not had any recent infections.

On examination there is a right knee effusion, and swollen and tender distal interphalangeal joints in right hand index and middle finger.

Here are the results of recent blood tests:

Haemoglobin 14 g/dl(13.0 - 18.0 g/dL)

WBC $9 \times 10^9/L$ ($4 - 11 \times 10^9/L$)

Neutrophils $6 \times 10^9/L$ ($1.5 - 7 \times 10^9/L$)

ESR 45 mm/hr(0 - 15 mm/1st hr)

Urea, electrolytes and creatinine: Normal

Rheumatoid factor: Negative

What is the most likely diagnosis?

- 1- Gout
- 2- Osteoarthritis
- 3- Psoriatic arthritis
- 4- Reactive arthritis (RA)
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 3- Psoriatic arthritis

This patient has psoriatic arthritis.

Among people who develop psoriatic arthritis, two-thirds develop joint symptoms after skin involvement. In the absence of psoriasis, a positive family history of psoriasis in a first degree relative supports the diagnosis of psoriatic arthritis.

RA is unlikely as there is asymmetrical joint involvement - with predominant involvement of the distal interphalangeal (DIP) joints in the hands. DIP joint involvement is a distinctive feature of psoriatic arthritis. DIP joint involvement associates with dactylitis, nail pitting and onycholysis (separation of nail from nail bed).

The absence of preceding infection makes reactive arthritis unlikely.

Gout is unlikely.

The alcohol intake is not excessive, and except for male gender, there is no other risk factor, for example, age greater than 40 years, diuretic use, renal failure and solid organ transplant.

[Q: 3326] OnExamination 2012 - Rheumatology

A 28-year-old woman without any past medical history presents with a three month history of arthralgia. She has no past medical history of note.

Examination reveals swelling of the distal interphalangeal joints of the middle and ring fingers of the hand and wrist on the right plus a swollen left ankle.

Investigations show:

ESR 40 mm/hr (0-10)

Which of the following is the most likely diagnosis?

- 1- Acute exacerbation of osteoarthritis
- 2- Psoriatic arthropathy
- 3- Reactive arthritis

- 4- Rheumatoid arthritis
5- Systemic lupus erythematosus

Answer & Comments

Answer: 2- Psoriatic arthropathy

This woman has psoriatic arthritis. Synovitis is indicative of an inflammatory arthritis. The rash typically predates the arthropathy by a number of years, but the opposite can be true. Small plaques should be looked for on the elbows and scalp. There are five patterns of disease:

- Symmetrical polyarthritis ('rheumatoid pattern') - affects wrists, hands, feet and ankles. The distal interphalangeal joints are more commonly affected than the metacarpophalangeal joints, which helps to distinguish it from rheumatoid arthritis.
- Asymmetrical oligoarticular arthritis: dactylitis.
- Distal interphalangeal joint disease: typically in men.
- Arthritis mutilans: rare.
- Spondylitis pattern with sacroileitis.

Rheumatoid arthritis typically affects the metacarpophalangeal and proximal interphalangeal joints symmetrically. Psoriatic arthritis affects the distal interphalangeal joints and tends to be asymmetrical.

Joint involvement in systemic lupus erythematosus occurs in the form of a polyarticular arthralgia, frequently symmetrical and episodic. Intense tendonitis is more common than synovitis and can lead to deforming reversible subluxation of joints without erosive disease (Jaccoud's arthropathy).

Osteoarthritis would be unusual in someone of this age group.

Reactive arthritis is a sterile inflammatory arthritis which develops as a sequel to

remote infection, usually of the gastrointestinal or urogenital tract. There is no history of such infection in this case.

[Q: 3327] OnExamination 2012 - Rheumatology

A 25-year-old student presents to the casualty department with a systemic illness.

She appears unwell, with a swinging fever, 3 kg weight loss over two months, generalised myalgia, polyarthralgia affecting wrists, knees, ankles, elbows and metacarpophalangeal joints, and a sore throat.

Investigations demonstrate normochromic normocytic anaemia 9.8 g/l, ESR 81 mm in the first hour, CRP 31 g/l, serum ferritin 1756 mg/dl, RF negative, ANA negative, ENA negative, ASO titre <200 IU.

What is the most likely diagnosis?

- 1- Adult onset Still's disease (AOSD)
- 2- Polymyositis
- 3- Rheumatic fever
- 4- Seronegative rheumatoid arthritis
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 1- Adult onset Still's disease (AOSD)

The most likely diagnosis in this case is adult onset Still's disease. This is a rare systemic inflammatory disease characterised by high spiking fever, evanescent salmon pink rash, polyarthralgia, lymphadenopathy, hepatosplenomegaly and neutrophilic leucocytosis. There is often an accompanying sore throat and myalgia.

The fever occurs once or twice daily and is described as quotidian or dquotidian returning to 37°C or below between episodes.

The characteristic evanescent salmon-coloured non-pruritic macular or macular-

popular rash occurs in approximately 90% of patients and is often seen only when the patient is febrile and is easily missed.

Aetiology is not clearly understood, but it is likely triggered by an infectious agent in a genetically predisposed host.

Diagnosis is clinical, and should include exclusion of infectious disease, neoplasms and other autoimmune disease. Laboratory tests reflect systemic inflammation, with a high ESR, leucocytosis and raised acute phase reactants (in particular ferritin). Rheumatoid factor and antinuclear antibody are typically negative. Liver function tests can be abnormal. High serum ferritin, with low glycosylated fraction, are characteristic and can be used as disease activity markers. Interleukin (IL)-1, IL-6, IL-18, macrophage colony stimulating factor, interferon gamma and TNF-alpha are all elevated.

The clinical course can be divided into:

Self-limited or monophasic intermittent

Polycyclic systemic

Chronic articular pattern.

Prognosis tends to be better when systemic symptoms predominate.

Therapy includes non-steroidal anti-inflammatory drugs (NSAIDs), corticosteroids, disease-modifying anti-rheumatic drugs and biological agents. Intravenous immunoglobulin may have a role.

Polymyositis is an inflammatory condition which typically presents with relatively painless, progressive, proximal muscle weakness.

Rheumatic fever develops in relation to group A streptococcal infection. It presents with chorea, carditis, subcutaneous nodules, erythema marginatum and migratory polyarthritides.

Systemic upset to the extent described in the above case is unusual with rheumatoid arthritis. One would expect ANA to be positive in systemic lupus erythematosus.

[Q: 3328] OnExamination 2012 - Rheumatology

A 60-year-old man presents with right foot drop, left foot and left hand numbness, fever, malaise, weight loss, polymyalgia and polyarthralgia of approximately one month duration.

On examination, he appears ill, with a temperature of 38.5°C and blood pressure of 180/100 mmHg.

Investigations reveal:

Haemoglobin 8.0 g/dL (13.0-18.0)

Erythrocyte sedimentation rate 100 mm/hr (0-20)

Serum Creatinine 180 µmol/L (60-110)

Urine analysis: Blood ++

Urine microscopy: White cells and red cell casts

Which one of the following is the most likely diagnosis?

- 1- Antiphospholipid syndrome
- 2- Giant cell arteritis
- 3- Paraneoplastic syndrome
- 4- POEMS syndrome
- 5- Polyarteritis nodosa (PAN)

Answer & Comments

Answer: 5- Polyarteritis nodosa (PAN)

This patient has a mononeuritis multiplex, fever, hypertension, and nephritic renal involvement which is most consistent with a diagnosis of polyarteritis nodosa.

PAN is a systemic transmural necrotising vasculitis that usually affects medium-sized arteries. Signs and symptoms are primarily

attributable to diffuse vascular inflammation and ischaemia of the affected organs. In adults it most commonly presents in men between 40-50y, and may be associated with hepatitis B. Virtually any organ with the exception of the lung can be affected, with peripheral neuropathy and symptoms from osteoarticular, renal artery and gastrointestinal tract involvement being the most frequent clinical manifestations.

The diagnostic criteria used are based on the American College of Rheumatology (ACR) and Chapel Hill Consensus criteria:

- Symptoms/signs must be compatible with a diagnosis of ANCA-associated vasculitis or PAN
- Plus one of:
 - o Histological proof of vasculitis and/or granuloma formation
 - o Positive ANCA serology
 - o Specific investigations strongly suggestive of vasculitis and/or granuloma
 - o Eosinophilia (>10%)
- No other potential diagnosis to explain the signs and symptoms:
 - o Malignancy
 - o Infection (HBV, HCV, HIV, TB, subacute bacterial endocarditis)
 - o Drugs (hydralazine, propylthiouracil, cocaine, allopurinol)
 - o Secondary vasculitis (resulting from rheumatoid arthritis, SLE, Sjogren's)
 - o Sarcoidosis or other vasculitic conditions
 - o Vasculitis mimicking diseases (e.g. cholesterol emboli, antiphospholipid)

Hepatitis B surface antigen is positive in 30%, and p-ANCA is usually positive. Angiography demonstrates microaneurysms in affected

organs, and biopsy shows necrotising inflammation.

PAN can be further classified into systemic vs limited (cutaneous) and idiopathic vs hepatitis B, and this is important due to differences in pathogenesis and therefore treatment and prognosis.

The mainstay of treatment for idiopathic PAN is currently corticosteroids and cyclophosphamide, whereas for hepatitis B related disease plasmapheresis and antiviral agents should be used. Azathioprine can be used as maintenance therapy, and typically has fewer side effects than cyclophosphamide.

Antiphospholipid syndrome is a thrombotic disorder that manifests clinically as recurrent venous or arterial thrombosis and/or foetal loss. It is not usually associated with a polyneuropathy.

POEMS is a rare systemic disorder which consists of polyneuropathy, organomegaly, endocrinopathy monoclonal gammopathy and skin changes, of which a few features are absent; and nephritic syndrome is not a feature.

Giant cell arteritis affects large and medium sized arteries, most commonly branches of the external carotid artery. It typically presents with unilateral headache and threatened sight, which does not fit with the clinical scenario above.

Vasculitis can be a paraneoplastic syndrome, but this is rare and you would expect symptoms from the primary tumour. In a recent case series it most commonly presented with features of a cutaneous vasculitis.

[Q: 3329] OnExamination 2012 - Rheumatology

A 25-year-old female is admitted with acute dyspnoea and chest pain.

A diagnosis of pulmonary embolism is confirmed and her investigations reveal urine dipstick protein ++ but no blood, anti-double stranded DNA antibodies of 200 U/mL (0 - 73), with a 24 hour urinary protein concentration of 5g (< 0.2).

Which one of the following diagnoses is most likely to be found on renal biopsy?

- 1- AA amyloid
- 2- Focal segmental glomerulosclerosis
- 3- IgA nephropathy
- 4- Membranous nephropathy
- 5- Minimal change nephropathy

Answer & Comments

Answer: 4- Membranous nephropathy

This young woman has thromboembolic disease, nephrotic syndrome and positive anti-ds DNA antibodies, all of which suggests a diagnosis of systemic lupus erythematosus.

The renal manifestations of SLE are highly variable, ranging from mild asymptomatic proteinuria and/or haematuria to rapidly progressive uraemia. The various presentations are difficult to classify into clinical syndromes and histological classes. Although lupus nephritis affects a third of patients early in the disease it is frequently unrecognised until nephritic and/or nephrotic syndrome with renal failure occur.

Histologically, a number of different types of renal disease are recognised in SLE, with immune-complex mediated glomerular disease being the most common. The standard classification divides these into five different patterns:

- I - no disease
- II - mesangial
- III - focal proliferative
- IV - diffuse proliferative

V - membranous

Mesangial nephritis represents the earliest and mildest form of glomerular involvement. It presents clinically as microscopic haematuria and/or proteinuria. Hypertension is uncommon and nephrotic syndrome and renal impairment are very rarely seen. Biopsy demonstrates segmental areas of increased mesangial matrix and cellularity. The prognosis is good and specific treatment is only indicated if the disease progresses.

Focal proliferative disease is more advanced, but still affects less than 50% of glomeruli. Haematuria and proteinuria is almost always seen, and nephrotic syndrome, hypertension and elevated creatinine may be present. Electron microscopy shows immune deposits in the subendothelial space of the glomerular capillary wall and the mesangium. Prognosis is variable.

Focal proliferative glomerulonephritis is the most common and severe form of lupus nephritis. Haematuria and proteinuria are almost always present, and nephrotic syndrome, hypertension and renal impairment common. Biopsies demonstrate profuse deposits of IgG within the glomeruli. Immunosuppressive therapy is required in these cases to prevent progressive to end-stage renal failure.

Patients with membranous lupus nephritis tend to present with nephrotic syndrome. Microscopic haematuria and hypertension may also be seen. Biopsies show diffuse thickening of the glomerular capillary wall. Progression is variable, and immunosuppression is not always needed.

With regard to the management of lupus nephritis a biopsy is indicated in those patients with abnormal urinalysis and/or reduced renal function. This can provide a histological classification as well as information regarding activity, chronicity and prognosis. Cyclophosphamide,

mycophenolate mofetil and azathioprine reduce mortality in proliferative forms of lupus glomerulonephritis.

IgA nephropathy is a form of glomerulonephritis characterised by the deposition of IgA in the glomeruli. It is a very rare lesion in SLE.

AA amyloidosis is a systemic disorder characterised by extracellular tissue deposition of fibrils that are composed of amyloid A protein (an acute-phase protein produced by hepatocytes). It occurs in the course of chronic inflammatory disease, but an association with SLE is very unusual.

Focal segmental glomerulosclerosis is one of the most common glomerular diseases to result in end stage renal failure. It may occur as a primary condition, or in association with a number of vasculitic disorders (rarely SLE).

Minimal change nephropathy is classically a diagnosis of childhood. There is diffuse loss of podocyte foot processes, which results in nephrotic syndrome but not usually the other features described above.

[Q: 3330] OnExamination 2012 - Rheumatology

A 43-year-old female presented with a week's history of pain and stiffness in her shoulders and wrists which was worse in the mornings.

On examination, there was synovitis of both wrists. There was no proximal muscle tenderness or weakness. Her erythrocyte sedimentation rate (ESR) was 50 mm/hr (0 - 20).

What is the most likely diagnosis?

- 1- Polymyalgia rheumatica (PMR)
- 2- Polymyositis
- 3- Reactive arthritis
- 4- Rheumatoid arthritis
- 5- Systemic lupus erythematosus

Answer & Comments

Answer: 4- Rheumatoid arthritis

This is a slightly difficult question, but you may experience similar during the exam. It tests your ability to consider epidemiology as well as your knowledge of disease presentations.

In this middle aged female, the acute bilateral arthritis of shoulders and wrists together with synovitis and raised ESR are highly suggestive of acute rheumatoid arthritis. The features given do not fully satisfy the ACR criteria (see the reference for updated guidelines), but it is not unusual for this to be the case in clinical practice.

Weakness and myalgia would be expected with polymyositis and a rash would be expected with systemic lupus erythematosus with less evidence of a synovitis.

There is no prior precipitant to suggest a reactive arthritis, although it is important to consider this diagnosis in young patients.

PMR would be less likely in this age group as it usually occurs in patients over 50 years of age

Proximal weakness in the morning with the gel phenomenon would be expected, and synovitis in the wrists would be less likely in PMR.

Reference:

2010 Rheumatoid Arthritis Classification Criteria. Aletaha D et al. *Arthritis & Rheumatism*. 2010 Sept;62(9):2569-2581

[Q: 3331] OnExamination 2012 - Rheumatology

A man in his 20s begins to note persistent lower back pain and stiffness that diminishes with activity.

In his 30s he also develops hip and shoulder arthritis and in his 40s he is bothered by decreased lumbar spine mobility.

He has no other major medical problems.

For which of the following are these findings most typical?

- 1- Ankylosing spondylitis
- 2- Calcium pyrophosphate dihydrate deposition disease
- 3- Lyme disease
- 4- Osteoarthritis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 1- Ankylosing spondylitis

The combination of lower back pain, stiffness and reduced spinal mobility makes ankylosing spondylitis the most likely diagnosis here.

Ankylosing spondylitis (AS) is a chronic, potentially disabling, form of seronegative spondyloarthropathy which primarily involves the axial skeleton. The aetiology is not clearly understood, but it involves the interaction of genetic and environmental factors. The pathology mainly affects the entheses, where ligaments, tendons and capsules are attached to the bone.

Current British Society for Rheumatology recommendations state that the modified New York criteria should be used to diagnose ankylosing spondylitis:

Clinical criteria

Low back pain, present for more than three months, improved by exercise but not relieved by rest

Limitation of lumbar spine motion in both the sagittal and frontal planes

Limitation of chest expansion relative to normal values for age and sex.

Radiological criteria

Sacroiliitis on x-ray.

Diagnosis

Definite AS if the radiological criterion is present plus at least one clinical criterion

Probable AS if three clinical criteria are present alone or if the radiological criterion is present but no clinical criteria are present.

It is widely accepted that making the diagnosis early is difficult because the onset is insidious, and there is no definitive diagnostic test. One study has stated that the average time from onset to diagnosis ranges from 3-11 years. Timely diagnosis therefore requires a high index of suspicion.

HLA-B27 is found in 90% patients with AS but also in 8% of the general population and therefore should not be relied upon in making a diagnosis.

MRI can visualise sacroiliitis in patients with typical symptoms of AS but normal radiographs, and it is evolving as the most important diagnostic imaging tool in early disease. However, as yet a diagnosis of ankylosing spondylitis cannot be made on MRI findings alone and these cases are currently termed non-radiographic axial spondyloarthritis (SpA).

Both HLA-B27 and sacroiliitis on MRI play a major role in the recently proposed Assessment of Spondylo-Arthritis International Society (ASAS) diagnostic algorithm. This may replace the modified New York criteria in the future.

An x ray of the lumbar spine may show bridging syndesmophytes between the vertebral bodies in keeping with ankylosing spondylitis but this is not part of the diagnostic criteria, and it is a late sign.

Radiographic sacroiliitis is a requirement for patients to be eligible for anti-TNF treatment for AS. The sacroiliitis is usually bilateral and symmetrical. It progresses from blurring of the subchondral bone plate to irregular erosions of the margins of the sacroiliac joints to sclerosis, narrowing, and finally fusion.

Erosions of the sacroiliac joint are generally seen earlier in the lower portion due to its synovial lining, and on the iliac side due to the thinner cartilage covering this side of the joint.

Calcium pyrophosphate dihydrate deposition is the pathological basis of pseudogout, which typically presents as acute monoarthritis of the peripheral joints. It is not typically associated with spinal disease, and would be unusual in some one of this age.

Borrelia burgdorferi causes Lyme disease, which classically presents with fever and erythema migrans following a tick bite in an endemic area (for example, the New Forest). Without treatment, it can progress to disseminated disease with a polyarticular arthritis but persistent back pain and stiffness is not usual.

Osteoarthritis can affect the lumbar spine with similar symptoms to those described above, but is very uncommon in patients in their twenties.

Rheumatoid arthritis typically affects the small joints of the hands, and cervical spine involvement is more common than lumbar disease.

[Q: 3332] OnExamination 2012 - Rheumatology

An otherwise healthy middle-aged man with no prior medical history has had increasing back pain and right hip pain for the past 10 years. The pain is worse at the end of the day. He has bony enlargement of the distal interphalangeal joints. A radiograph of the spine reveals the presence of prominent osteophytes involving the vertebral bodies. There is sclerosis with narrowing of the joint space at the right acetabulum seen on a radiograph of the pelvis.

Which of the following pathologic processes is most likely to be taking place in this patient?

- 1- Gout
- 2- Lyme disease
- 3- Osteoarthritis
- 4- Osteomyelitis
- 5- Rheumatoid arthritis

Answer & Comments

Answer: 3- Osteoarthritis

Degenerative osteoarthritis is a common and progressive condition that becomes more frequent and symptomatic with aging. There is erosion and loss of articular cartilage.

Rheumatoid arthritis typically involves small joints of the hands and feet most severely, and there is a destructive pannus that leads to marked joint deformity.

A gouty arthritis is more likely to be accompanied by swelling, and deformity with joint destruction. The pain is not related to usage.

Osteomyelitis represents an ongoing infection that produces marked bone deformity, not just joint narrowing.

Lyme disease produces a chronic arthritis, but it is typically preceded by a deer tick bite with a skin lesion. It is much less common than osteoarthritis.

[Q: 3333] OnExamination 2012 - Rheumatology

Which of the following is a pro-inflammatory cytokine?

- 1- C reactive protein
- 2- IL-4
- 3- IL-10
- 4- Serum amyloid precursor protein
- 5- Tumour necrosis factor - alpha

Answer & Comments

Answer: 5- Tumour necrosis factor - alpha

C reactive protein and serum amyloid precursor protein are acute phase reactants.

IL-4 and IL-10 are anti-inflammatory cytokines.

TNF-alpha is a pro-inflammatory cytokine.

In inflammatory disorders such as rheumatoid arthritis, the levels of TNF-alpha are markedly elevated in inflamed joints.

Treatments directed at the inhibition of TNF-alpha such as infliximab (a monoclonal antibody against TNF-alpha) have been shown to be very effective in the treatment of rheumatoid arthritis and also effective in fistulating Crohn's disease.

[Q: 3334] OnExamination 2012 - Rheumatology

A 16-year-old girl presents with a three month history of polyarthralgia and marked early morning stiffness.

Her symptoms respond well to diclofenac but she is becoming increasingly concerned about her symptoms which appear to be progressing. She is otherwise well apart from a history of acne which is well controlled on minocycline. Her mother has severe rheumatoid arthritis.

Investigations:

ESR 50 mm/hr (0-20)

CRP 100 mg/L (<10)

Rheumatoid factor negative

ANAStrongly positive (1:1600)

Anti-dsDNA antibodies negative

IgG25 g/L (<15)

What is the most likely cause?

1- Drug-induced SLE

2- Fibromyalgia

3- Rheumatoid arthritis

4- Sero-negative spondyloarthropathy

5- Systemic lupus erythematosus (SLE)

Answer & Comments

Answer: 1- Drug-induced SLE

The history strongly suggests an inflammatory problem and the elevated erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) confirm this.

Rheumatoid arthritis and connective tissue disorders such as SLE would be on the differential diagnosis.

The serology is atypical for rheumatoid arthritis and the marked elevation of the CRP would be very unusual for SLE where characteristically CRP elevation indicates underlying bacterial infection or widespread serositis.

The most likely diagnosis is drug-induced SLE.

Minocycline has been well documented as a cause of drug-induced SLE.

Characteristically, the ESR and CRP are both markedly elevated, the antinuclear antibody (ANA) is strongly positive and there is a hypergammaglobulinaemia. Anti-dsDNA antibodies are usually negative.

Symptoms usually improve following withdrawal of the drug but can take several months to resolve.

[Q: 3335] OnExamination 2012 - Rheumatology

Which of the following has the greatest specificity for Wegener's granulomatosis?

1- Atypical ANCA and positive antibodies to myeloperoxidase

2- cANCA and positive antibodies to lactoferrin

- 3- cANCA and positive antibodies to myeloperoxidase
- 4- cANCA and positive antibodies to proteinase 3
- 5- pANCA and positive antibodies to myeloperoxidase

Answer & Comments

Answer: 4- cANCA and positive antibodies to proteinase 3

Antineutrophil cytoplasmic antibodies (ANCA) are detected in two ways:

A. An indirect immunofluorescence assay to identify specific staining patterns. Serum samples are mixed with neutrophils to allow any autoantibodies present to react with the cells.

B. An enzyme linked immunosorbant assay (ELISA) to quantify the antibodies against the two common target antigens (myeloperoxidase and proteinase-3).

Several different staining patterns and antigen specificities are recognised:

Perinuclear (pANCA): fluorescence around the nucleus; 90% of antibodies which show this pattern are against myeloperoxidase (MPO)

Cytoplasmic (cANCA): a coarse, clumpy, granular cytoplasmic staining of neutrophils, which is associated with anti-proteinase-3 (PR3) antibodies in 85% of cases

Atypical pANCA: patterns of neutrophil cytoplasmic and/or perinuclear fluorescence other than the two above, which occurs when neutrophil antigens other than MPO or PR3 are the antibody target. This is seen in most cases of ulcerative colitis, and some patients with Crohn's disease, drug-induced vasculitis and rheumatoid arthritis

Negative ANCA: very little or no fluorescence.

If ANCA is positive, an additional test is performed to determine the titre of antibody

present. A serum sample is diluted in steps and each dilution tested for the presence of the antibody. The greatest dilution at which the antibody can be detected is the titre (for example, 1:64 - serum tests remain positive after being diluted 64-fold).

cANCA and specificity for the PR-3 antigen is most specific for Wegener's granulomatosis. Proteinase-3 is a neutral serine proteinase present in azurophil granules of human neutrophils. Antibodies against it may be present in isolation without a cANCA. In Wegener's, the level of PR3 antibody and ANCA titre are related to disease activity and the antibodies typically disappear when the disease is in remission.

pANCA and/or antibody to MPO are far less specific than cANCA and can be present in a range of inflammatory conditions such as microscopic polyangiitis, Churg-Strauss syndrome and Goodpasture's syndrome. MPO and pANCA may also be present in systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjogren syndrome and occasionally in chronic infections.

ANCA levels can change over time and, as such, can be used to monitor disease activity and/or response to therapy.

Reference:

Prevalence and spectrum of rheumatic diseases associated with proteinase 3-antineutrophil cytoplasmic antibodies (ANCA) and myeloperoxidase-ANCA. Schonermarck et al. Rheumatology (2001) 40 (2): 178-184

[Q: 3336] OnExamination 2012 - Rheumatology

A 23-year-old teacher presents with a three week history of fever, weight loss, and erythematous nodular lesions on the shin. There is no peripheral adenopathy nor abnormal enlargement of an organ (organomegaly).

A chest x ray showed bilateral hilar adenopathy and a CT guided biopsy of the mediastinal lymph nodes was performed. This showed chronic inflammation with multiple non-caseating granulomas.

What is the most likely diagnosis?

- 1- Histoplasmosis
- 2- HIV
- 3- Lymphoma
- 4- Sarcoidosis
- 5- Tuberculosis

Answer & Comments

Answer: 4- Sarcoidosis

The presence of bilateral hilar adenopathy in someone with erythema nodosum-like lesions, fever and weight loss suggests the diagnosis of sarcoidosis.

Sarcoidosis is a multisystem granulomatous disorder that commonly presents with pulmonary involvement. It is diagnosed on the basis of clinical and radiological manifestations, which can be supported by histological demonstration of non-caseating granulomas in biopsy tissue. Bilateral hilar lymphadenopathy is a classical feature demonstrated on chest radiograph.

The aetiology of sarcoidosis is still not fully understood but may include exposure to an environmental antigen in combination with a genetic predisposition.

Traditionally pulmonary involvement is classified in to five stages based on chest radiograph findings:

Stage 0 - normal chest radiograph

Stage 1 - bilateral hilar lymphadenopathy (BHL)

Stage 2 - BHL with pulmonary infiltrates

Stage 3 - parenchymal infiltrates without hilar lymphadenopathy

Stage 4 - pulmonary fibrosis (volume loss) +/- cavitations, calcifications, bullae.

Treatment of sarcoidosis is symptomatic and the mainstay remains oral corticosteroids. These should be continued for 12 months and the dose tapered to stop within two years maximum.

There is insufficient evidence to recommend the use of immunosuppressants routinely.

Methotrexate and azathioprine can be used in refractory cases. Surgical intervention can be considered in severe cases. Cutaneous disease typically responds to oral non-steroidal anti-inflammatory treatment.

Differential diagnosis of bilateral hilar adenopathy includes

Sarcoidosis

Lymphoma

Tuberculosis

Pneumoconiosis

Berylliosis, and

Fungal diseases like histoplasmosis.

Ninety per cent of people infected with histoplasma are asymptomatic. If symptoms are present they typically commence within three to 10 days of exposure, and consist of fever, headache and malaise.

HIV has a variety of clinical manifestations often due to opportunistic infection, but it is not the most likely diagnosis in this case.

Biopsy of lymphoma would be expected to demonstrate malignant cells.

Tuberculosis is an important differential diagnosis, but histology is typically caseating granulomas.

[Q: 3337] OnExamination 2012 - Rheumatology

A 27-year-old British man presents with a two year history of progressively worsening, atraumatic lower back pain and stiffness. The pain radiates to the gluteal region bilaterally and is worse in the evenings. He reports some relief with exercise. Recently, he has also noted intermittent pains in his left shoulder and the heel of his left foot.

Clinical examination demonstrated limited spinal flexion in the sagittal and frontal planes. Left shoulder pain was reproducible with resisted abduction; there was a diminished left calf squeeze test with a tender and swollen left Achilles tendon.

Given the probable diagnosis, which of the following is likely to be positive?

- 1- Anti-CCP antibody
- 2- HLA B*2705
- 3- HLA B*2706
- 4- Gonorrhoea antigen
- 5- None of the above

Answer & Comments

Answer: 2- HLA B*2705

Learning points:

Distinguishing features of chronic inflammatory back pain

Population specific HLA association

Common differentials for ankylosing spondylitis.

This man has ankylosing spondylitis (AS).

The commonest subtype HLA associations are HLA B*2705 (Caucasians), B*2704 (Chinese, Japanese) and B*2702 (Mediterranean). The B*2706 subtype is weakly associated and commonly found in normal south east Asian individuals.

Chronic (more than three months) back pain characteristics that favour a spondyloarthritic aetiology include;

Age of onset before 40 years

Insidious onset

Amelioration with exercise

Refractory with rest

Night pain (with improvement upon arising).

His associated extra-articular manifestations include enthesitis of the Achilles and supraspinatus tendons.

[Q: 3338] OnExamination 2012 - Rheumatology

A 62-year-old lady is suffering from pain and stiffness of her shoulders and difficulty getting out of a chair.

Which of the following would support a diagnosis of polymyalgia rheumatica?

- 1- Ankle stiffness
- 2- Low grade fever
- 3- Muscle tenderness
- 4- Proximal muscle weakness
- 5- Weight gain

Answer & Comments

Answer: 2- Low grade fever

Polymyalgia rheumatica is an inflammatory disease which typically presents with pain and stiffness of the the shoulder and pelvic girdle muscles. It can have either an acute or subacute onset and is associated with a systemic inflammatory response and therefore constitutional symptoms such as fever, anorexia, weight loss and malaise.

The course of the disease is unpredictable, and 30% of patients also have giant cell arteritis. The cause is unknown, although

studies showing a cyclical incidence have led to theories regarding an infectious trigger.

Diagnosis of PMR can prove difficult, and other inflammatory conditions should be excluded. Patients are usually over 60 years, and PMR is very rarely seen in the under 50s. Muscle weakness is not a feature of PMR, but this can be difficult to assess in the presence of pain. Due to chronic inflammation, low grade fever and weight loss are often present. Weight gain is unusual, and peripheral joints are only rarely affected.

Investigations typically reveal:

Normochromic / normocytic anaemia

Raised erythrocyte sedimentation rate (ESR) often > 50 mm/hr (although this may be normal)

Raised C reactive protein (CRP).

Features of giant cell arteritis should be sought:

Headache

Visual disturbance

Transient ischaemic attacks (TIAs)

Jaw claudication and

Thickened and tender, temporal arteries.

Response to a moderate dose of steroids can be useful in confirming the diagnosis of PMR. The maximum dose of prednisolone should not exceed 20 mg once daily. Patients should report 70% improvement in symptoms within three to four weeks, and inflammatory markers should have normalised by this point.

In general, non-steroidal anti-inflammatories have little use and are associated with significant morbidity. There is little evidence for the use of steroid-sparing agents.

[Q: 3339] OnExamination 2012 - Rheumatology

A 36-year-old alcoholic has an endoscopy some 16 hours after his admission with a variceal haemorrhage. This is his second admission in six months with an upper GI bleed and he has required a 4 unit blood transfusion.

Endoscopy reveals a number of large varices, including one with adherent clot.

Which of the following is the therapy with the best evidence with respect to reducing the risk of a variceal bleed over the next few months?

- 1- High dose omeprazole
- 2- Propanolol
- 3- Sclerotherapy
- 4- Variceal banding
- 5- Vasopressin

Answer & Comments

Answer: 4- Variceal banding

The answer is option D, variceal banding.

Banding is proven to eliminate varices with fewer procedures and complications than injection sclerotherapy.

A recent trial has demonstrated that beta blockade and sclerotherapy are better than beta blockade alone in prophylaxis against bleeding.

The vasopressin analogue, terlipressin, is used to control bleeding acutely, along with somatostatin analogues.

[Q: 3340] OnExamination 2012 - Rheumatology

A 34-year-old skier comes to the Emergency department with pain and swelling over the first metacarpophalangeal joint (MCP joint) after a fall whilst practising on the dry ski slope.

On examination there is extensive swelling and bruising over the ulnar aspect of the joint.

What is he most likely to have injured?

- 1- Accessory collateral ligament
- 2- Proximal phalanx
- 3- Radial collateral ligament
- 4- Scaphoid bone
- 5- Ulnar collateral ligament

Answer & Comments

Answer: 5- Ulnar collateral ligament

The answer is option E, ulnar collateral ligament.

Skier's thumb was formerly known as gamekeeper's thumb, and it relates to injury to the base of the thumb, resulting in damage/rupture of the ulnar collateral ligament. Once acute swelling has subsided then gross instability of the thumb may result.

Where a complete tear of the ligament is suspected MRI may be valuable in confirming the diagnosis as surgical repair is required.

In cases of a partial rupture immobilisation in a thumb spica is the standard therapy.

[Q: 3341] OnExamination 2012 - Rheumatology

A 24-year-old woman who is known to suffer from mitral valve prolapse comes to the emergency department complaining of sudden, terrible, tearing pain between her shoulder blades. She notes that her mother died suddenly when she was aged 38.

On examination her BP is 166/94 mmHg, her pulse is 95 and regular. Her chest is clear. Her skin seems rather thin and pale white, you can see extensive bruising over her shins, and her blood vessels are easily visible as you look at her arms.

She has a number of keloid scars, which appear to have occurred after relatively minor skin injuries. She is given oxygen and diamorphine for pain relief.

Investigations show

Haemoglobin 12.0 g/dl(11.5-16.5)

White cells $6.8 \times 10^9/L$ (4-11)

Platelets $180 \times 10^9/L$ (150-400)

Sodium 140 mmol/l (135-146)

Potassium 4.2 mmol/l (3.5-5)

Creatinine 90 $\mu\text{mol/l}$ (79-118)

AP chest x ray Mediastinum width 9.5 cm

ECG 3 mm inferior ST elevation

Which of the following is the most appropriate initial therapy?

- 1- Alteplase
- 2- Angioplasty
- 3- Heparin and IV nitrate
- 4- IV beta-blockade
- 5- Streptokinase

Answer & Comments

Answer: 4- IV beta-blockade

The history is highly suspicious of aortic dissection, with involvement of the right coronary artery suggesting a type A dissection.

This patient needs beta-blockade to reduce her BP and myocardial oxygen demand and investigation to confirm the diagnosis. Most emergency departments have rapid access to CT pulmonary angiogram and this is the investigation of choice.

Regarding type A dissection, progression to surgery is inevitable.

The underlying clinical features are suggestive of Ehlers-Danlos syndrome which puts her at high risk of vascular rupture/dissections.

[Q: 3342] OnExamination 2012 - Rheumatology

A previously fit 47-year-old man presents with lower back pain which is shown to be a consequence of vertebral collapse due to osteoporosis.

Which of the following would be the most appropriate investigation for this patient?

- 1- Oestrogen concentration
- 2- Prolactin concentration
- 3- Prostate-specific antigen concentration
- 4- Testosterone concentration
- 5- Thyroid function tests

Answer & Comments

Answer: 4- Testosterone concentration

Osteoporosis in a young man would be unusual.

Any symptoms or features of hypogonadism or hypercalcaemia should be elicited. Hyperprolactinaemia causes hypogonadism so a testosterone concentration would be far more relevant.

Hyperthyroidism would need to be present for a considerable length of time before producing osteoporosis.

Hypogonadism often goes unnoticed.

Prostate malignancy does not cause osteoporosis.

[Q: 3343] OnExamination 2012 - Rheumatology

A 23-year-old student presents with a four month history of low back pain and buttock pain worse in the morning. This improves with activity and with over the counter ibuprofen.

There is no significant past or family history.

On examination there is restricted chest wall expansion (3 cm) and the Schober's test is

positive. Lumbar spine and pelvic radiographs are normal. Blood tests show a normal FBC, UEC and liver function tests. The CRP is 13 mg/L and the ESR is 32 mm/hr.

Which of the following is the most appropriate investigation for this patient?

- 1- 99m-Tc bone scan
- 2- HLA B-27
- 3- MRI lumbar spine
- 4- MRI sacroiliac joints
- 5- PET-CT

Answer & Comments

Answer: 4- MRI sacroiliac joints

Based on the presence of back pain, raised inflammatory markers and reduced spinal mobility, this patient has ankylosing spondylitis (AS).

Ankylosing spondylitis (AS) is a chronic, potentially disabling, form of seronegative spondyloarthropathy which primarily involves the axial skeleton. The aetiology is not clearly understood, but it involves the interaction of genetic and environmental factors. The pathology mainly affects the entheses, where ligaments, tendons and capsules are attached to the bone.

Current British Society for Rheumatology recommendations state that the modified New York criteria should be used to diagnose ankylosing spondylitis:

Clinical criteria

Low back pain, present for more than three months, improved by exercise but not relieved by rest

Limitation of lumbar spine motion in both the sagittal and frontal planes

Limitation of chest expansion relative to normal values for age and sex

Radiological criteria

Sacroiliitis on x ray

Diagnose

Definite AS if the radiological criterion is present plus at least one clinical criterion

Probable AS if three clinical criteria are present alone or if the radiological criterion is present but no clinical criteria are present.

It is widely accepted that making the diagnosis early is difficult because the onset is insidious, and there is no definitive diagnostic test. One study has stated that the average time from onset to diagnosis ranges from three to 11 years. Timely diagnosis therefore requires a high index of suspicion.

HLA-B27 is found in 90% patients with AS but also 8% of the general population and therefore should not be relied upon in making a diagnosis.

MRI can visualise sacroiliitis in patients with typical symptoms of AS but normal radiographs, and it is evolving as the most important diagnostic imaging tool in early disease. However, as yet a diagnosis of ankylosing spondylitis cannot be made on MRI findings alone and these cases are currently termed non-radiographic axial spondyloarthritis (SpA).

Both HLA-B27 and sacroiliitis on MRI play a major role in the recently proposed Assessment of SpondyloArthritis International Society (ASAS) diagnostic algorithm. This may replace the modified New York criteria in the future.

An x ray of the lumbar spine may show bridging syndesmophytes between the vertebral bodies in keeping with ankylosing spondylitis but this is not part of the diagnostic criteria, and it is a late sign.

Radiographic sacroiliitis is a requirement for patients to be eligible for anti-TNF treatment for AS.

The sacroiliitis is usually bilateral and symmetrical. It progresses from blurring of the subchondral bone plate to irregular erosions of the margins of the sacroiliac joints to sclerosis, narrowing, and finally fusion.

Erosions of the sacroiliac joint are generally seen earlier in the lower portion due to its synovial lining, and on the iliac side due to the thinner cartilage covering this side of the joint.

As x ray is not available as an option here, MRI of the sacroiliac joints is the most appropriate answer.

PET-CT and bone scans do not have a role in the diagnosis and investigation of ankylosing spondylitis.

[Q: 3344] OnExamination 2012 - Rheumatology

A 25-year-old lady with SLE (anti-nuclear antibody positive [1:6400], anti-dsDNA antibody positive) presents with a few weeks' history of feeling generally unwell, tired, worsening malar rash, and has mild pedal oedema.

On examination, the BP is 190/100 mm Hg, and there are 3+ proteins, 3+ blood in her urine.

What is the diagnosis?

- 1- Diffuse proliferative glomerulonephritis
- 2- Membranous glomerulonephritis
- 3- Mesangial glomerulonephritis
- 4- Minimal change glomerulonephritis
- 5- Nephrotic syndrome

Answer & Comments

Answer: 1- Diffuse proliferative glomerulonephritis

Hypertension, pedal oedema, nephritic urinary sediments (blood and protein positive) in a patient with systemic lupus

erythematosus (SLE) suggests the diagnosis of class IV (diffuse proliferative glomerulonephritis) or class III (focal segmental glomerulonephritis) lupus nephritis. ds-DNA antibodies increase the risk of lupus nephritis.

Mesangial glomerulonephritis presents with mild proteinuria.

Minimal change, or membranous glomerulonephritis present with proteinuria, which may be in the nephrotic range.

The renal manifestations of SLE are highly variable, ranging from mild asymptomatic proteinuria and/or haematuria to rapidly progressive uraemia. The various presentations are difficult to classify into clinical syndromes and histological classes. Although lupus nephritis affects a third of patients early in the disease it is frequently unrecognised until nephritic and/or nephrotic syndrome with renal failure occur.

Histologically, a number of different types of renal disease are recognised in SLE, with immune-complex mediated glomerular disease being the most common.

The standard classification divides these into five different patterns:

I - No disease

II - Mesangial

III - Focal proliferative

IV - Diffuse proliferative

V - Membranous.

Mesangial nephritis represents the earliest and mildest form of glomerular involvement. It presents clinically as microscopic haematuria and/or proteinuria. Hypertension is uncommon and nephrotic syndrome and renal impairment are very rarely seen. Biopsy demonstrates segmental areas of increased mesangial matrix and cellularity. The

prognosis is good and specific treatment is indicated only if the disease progresses.

Focal proliferative disease is more advanced, but still affects less than 50% of glomeruli. Haematuria and proteinuria is almost always seen, and nephrotic syndrome, hypertension and elevated creatinine may be present. Electron microscopy shows immune deposits in the subendothelial space of the glomerular capillary wall and the mesangium. Prognosis is variable.

Diffuse proliferative glomerulonephritis is the most common and severe form of lupus nephritis. Haematuria and proteinuria are almost always present, and nephrotic syndrome, hypertension and renal impairment common. Biopsies demonstrate profuse deposits of IgG within the glomeruli. Immunosuppressive therapy is required in these cases to prevent progression to end-stage renal failure.

Patients with membranous lupus nephritis tend to present with nephrotic syndrome. Microscopic haematuria and hypertension may also be seen. Biopsies show diffuse thickening of the glomerular capillary wall. Progression is variable, and immunosuppression is not always needed.

With regard to the management of lupus nephritis a biopsy is indicated in those patients with abnormal urinalysis and/or reduced renal function. This can provide a histological classification as well as information regarding activity, chronicity and prognosis.

Cyclophosphamide, mycophenolate mofetil and azathioprine reduce mortality in proliferative forms of lupus glomerulonephritis.

[Q: 3345] OnExamination 2012 - Rheumatology

A 25-year-old woman with Sjogren's syndrome (dry eyes, dry mouth, anti-Ro/La positive) is 32 weeks pregnant.

Which of the following is a risk to the fetus?

- 1- Complete heart block
- 2- Congestive cardiac failure (CCF)
- 3- Hydrops fetalis
- 4- Neonatal lupus
- 5- All of the above

Answer & Comments

Answer: 5- All of the above

Anti-Ro, and anti-La antibodies cross the placenta, and cause fetal AV nodal conduction defect, which may progress to complete heart block. This may be complicated by CCF, and hydrops fetalis.

Neonatal lupus presents as erythematous macular rash on face or trunk, which may be photosensitive.

Permanent pacemaker is required for the treatment of complete heart block.

On the other hand, neonatal lupus is a transient self-resolving illness due to passively transmitted maternal antibodies.

[Q: 3346] OnExamination 2012 - Rheumatology

A 45-year-old man with poorly controlled diabetes presents with a painful swollen right knee and difficulty in walking which he has had for one day.

He has had no recent infections, rarely drinks alcohol, and there is no significant past or family history.

On examination, his temperature is 37.8°. The right knee is warm, tender, and there is a

tense right knee effusion. Knee flexion is painful and restricted.

Which of the following is the most appropriate investigation for this patient?

- 1- Aspirate right knee
- 2- Blood culture
- 3- CRP
- 4- MRI right knee
- 5- Serum urate

Answer & Comments

Answer: 1- Aspirate right knee

Septic arthritis must be excluded in an individual with acute mono-arthritis.

Septic arthritis may be oligo- or polyarticular in the immunosuppressed, and may present without pyrexia. Joint aspiration, followed by microscopy and culture of the synovial fluid is critical to the diagnosis of septic arthritis.

Examination of joint fluid under polarised microscope may show monosodium urate (negatively birefringent) or calcium pyrophosphate (weakly positively birefringent) crystals, and lead to a diagnosis of acute gout or acute CPP crystal arthritis (pseudogout).

Knee radiograph is likely to be normal in someone with inflammatory joint symptoms of short duration.

A blood culture may be negative in over half of patients with septic arthritis, and a high CRP does not differentiate between causes of acute hot swollen joint.

Knee MRI will show a wide range of non-specific changes in this scenario, for example, effusion, synovial proliferation, bone marrow oedema, none of which is specific to septic arthritis.

There is no role for serum urate in the diagnosis of acute gout. Serum urate, a

negative acute phase reactant (like albumin), reduces during an acute illness.

[Q: 3347] OnExamination 2012 - Rheumatology

A 55-year-old woman with longstanding well controlled sero-positive rheumatoid arthritis, treated with methotrexate (20 mg/week) and folic acid 5 mg/day, presents with neck pain, gradually worsening difficulty in walking and getting up from sitting position.

On examination, the power is 4/5 in lower limbs. The knee and ankle jerks are brisk bilaterally, and the plantars are extensor.

What is the most likely cause of her symptoms?

- 1- Atlantoaxial subluxation
- 2- Cauda equina syndrome
- 3- Cervical spine disc prolapsed
- 4- Pseudobulbar palsy
- 5- Spinal stenosis

Answer & Comments

Answer: 1- Atlantoaxial subluxation

Rheumatoid arthritis is the most common inflammatory disease involving the spine. It has a predilection for the craniocervical spine.

The three different patterns of instability which can result are:

Atlantoaxial subluxation

Atlantoaxial impaction and

Subaxial subluxation.

Atlantoaxial subluxation (distance between the arch of atlas and odontoid peg >2.5 mm) may occur due to erosion of the odontoid process or due to laxity of the transverse ligament from rheumatoid pannus resulting in posterior subluxation of the odontoid. This can lead to cervical cord compression.

In some patients, exuberant rheumatoid pannus around the odontoid peg may cause cervical spine compression without atlantoaxial subluxation.

Basilar invagination, with upward migration of the odontoid peg into the foramen magnum may lead to cord compression, or to medullary compression (which may be fatal).

Although radiographic changes are seen in up to 86% of patients, the prevalence of neurological deficit is relatively low. Radiographs should be taken laterally with the neck held in flexion.

Only a minority of patients require surgical management.

Non-surgical treatment options include patient education, lifestyle modification and regular radiographic follow up.

MRI is indicated when myelopathy occurs or when plain radiographs show atlantoaxial subluxation with a posterior atlantodental interval less than 14 mm, any degree of atlantoaxial impaction or subaxial stenosis with a canal diameter less than 14 mm.

Pseudobulbar palsy results from the degeneration of corticobulbar pathways to the lower cranial nerve nuclei. It presents with dysarthria, difficulty swallowing and weakness of the muscles of mastication. It is not commonly associated with rheumatoid arthritis.

Spinal stenosis, cauda equine syndrome and a prolapsed cervical disc could all present as described here but in the setting of rheumatoid arthritis atlantoaxial subluxation is more likely.

[Q: 3348] OnExamination 2012 - Rheumatology

According to NICE guidelines, which of the following has a role in the treatment of osteoarthritis (OA)?

- 1- Acupuncture
- 2- Chondroitin sulphate
- 3- Glucosamine hydrochloride
- 4- Intra-articular hyaluronic acid
- 5- Transcutaneous electrical nerve stimulation

Answer & Comments

Answer: 5- Transcutaneous electrical nerve stimulation

NICE guidelines recommend formulating individualised management plans for patients with osteoarthritis.

Behavioural change, such as exercise, weight loss and suitable footwear should be encouraged. Comorbidities which compound the effect of osteoarthritis symptoms should be identified and their treatment optimised.

Paracetamol and/or topical NSAIDs (for knee or hand OA) should be offered before considering oral NSAIDs.

If symptoms are not controlled with the above strategies, oral NSAIDs or COX-2 inhibitors (but not etoricoxib) can be used. A proton pump inhibitor should be co-prescribed. The lowest effective dose should be prescribed for the shortest period possible. If the patient is already taking low-dose aspirin, an alternative analgesic should be considered.

Treatments which are not recommended include rubefacients, intra-articular hyaluronan, electro-acupuncture and chondroitin or glucosamine products.

Adjuvants which can be used include opioid analgesics, topical capsaicin and intra-articular corticosteroids. Application of heat or cold packs, or TENS, can be considered if other strategies are ineffective.

Manipulation and stretching can be helpful, particularly for hip osteoarthritis.

Bracing/joint supports can be used for patients with biomechanical joint pain or instability.

Patients should be referred for joint surgery if they have already been offered all of the core treatments or if they have refractory joint symptoms which have a substantial impact on their quality of life.

If there is a clear history of mechanical locking, referral for arthroscopic lavage and debridement should be considered.

[Q: 3349] OnExamination 2012 - Rheumatology

A 24-year-old woman presents to her physician with triphasic Raynaud's phenomenon.

It affects her daily activities and can be very painful. In particular, it is exacerbated when handling refrigerated items at her work in the local supermarket.

She smokes 20 cigarettes a day. An examination is unremarkable. Initial investigations show her to be antinuclear antibody (ANA) negative.

What is the best initial line of management?

- 1- Admit to hospital electively for five days of IV iloprost
- 2- Advise on lifestyle changes to reduce the frequency of the attacks, such as heated gloves, stopping smoking and liaising with her employer's occupational therapy department to change her duties avoiding the cold environments
- 3- Commence on nifedipine Retard
- 4- Sympathectomy
- 5- Refer for nail fold capillaroscopy

Answer & Comments

Answer: 2- Advise on lifestyle changes to reduce the frequency of the attacks, such as heated gloves, stopping smoking and liaising

with her employer's occupational therapy department to change her duties avoiding the cold environments

This question recognises the importance of using conservative management before embarking on potentially long term medication with risks of side effects, and the recognition of the vasospastic effect of cigarette smoking.

Regarding the options:

A. The prostaglandin iloprost is useful in the treatment of Raynaud's phenomenon and can be considered if the patient does not respond to nifedipine Retard or has developed digital ulceration or ischaemia.

C. Raynaud's phenomenon responds well to calcium channel blockers such as nifedipine but given that this lady has so many factors that can be altered in her lifestyle, such as smoking and working in a cold environment, more simple measures to change these could avoid daily medication with its side effects.

D. Digital sympathectomy should be considered as a last resort when drug therapy has failed or has not been tolerated.

E. Capillaroscopy is useful especially when serum antibodies are positive but it would not change the management at this stage.

[Q: 3350] OnExamination 2012 - Rheumatology

A 37-year-old carpenter comes to the rheumatology clinic complaining of pain going from the lateral aspect of his elbow and down his forearm, with further pain on flexion of the wrist. He has been recently working excessive overtime on a housing project.

On examination he has pain on palpation over the lateral aspect of the humerus, and on resisted dorsiflexion of the wrist.

Which of the following is the most likely diagnosis?

- 1- Carpal tunnel syndrome
- 2- Cervical nerve root entrapment
- 3- Lateral epicondylitis
- 4- Olecranon bursitis
- 5- Osteoarthritis of the elbow

Answer & Comments

Answer: 3- Lateral epicondylitis

This patient has symptoms that are consistent with tennis elbow, most probably due to excessive forearm extension as a result of his work as a carpenter.

Many will improve with rest and avoiding any movement that causes pain. Physiotherapy is the mainstay of therapy, and many patients benefit from exercises, placement of a tension band device around the elbow and use of non-steroidals.

In those who do not respond to physiotherapy, a lateral release procedure is highly effective.

[Q: 3351] OnExamination 2012 - Rheumatology

A 52-year-old woman presents with left loin pain. Past history includes hypertension and progressive cognitive decline.

On examination she is pyrexial, has livedo reticularis and a blood pressure of 180/100 mmHg. Examination of the abdomen reveals no masses but there is tenderness in the left flank.

Investigations revealed:

Haemoglobin 12.9 g/dl(11.5-16.5)

White cell count $8.7 \times 10^9/L$ (4-11)

Platelet count $83 \times 10^9/L$ (150-400)

Serum Creatinine 106 mol/l (60-110)

Urine dipstick analysis:

Blood +++

Protein +

Which one of the following tests is most likely to be positive?

- 1- Anticardiolipin antibody
- 2- Antiglomerular basement membrane antibody
- 3- Antimitochondrial antibody
- 4- Antineutrophil cytoplasmic antibody
- 5- Antistreptolysin O antibody

Answer & Comments

Answer: 1- Anticardiolipin antibody

The presence of thrombocytopenia, hypertension and livedo reticularis, make systemic lupus erythematosus (SLE) the most likely diagnosis in this case.

This presentation is likely due to renal vein thrombosis (causing flank pain with haematuria and proteinuria), highlighting the possibility of antiphospholipid syndrome (APS). Antibodies commonly associated with APS are anticardiolipin antibodies.

Antiphospholipid syndrome is a common cause of acquired thrombophilia and characterised by arterial and/or venous thrombosis and pregnancy mortality in association with circulating antiphospholipid antibodies.

These are a heterogeneous group of approximately twenty autoantibodies directed against phospholipid binding plasma proteins.

Three of the most clinically important are

The lupus anticoagulant

Anti-beta-2 glycoprotein I antibodies and

The anticardiolipin antibodies.

They can be detected either by phospholipid-dependent coagulation test for lupus anticoagulant or ELISA test for anticoagulation and anti-β2GPI antibodies.

Antibodies should be demonstrated on at least two occasions separated by 12 weeks.

Antiphospholipid syndrome may be primary, or associated with other conditions (such as systemic lupus erythematosus).

Antiglomerular basement membrane antibodies are characteristic of Goodpasture's syndrome, which presents with acute kidney injury with or without alveolar haemorrhage.

Antimitochondrial antibodies are seen in primary biliary cirrhosis, which causes fatigue, pruritis and abdominal pain, with jaundice as a late sign.

Antineutrophil cytoplasmic antibodies (ANCA) are a heterogeneous group of antibodies which are seen in a variety of vasculitides.

Antistreptolysin-O antibodies are directed against group A Streptococci, which can be associated with a variety of clinical presentations including scarlet fever.

Reference:

Antiphospholipid syndrome diagnosis: an update.
Visseaux B et al. *Ann Biol Clin (Paris)* 2001 Aug 1;69(4):411-418

Antiphospholipid antibody syndrome. Sangle NA and Smock KJ. *Arch Pathol Lab Med.* 2011 Sep;135(9):1092-1096

[Q: 3352] OnExamination 2012 - Rheumatology

A 31-year-old nurse presents with chronic pain. The pain changes from day to day, but often focuses in the lower back.

She is pale and looks unwell. She complains of waking up frequently at night, and feels unrefreshed in the morning. She also complains of intermittent constipation and diarrhoea.

Examination is essentially normal - but the patient complains of tenderness in multiple areas on palpation. Basic blood tests are normal.

What is the most likely diagnosis?

- 1- Depressive disorder
- 2- Fibromyalgia
- 3- Hypothyroidism
- 4- Schizophrenia
- 5- Somatoform disorder

Answer & Comments

Answer: 2- Fibromyalgia

Fibromyalgia is becoming a recognised medical diagnosis, and is based on the presence of pain in all four quadrants of the body, as well as tenderness in 11 of 18 anatomically defined trigger areas. The aetiology is not fully understood, but may involve hyperexcitability within the spinal cord or brainstem, altered pain perception and somatisation.

Approximately 50% of patients with fibromyalgia complain of diarrhoea and constipation, often associated with abdominal bloating. Morning fatigue is present in a large proportion of these patients, and patients often look unwell, and may appear depressed and anxious. Other features include tissue swelling, morning stiffness and sleep disorders.

Somatoform disorders are a group of psychological disorders in which a patient experiences physical symptoms despite the absence of an underlying medical condition that can fully explain their presence. The clinical picture here is too close to that of fibromyalgia to be a somatoform disorder.

Depression should be a diagnosis of exclusion, and fibromyalgia is a more likely diagnosis here. If the patient had hypothyroidism you would expect other features in the history, such as cold intolerance. Schizophrenia would not explain the clinical findings in this case.

[Q: 3353] OnExamination 2012 - Rheumatology

A 56-year-old woman presents with a six day history of sharp shooting pain radiating to her right forearm, with paraesthesia.

On examination, she has sensory loss affecting the centre of her palm and the right hand middle finger. Elbow and finger extension are weak and the triceps jerk is absent.

Which cervical spine nerve root is affected?

- 1- C5
- 2- C6
- 3- C7
- 4- C8
- 5- T1

Answer & Comments

Answer: 3- C7

This patient has cervical disc prolapse pressing on the C7 nerve root.

It is possible to identify the compressed nerve root by examining the power, sensation, reflexes in the upper lower limbs.

Root	Dermatome distribution	Myotome distribution	Tendon reflex
C4	Upper outer shoulder	Shoulder abduction	Nil
C5	Outer arm, forearm	Shoulder abduction, elbow flexion	Bicep
C6	Index and thumb	Wrist extension	Supinator
C7	Middle finger centre of palm	Finger and elbow extension	Triceps
C8	Little finger, ulnar border of hand	Wrist/finger flexion	Finger jerk

[Q: 3354] OnExamination 2012 -
Rheumatology

A 47-year-old woman presented with a history several years of dysphagia, hard calcified nodules in the fingers, and cold hands.

Examination revealed calcified nodules, sclerodactyly and facial telangiectasia.

Which one of the following antibodies is most likely to be found in the blood?

- 1- Anticardiolipin
- 2- Anticentromere
- 3- Anti-DNA antibodies
- 4- Antimitochondrial
- 5- Antimyeloperoxidase

Answer & Comments

Answer: 2- Anticentromere

This patient has features of CREST syndrome, making systemic sclerosis the most likely diagnosis.

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. Ninety to 95% of patients have positive antinuclear antibodies.

There are two major subtypes:

Limited cutaneous and

Diffuse cutaneous.

CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynauds' phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia).

Patients with systemic sclerosis can present with

Skin abnormalities

Musculoskeletal changes

Gastrointestinal complications

Pulmonary disease

Renal crisis and

Dry eyes and mouth.

A number of autoantibodies against extractable nuclear antigens can be detected in patients with systemic sclerosis. Anticentromere antibodies and antitopoisomerase I antibodies are the classic autoantibodies associated with the disease.

Anticentromere antibodies are linked with limited cutaneous involvement and isolated pulmonary hypertension, and a good prognosis, whereas antitopoisomerase I is linked with diffuse skin disease and pulmonary fibrosis and a higher mortality.

Additional autoantibodies which can be detected are antiRNA polymerase, antiU3RNP, antiKu and antiU1RNP.

Anticardiolipin antibodies are seen in antiphospholipid syndrome.

AntiDNA antibodies are associated with systemic lupus erythematosus.

Antimitochondrial antibodies are seen in primary biliary cirrhosis.

Antimyeloperoxidase antibodies are also referred to as pANCA, and can be seen in a variety of vasculitides.

[Q: 3355] OnExamination 2012 -
Rheumatology

A 30-year-old male presents with a week history of a painful right leg.

Past medical history reveals that he had erythema nodosum and recurrent oral and scrotal ulceration.

Examination reveals a diffusely swollen left leg, and acute tenderness with erythema of the right lower leg..

What is the most likely cause of his swollen leg?

- 1- Cellulitis
- 2- Lymphoedema
- 3- Pyomyositis
- 4- Ruptured popliteal (Baker's) cyst
- 5- Venous thrombosis

Answer & Comments

Answer: 5- Venous thrombosis

This man has clinical features of Behçet's syndrome.

Behçet's syndrome is a systemic vasculitis with an unknown aetiology, which affects small and large vessels (venous and arterial).

More than 60% of patients are HLA-B51, and there is an increased prevalence in the Mediterranean countries.

It is commonly associated with mucocutaneous manifestations (oro-genital ulceration, erythema nodosum), ocular disease, gastrointestinal involvement and neurological features. Venous thrombosis is a common complication, and therefore there should be a high clinical suspicion of a left sided DVT in this case. The tenderness and erythema of the right leg is most likely due to erythema nodosum.

None of the other conditions listed above are commonly associated with Behçet's syndrome.

[Q: 3356] OnExamination 2012 - Rheumatology

A 52-year-old man who has a long history of chronic alcohol abuse presents with gouty tophi.

He is commenced on allopurinol but develops severe joint pains two days later.

On examination he has a temperature of 39°C, and erythematous swelling of his hands, knees and ankles.

Investigations reveal:

Urate 0.55 mmol/L (0.23-0.46)

C reactive protein 150 mg/L (<10)

Which of the following is the most likely cause for his presentation?

- 1- Acute pyrophosphate arthropathy
- 2- Acute rheumatoid arthritis
- 3- Allopurinol allergy
- 4- Septic arthritis
- 5- Treatment with allopurinol

Answer & Comments

Answer: 5- Treatment with allopurinol

This man is having an acute attack of gout following the initiation of antihyperuricaemic (allopurinol) therapy.

This can be minimised by not starting allopurinol immediately during or shortly after an acute attack of gout, abstaining from alcohol bingeing and gradually increasing the dose of allopurinol.

Alcohol ingestion may also trigger an acute attack of gout, but in this case given the recent commencement of allopurinol, this is more likely to be the trigger.

The most common features of allopurinol hypersensitivity are rash and fever.

Joint sepsis affecting multiple joints is unlikely.

Acute pseudogout (pyrophosphate arthropathy) presents with inflammation of the larger joints, the knees being most commonly affected.

Given the history of alcohol abuse, gouty tophi and raised urate rheumatoid arthritis is not the most likely explanation.

[Q: 3357] OnExamination 2012 - Rheumatology

A 50-year-old woman complains of arthritis

and swelling of approximately four months duration.

On examination she has a symmetrical inflammation with painful movements of the hands and feet and also swelling of both knees suggesting a diagnosis of rheumatoid arthritis.

Regarding her joint disease which of the following suggest an adverse prognosis?

- 1- Acuteness of presentation
- 2- Articular erosions on x ray
- 3- Elevated C reactive protein
- 4- Enthesitis
- 5- Sero-negative for rheumatoid factor

Answer & Comments

Answer: 2- Articular erosions on x ray

Articular erosions in rheumatoid arthritis occurring early on in the course of the disease especially within the first six months of presentation indicate a poor prognosis. Over time joint damage will relate to disability.

A positive rheumatoid factor is associated with:

More severe erosive disease

Extra-articular manifestations including subcutaneous nodules and

Increased mortality.

An acute onset of presentation is not a poor prognostic factor.

Raised inflammatory markers (C reactive protein [CRP], erythrocyte sedimentation rate [ESR]) and the duration of the early morning stiffness both correlate with disease activity.

[Q: 3358] OnExamination 2012 - Rheumatology

A 60-year-old woman attends the casualty department with a six week history of

lethargy, neck pain, weakness in the upper limbs and gait disturbance. She describes occasional episodes of electrical sensation shooting down her spine on flexing her neck.

She has a long history of lower back pain, primary generalised osteoarthritis, and vitiligo. She takes Voltarol regularly. She neither smokes nor drinks.

She is of Pakistani origin and has been in this country for the past six years. There is no history of recent foreign travel.

On examination she is afebrile. General examination is unremarkable except for vitiligo. Examination of the cranial nerves is normal. There is no wasting of the limbs but there are a few fasciculations in brachioradialis and biceps on the right. Tone is mildly increased. Apart from mild weakness of elbow, wrist and finger flexion and extension, more marked on the right, power is normal. There is inversion of the right supinator reflex, and triceps, jerks are reduced bilaterally. Sensation is mildly reduced in the C5 and C6 dermatomes.

Investigations show:

Hb 11.3 g/L(11.5-16.5)

WCC $7 \times 10^9/L$ (4-11 $\times 10^9$)

Platelets $160 \times 10^9/L$ (150-400 $\times 10^9$)

Coagulation screen Normal

ESR 27 mm/h(0-30mm/1st hour)

CRP 17 mg/L(<10)

Sodium 137 mmol/l (137-144)

Potassium 4.2 mmol/l (3.5-4.9)

Urea 5.7 mmol/l (2.5-7.5)

Creatinine 87 $\mu\text{mol/l}$ (60-110)

Protein 73 g/L(61-76)

Albumin 38 g/L(37-49)

Calcium 2.23 mmol/l (2.2-2.6)

Phosphate 1.2 mmol/l (0.8-1.4)

LFTs Normal

CXR: Normal

x Ray cervical spine: Extensive osteophytes. Normal alignment.

What is the most likely diagnosis?

- 1- Degenerative cervical spondylosis
- 2- Motor neurone disease
- 3- Multiple myeloma
- 4- Polymyalgia rheumatica
- 5- Syringomyelia

Answer & Comments

Answer: 1- Degenerative cervical spondylosis

Cervical spondylosis is the most common progressive disorder of the spine, and is associated with normal aging. It results from degeneration of the intervertebral disc and facet joints in the cervical spine. Radiographic evidence of disc degeneration is present in 25% of patients younger than 40y, 50% over 40 and 85% over 60. In the majority of cases it is asymptomatic, and it is difficult to define the boundary between normal aging and the disease process. Risk factors include rugby, horse-riding and flying, all of which increase loads on the head. Both sexes are affected equally, but problems begin earlier in males.

Degenerative changes affecting the intervertebral discs, vertebrae, facet joints, and ligamentous structures encroach on the cervical spinal canal and damage the cord, especially in patients with a congenitally small canal.

Symptoms related to myelopathy and radiculopathy are caused by the formation of osteophytes, which narrow the diameter of the spinal canal at one or multiple levels. This may produce direct neurological damage or ischaemic changes and therefore lead to spinal cord disturbances. Radiculopathy is due to compression, stretching or angulation of the cervical nerve roots. Myelopathy is due to compression, ischaemia or recurring minor

trauma to the cord. Cervical spondylitic myelopathy is the most common cause of myelopathy in adults. Patients present with signs and symptoms of cervical spinal cord dysfunction with or without cervical nerve root injury. There is therefore a mixture of upper and lower motor neurone signs. These may or may not be accompanied by pain in the neck and/or upper limb, orbits or temporal regions. In addition there is often cervical stiffness, and poor balance. On examination there is limited range of movement of the cervical spine and poorly localised tenderness.

Radiculopathy causes dermatomal pain, often with accompanying changes in sensation or weakness in related muscles. The most commonly affected nerve roots are C5-7, and sensory symptoms (shooting pain, numbness, hyperaesthesia) are more common than weakness. Dural irritation can be demonstrated with the Spurling test in which radicular pain is reproduced with lateral flexion and rotation of the neck, with pressure on top of the patient's head. Reflexes are usually reduced.

The differential diagnosis is broad, and includes acute neck strain, osteomyelitis, fibromyalgia, inflammatory arthritis and osteoporosis. The diagnosis can often be made on clinical grounds, but if neurological abnormality is present appropriate investigations include MRI and electrophysiology. High signal-intensity lesions on MRI indicate a poor prognosis.

Management can be medical or surgical. Initially conservative measures such as regular activity, physiotherapy and addressing risk factors should be instigated. A cervical collar should not be used. Analgesia, anti-inflammatories and tricyclic antidepressants can be helpful. Indications for surgery include progressive neurological defects, compression of the cervical nerve root and/or spinal cord and intractable pain. Decompression improves neurologic function

in some patients and prevents worsening in others, but there are significant risks. Epidural injection can be considered where surgical intervention is not an option.

In general, progression of cervical spondylosis is slow, although 10% develop chronic neck pain.

Motor neurone disease is an important differential diagnosis of upper and lower motor neuron dysfunction in this age group. It is slightly more prevalent in men than women. However, you would expect muscular weakness to be the predominant symptom and this is only minor in the above case. Sensory disturbance is uncommon.

Myeloma can cause spinal cord and/or nerve/root compression but one would expect other features to be present such as bone pain, bleeding or bruising and symptoms of hypercalcaemia. Blood tests typically show anaemia, leucopenia and thrombocytopenia, none of which are present in this case.

Polymyalgia rheumatica is an inflammatory disorder characterised by severe bilateral pain and morning stiffness of the neck, shoulder and pelvic girdle. The ESR and CRP are markedly raised, and neurological signs are uncommon.

In syringomyelia there is a fluid-filled cavity within the central spinal cord (usually cervical). As this enlarges and expands it compresses the corticospinal and spinothalamic tracts, and later the anterior horn cells. Sensory symptoms are therefore a dominant feature. It most commonly presents in the 20s and 30s.

[Q: 3359] OnExamination 2012 - Rheumatology

Which of the following regarding infliximab is most true?

- 1- Is a monoclonal antibody to the glycoprotein IIb-IIIa receptor
- 2- Is authorised for the treatment of severe ulcerative colitis
- 3- Is licensed for the treatment of rheumatoid arthritis
- 4- It prevents relapse of Crohn's disease in patients who are in remission
- 5- Must not be used in combination with methotrexate due to increased toxicity

Answer & Comments

Answer: 3- Is licensed for the treatment of rheumatoid arthritis

Infliximab is a monoclonal antibody to tumour necrosis factor (TNF) alpha. It is recommended by NICE for adults with rheumatoid arthritis who have both the following:

- Active rheumatoid arthritis as measured by disease activity score greater than 5.1 on at least two occasions one month apart.
- Undergone trials of two disease-modifying anti-rheumatic drugs including methotrexate (unless contraindicated); defined as 6 months of therapy with 2 months at standard dose (unless toxicity has limited treatment).

Before starting therapy and throughout treatment, patients should be evaluated carefully for tuberculosis as there have been reports of the onset or reactivation of TB including miliary TB and some unusual extrapulmonary TB.

Infliximab should normally be used in combination with methotrexate and requires intravenous infusion in a hospital setting. If a patient is intolerant of methotrexate, adalimumab (humanised anti-TNF antibody) and etanercept (anti-TNF receptor antibody) are alternatives to infliximab which can be given as monotherapy. Response to treatment is assessed at 6 months, and only

continued if there is an improvement in disease activity score of 1.2 points or more. Treatment is typically initiated with the least expensive drug, and the other agents only used if there is toxicity.

In addition, infliximab has a role to play in refractory Crohn's disease. Some other monoclonal antibodies in clinical use include:

Digibind - digoxin-binding antibody for treatment of overdoses (increases clearance)

Abciximab: glycoprotein IIb/IIIa receptor (for unstable angina)

Pexelizumab: anti-C5 (complement) - anti-inflammatory: reduces myocardial infarction and death following CABG and angioplasty.

[Q: 3360] OnExamination 2012 - Rheumatology

In which of the following situations would a percutaneous needle biopsy of the kidney be most helpful and appropriate?

- 1- Fever with suspected acute pyelonephritis
- 2- Premature neonate with suspected polycystic kidney disease
- 3- Prostatic hyperplasia with suspected hydronephrosis
- 4- Suspected renal cyst
- 5- Systemic lupus erythematosus (SLE) and acute renal failure

Answer & Comments

Answer: 5- Systemic lupus erythematosus (SLE) and acute renal failure

The renal manifestations of SLE are highly variable, ranging from mild asymptomatic proteinuria and/or haematuria to rapidly progressive uraemia.

The various presentations are difficult to classify into clinical syndromes and histological classes. Although lupus nephritis affects a third of patients early in the disease

it is frequently unrecognised until nephritic and/or nephrotic syndrome with renal failure occur.

Therapy may depend upon determination of the severity and nature of the renal disease with SLE. A biopsy is indicated in those patients with abnormal urinalysis and/or reduced renal function. This can provide a histological classification as well as information regarding activity, chronicity and prognosis.

Histologically, a number of different types of renal disease are recognised in SLE, with immune-complex mediated glomerular disease being the most common.

The standard classification divides these into five different patterns:

No disease

Mesangial

Focal proliferative

Diffuse proliferative

Membranous.

Mesangial nephritis represents the earliest and mildest form of glomerular involvement. It presents clinically as microscopic haematuria and/or proteinuria. Hypertension is uncommon and nephrotic syndrome and renal impairment are very rarely seen.

Biopsy demonstrates segmental areas of increased mesangial matrix and cellularity. The prognosis is good and specific treatment is only indicated if the disease progresses. Prednisolone can be used in the presence of high anti-ds DNA, low complement and over a gram of protein in the urine.

Diffuse proliferative disease is more advanced, but still affects less than 50% of glomeruli. Haematuria and proteinuria are almost always seen, and nephrotic syndrome, hypertension and elevated creatinine may be present. Electron microscopy shows immune

deposititis in the subendothelial space of the glomerular capillary wall and the mesangium. Prognosis is variable.

Focal proliferative glomerulonephritis is the most common and severe form of lupus nephritis. Haematuria and proteinuria are almost always present, and nephrotic syndrome, hypertension and renal impairment common. Biopsies demonstrate profuse deposits of IgG within the glomeruli. Immunosuppressive therapy is required in these cases to prevent progressive to end-stage renal failure.

Patients with membranous lupus nephritis tend to present with nephrotic syndrome. Microscopic haematuria and hypertension may also be seen. Biopsies show diffuse thickening of the glomerular capillary wall. Progression is variable, and immunosuppression is not always needed.

Features associated with a poorer prognosis, and increased risk of progression to end stage renal failure include:

The presence of young age (<23)

Increased serum creatinine

Diffuse proliferative lesions (WHO classification class IV) and

A high chronicity index on renal histologic analysis.

The diagnosis of pyelonephritis is made on the basis of clinical presentation and positive urine culture, with or without ultrasound findings. Renal biopsy is rarely required.

Polycystic kidney disease is usually diagnosed with characteristic appearances on ultrasound.

Hydronephrosis associated with prostatic disease can be diagnosed on ultrasound, and biopsy is not indicated.

Renal cysts are usually found on ultrasound and CT. Tissue may be needed to differentiate

between malignant and benign cysts, but this is obtained via aspiration rather than renal parenchymal biopsy.

[Q: 3361] OnExamination 2012 - Rheumatology

Which of the following statements is true of the immunology of rheumatoid arthritis?

- 1- It is an example of an organ-specific disease.
- 2- It is likely that joint specific antigens have been sequestered during the time when immunological tolerance was being established.
- 3- Joint damage is the consequence of mast cell degranulation.
- 4- Rheumatoid factor is an antibody with reactivity to the heavy chain of IgG.
- 5- Rheumatoid factor is detected by a test utilising the patient's B lymphocytes.

Answer & Comments

Answer: 4- Rheumatoid factor is an antibody with reactivity to the heavy chain of IgG.

Rheumatoid arthritis is associated with several antibodies such as rheumatoid factor, collagen antibody, capable of reaction at sites other than the joints.

Additionally, the disease is not confined to the joints.

Damage is mediated by several means, including macrophages activated by CD4+ T cells, and by complement fixing immune complexes.

There is no evidence for the creation of joint-specific antibodies in development. All the components of the joint are present during fetal life.

The rheumatoid factor test utilises the patient's serum, to agglutinate cells coated with antibody. Rheumatoid factor (RF) is an

antibody whose specificity is directed to a domain situated within the Fc portion of IgG. The rheumatoid factor may be of IgM, IgG or IgA class.

The conventional (agglutination) test, detects only IgM RF.

[Q: 3362] OnExamination 2012 - Rheumatology

Which of the following is associated with hyperuricaemia?

- 1- Can be reduced with low dose aspirin therapy
- 2- Can be treated with uricosuric drugs even in renal failure
- 3- In primary gout is inherited in an autosomal dominant manner
- 4- Is usually due to an excess purine consumption
- 5- Occurs in association with acute lymphoblastic leukaemia

Answer & Comments

Answer: 5- Occurs in association with acute lymphoblastic leukaemia

Hyperuricaemia may be due to increased purine intake, urate production or reduced urate clearance, and is most commonly due to the latter.

Therefore it can occur in association with enhanced cell destruction, particularly leukaemias.

Primary gout has no obvious mode of inheritance, but familial juvenile gouty nephropathy is an autosomal dominantly inherited disorder.

Low dose aspirin may exacerbate gout but high dose aspirin is uricosuric.

Many of the uricosuric drugs may be detrimental in renal failure and may not be effective.

[Q: 3363] OnExamination 2012 - Rheumatology

Which one of the following diagnoses is associated with acute iritis?

- 1- Keratoconus
- 2- Lyme disease
- 3- Osteogenesis imperfecta
- 4- Psoriatic arthropathy
- 5- Refsum's disease

Answer & Comments

Answer: 4- Psoriatic arthropathy

Iritis is associated with conditions such as Reiter's, Behcet's, psoriatic arthropathy (about 20%) and inflammatory bowel disease.

A chronic iritis is rarely described in association with Lyme disease.

Osteogenesis imperfecta is associated with blue sclera.

Keratoconus, meaning "cone shaped," describes a condition in which the cornea (the clear front window of the eye) becomes thin and protrudes. This abnormal shape can cause serious distortion of visual images. It is not associated with iritis.

Refsum's disease is associated with retinitis pigmentosa.

[Q: 3364] OnExamination 2012 - Rheumatology

A 30-year-old housewife with SLE (ANA positive 1:1280, dsDNA positive, and anti-cardiolipin antibody positive on two occasions), developed a right below knee DVT.

She has no past history of arterial or venous thrombosis.

Which of the following is the most appropriate management plan for her?

- 1- Warfarin, and aspirin 75 mg/day for life

- 2- Warfarin for 3 months
- 3- Warfarin for 3 months, followed by aspirin 75 mg/day
- 4- Warfarin for 6 months, followed by aspirin 75 mg/day
- 5- Warfarin for life

Answer & Comments

Answer: 5- Warfarin for life

This patient has antiphospholipid antibody syndrome (APAS). APAS can be diagnosed

If the patient has anticardiolipin antibodies, or lupus anticoagulant on two occasions, over a period of 12 weeks

and either

Has had a thrombus or

A history of recurrent < 10 week pregnancy loss, or one pregnancy loss > 10 weeks in gestation when other causes of pregnancy loss have been excluded.

The occurrence of even a single thrombotic event in a patient with antiphospholipid syndrome warrants lifelong anticoagulation, as the risk of recurrence is 20-70%. Low molecular weight heparin should be used initially whilst loading warfarin. In general, it is recommended that the INR is maintained above 2.0, although a higher level (above 3) may be indicated for patients with recurrent thrombosis on treatment. Anticoagulation to prevent foetal loss remains controversial.

[Q: 3365] OnExamination 2012 - Rheumatology

A 70-year-old man complains of pain and stiffness in both his shoulders. He has lost one stone in the last eight weeks and complains of feeling lethargic with loss of appetite.

Investigations revealed a very high ESR (100 mm/hr), normochromic normocytic anaemia and a positive rheumatoid factor.

Which of the following is the most likely diagnosis?

- 1- Polyarteritis nodosa
- 2- Polymyalgia rheumatica
- 3- Polymyositis
- 4- Rheumatoid arthritis
- 5- SLE

Answer & Comments

Answer: 2- Polymyalgia rheumatica

Polymyalgia rheumatica is an inflammatory disease which typically presents with pain and stiffness of the the shoulder and pelvic girdle muscles. It can have either an acute or subacute onset and is associated with a systemic inflammatory response and therefore constitutional symptoms such as fever, anorexia, weight loss and malaise.

The course of the disease is unpredictable, and 30% of patients also have giant cell arteritis. The cause is unknown, although studies showing a cyclical incidence have led to theories regarding an infectious trigger. Muscle weakness is not a feature of PMR, but this can be difficult to assess in the presence of pain.

Investigations typically reveal:

Normochromic / normocytic anaemia

Raised erythrocyte sedimentation rate (ESR) often > 50 mm/hr (although this may be normal)

Raised C reactive protein (CRP).

PMR is not usually associated with an elevated rheumatoid factor, but it is important to note that this is present in 1-2% of the normal population. It is not specific for rheumatoid arthritis.

Features of giant cell arteritis should be sought:

Headache

Visual disturbance

Jaw claudication

Thickened and tender temporal arteries.

Diagnosis of PMR can prove difficult, and other inflammatory conditions should be excluded. Patients are usually over 60 years, and PMR is very rarely seen in the under 50s.

Response to a moderate dose of steroids can be useful. The maximum dose of prednisolone should not exceed 20 mg once daily. Patients should report 70% improvement in symptoms within three to four weeks, and inflammatory markers should have normalised by this point.

In general, non-steroidal anti-inflammatories have little use and are associated with significant morbidity. There is little evidence for the use of steroid-sparing agents.

Rheumatoid arthritis more commonly involves the distal joints, and there is erosive joint disease on radiography. Anti-cyclic citrullinated peptide antibodies are typically positive.

Systemic lupus erythematosus (SLE) rarely presents in elderly males, and there is usually more evidence of systemic disease (for example, renal impairment).

Polymyositis causes proximal muscle weakness in addition to pain, and creatinine kinase is typically raised.

Polyarteritis nodosa is a small vessel vasculitis which does not commonly present with isolated muscle pain and stiffness. Central and peripheral nervous system signs are often present at diagnosis.

[Q: 3366] OnExamination 2012 - Rheumatology

A 65-year-old man who has recently fractured his left femur presents with thirst, headache and lower back pain.

Blood tests reveal a haemoglobin of 8.2 and corrected calcium of 2.89. Radiographs revealed lytic lesions in the vertebrae and skull.

Which of the following is least likely to be present in this patient?

- 1- Bence Jones protein
- 2- Decreased resistance to infection
- 3- Infiltration of flat bones by plasma cells
- 4- Macroglobulinaemia
- 5- Monoclonal gammopathy

Answer & Comments

Answer: 4- Macroglobulinaemia

This gentleman presents with the classic symptoms of multiple myeloma: bone pain, pathological fracture, anaemia and hypercalcaemia (leading to thirst).

Multiple myeloma is a relatively common malignancy that is part of a spectrum of disorders ranging from monoclonal gammopathy of unknown significance (MGUS) to plasma cell leukaemias. It is characterised by a proliferation of malignant plasma cells involving more than 10% of the bone marrow, and a subsequent excess of monoclonal paraprotein. Additional presenting features include hyperviscosity (confusion, hazy vision), peripheral neuropathies, bleeding and spinal cord compression.

The four incorrect answers here are typical features of multiple myeloma.

Bones commonly affected are the flat bones of the spine, and as such lower back pain is one of the most common presenting features.

The aberrant antibodies that are produced lead to impaired humoral immunity, often compounded by leucopenia secondary to bone marrow infiltration. Patients therefore have a high prevalence of infection, especially with encapsulated organisms such as *Pneumococcus*.

Lambda light chains are secreted in the urine as Bence Jones protein. This is most accurately detected by urine protein electrophoresis. Immunofixation allows confirmation of the monoclonal nature of the light chains.

Gammopathy is a disturbance in the synthesis of immunoglobulins. Monoclonal gammopathy suggests there is a single neoplastic clone causing an excess of immunoglobulin, as is the case in multiple myeloma.

An important differential diagnosis to be aware of is monoclonal gammopathy of unknown significance (MGUS).

Macroglobulins are plasma globulins of high molecular weight. They are a central feature of Waldenstrom's macroglobulinaemia, where proliferation of lymphocytes cause an excess of IgM. This is an important differential diagnosis when multiple myeloma is suspected. Macroglobulins are not typically a feature of multiple myeloma.

[Q: 3367] OnExamination 2012 - Rheumatology

A 22-year-old boy with known hereditary angioneurotic oedema (HAO) presents with a recurrent fever, arthralgia and a rash on the face and the upper chest.

Despite treatment for his HAO, he has always been troubled by recurrent attacks and has required adrenaline on several occasions.

His C4 levels have been persistently reduced secondary to his HAO.

What is the most likely cause for his current symptoms?

- 1- Dermatomyositis
- 2- Drug rash
- 3- Psoriasis with arthropathy
- 4- Systemic lupus erythematosus (SLE)
- 5- Viral illness

Answer & Comments

Answer: 4- Systemic lupus erythematosus (SLE)

HAO is characterised by deficiency of C1 esterase inhibitor.

This leads to persistent activation of the classical complement pathway and C4 levels are frequently low secondary to activation and consumption.

If treatment fails to normalise the C4 levels and they remain persistently low, these patients are at an increased risk of developing SLE.

[Q: 3368] OnExamination 2012 - Rheumatology

A 69-year-old lady presents for follow up of her rheumatoid arthritis. She complains of only satisfactory symptomatic control, but admits to intermittently missed doses.

She has a past medical history of a perforated gastric ulcer, likely secondary to chronic alcohol abuse. She consumes approximately 45 units of alcohol per week.

A recent DXA scan is performed and demonstrates a T-score of -4.0 SD below the peak bone mineral density.

What is the best strategy for primary prevention of osteoporosis?

- 1- Alendronate
- 2- Calcium and vitamin D
- 3- Denosumab

4- Parathyroid hormone replacement

5- Raloxifene

Answer & Comments

Answer: 3- Denosumab

Learning points:

Treatment modalities for the primary prevention of osteoporosis in postmenopausal women

Risk factors for the development of osteoporosis in postmenopausal women.

This is a 69-year-old lady with two independent clinical risk factors for fracture (rheumatoid arthritis, alcohol intake greater than 4 units per day) and a correspondingly low T-score.

These factors make her eligible for primary prevention with a bisphosphonate. Bisphosphonate therapy is relatively contraindicated however, given her history of gastric ulcer perforation and ongoing alcohol abuse. More, it is doubtful that she would comply with the special instructions relating to the administration of a bisphosphonate.

For these reasons, current NICE guidance recommends denosumab, a monoclonal antibody targeted against the nuclear factor-kappa ligand (RANKL) involved in osteoclast activation.

Raloxifene is not recommended for the primary prevention of osteoporotic fragility fractures in postmenopausal women.

[Q: 3369] OnExamination 2012 - Rheumatology

A 35-year-old lady presents for follow up for a right-sided Colles' fracture. This was sustained following a slip in the kitchen at home. You are suspicious given the apparent low velocity mechanism of injury.

Which of the following measurements would correspond to a diagnosis of osteoporosis?

1- T-score -1.5

2- T-score -2.5

3- Z-score -1.5

4- Z-score -2.0

5- None of the above

Answer & Comments

Answer: 4- Z-score -2.0

Learning points:

Bone mineral density (BMD) measurement in premenopausal women

Risk factors for low BMD in premenopausal women

Definition of fragility fracture.

The scoring systems are differentiated by their reference populations:

T-scores compare the patient's bone mineral density (BMD) with that of a healthy young adult

Z-scores compare the individual's BMD with that of a population of peers.

Accordingly the T-score is validated for use in peri/post menopausal women and men aged over 50 years.

The relationship between BMD and fracture risk is not well established in premenopausal women and a Z-score is utilised instead.

This fracture is suspicious of a fragility state because it has resulted from a mechanical force equivalent to a fall from standing height, which should not ordinarily cause a fracture. This result should prompt a search for osteoporotic risk factors.

[Q: 3370] OnExamination 2012 - Rheumatology

You are reviewing a 42-year-old woman in clinic. She was diagnosed with rheumatoid arthritis last year after presenting with small hand joint synovitis and stiffness.

At that time her rheumatoid factor and anti-CCP levels were 1:20 titre and 700U/ml respectively. Unfortunately, despite 12 months on a combination of prednisolone, methotrexate and leflunomide, she still has moderate disease activity based on a DAS-28 (disease activity score) score of 3.2.

She is being considered for etanercept.

Preliminary tests demonstrate a normal chest radiograph, but positive QuantiFERON test. She is asymptomatic. Her only other medical history is multiple sclerosis.

From the following options, which is the most appropriate treatment?

- 1- Consider infliximab as an alternative
- 2- Hold etanercept until treatment is completed for active TB
- 3- None of these
- 4- Prescribe etanercept and monitor closely
- 5- Prescribe etanercept with TB prophylaxis

Answer & Comments

Answer: 3- None of these

Teaching points:

Recommendations for biologic therapy in rheumatoid arthritis (RA)

Absolute contraindications to biologic therapy

Basic disease scoring in RA.

This lady has a DAS-28 score persistently greater than 3.2 and has failed on a combination of more than two disease modifying agents, thus fulfilling the criteria

for consideration of anti-TNF (biologic) therapy.

Absolute contraindications to this therapy include

Active or latent mycobacterial infection

Patients with New York Heart Association (NYHA) grade 3 or 4 cardiac failure

Multiple sclerosis.

In addition, anti-TNF therapy should be used with caution in other demyelinating diseases including Guillain-Barre syndrome, Miller Fisher syndrome and chronic inflammatory demyelinating polyneuropathy.

[Q: 3371] OnExamination 2012 - Rheumatology

A 68-year-old woman presents with a one week history of acute onset right-sided headache, symmetrical shoulder pains and malaise. Her food intake has reduced which she attributes to a loss of appetite and aching of her jaw and tongue occurring during meals. She reports one transient episode of a curtain apparently descending over her right eye before spontaneously resolving.

Clinical examination demonstrated a tender, beaded and pulseless temporal artery. Fundoscopy revealed a swollen and pale right optic disc with haemorrhages. There was a relative afferent pupillary defect.

Her ESR measured 55 mm/Hr (0 - 30).

Which one of the following increases the likelihood of a positive temporal artery biopsy?

- 1- Arthralgia
- 2- Jaw claudication
- 3- Lethargy
- 4- Loss of appetite
- 5- Subjective fever

Answer & Comments

Answer: 2- Jaw claudication

Learning points:

- i. Clinical features of temporal arteritis (TA)
- ii. Diagnosis of TA
- iii. Significance of associated clinical features in relation to obtaining a positive diagnostic biopsy.

A 2002 meta-analysis evaluated the relationship between the clinical features of temporal arteritis (TA) and the likelihood ratio (LR) of obtaining a positive temporal artery biopsy (TAB).

It found the following historical features increased the likelihood of a positive TAB;

Jaw claudication (LR 4.2)

Diplopia (LR 3.4).

The following physical findings also increased the likelihood;

Temporal artery tenderness (LR 2.6)

Prominence (LR 4.3) and

Beading (LR 4.6).

Neuro-ophthalmic complications are closely linked with TAB positivity. The following were associated with a reduction in likelihood of TAB positivity;

Absence of temporal artery abnormality (LR 0.53)

Normal ESR (LR 0.2).

The presence of skip lesions and suboptimal sampling (for example, less than 1 cm, ideally should be more than 2 cm) are also associated with a negative TAB.

[Q: 3372] OnExamination 2012 - Rheumatology

A 75-year-old lady presents with a six week

history of shoulder and hip pain, restriction in movement, and early morning stiffness lasting for more than an hour. There is no history of weight loss and fever.

On examination, active shoulder movements are restricted globally due to pain while there is full range of shoulder movement passively. Muscle strength is normal.

Recent blood tests show:

Hb 11.1g/dl(11.5 - 16.5 g/dL)

WBC $7.8 \times 10^9/L$ ($4 - 11 \times 10^9/L$)

Neutrophils 70%(40-75%)

Platelet $270 \times 10^9/L$ ($150 - 400 \times 10^9/L$)

ESR 86 mm/hr(0 - 20 mm/1st hr)

Urea, electrolytes and creatinine Normal

CRP 43 mg/L(< 10 mg/L)

Rheumatoid factor negative

What is the diagnosis?

- 1- Frozen shoulder
- 2- Polymyalgia rheumatica
- 3- RA
- 4- Rotator cuff tear
- 5- Subacromial bursitis

Answer & Comments

Answer: 2- Polymyalgia rheumatica

This patient has polymyalgia rheumatica (PMR).

PMR is an inflammatory condition that occurs in those older than 50 years, and is characterised by a fairly abrupt onset of pain, early morning stiffness, and restriction in movement.

Although not an absolute essential for diagnosis, symptoms tend to be symmetric and typically involve both shoulder and pelvic girdle musculature. There is no muscle weakness, and constitutional symptoms like fatigue and malaise may be present.

PMR does not involve distal appendicular joints, and has a dramatic response to low dose prednisolone (10-20 mg/day), with marked resolution of symptoms in two to three days.

Corticosteroid dose is tapered and may be stopped in one to two years time.

Ten per cent of patients with PMR have a normal erythrocyte sedimentation rate (ESR).

The differential diagnosis of PMR includes

Rheumatoid arthritis (RA)

Rotator cuff syndrome

Osteoarthritis (OA)

Frozen shoulder

Fibromyalgia

Myositis

Parkinson's disease and

Hypothyroidism.

In frozen shoulder there is restriction of active and passive movements in all directions.

[Q: 3373] OnExamination 2012 - Rheumatology

A 23-year-old teacher presents with an eight month history of pain and stiffness in the lower back. This is worse in the morning and improves with activity, and with ibuprofen.

There is no significant past or family history. The Schober's test is positive. Sacroiliac joint MRI shows sacroiliitis and erosions. The FBC, UEC and liver function tests are normal.

What is the next step in his management?

- 1- Anti-TNFα agents
- 2- Methotrexate
- 3- NSAIDs - regular
- 4- Pamidronate

5- Tramadol

Answer & Comments

Answer: 3- NSAIDs - regular

This patient has ankylosing spondylitis (AS), based on the history of back pain and stiffness which improves with activity.

The aim of treatment of AS is symptom control and maintenance of function. Physiotherapy is critical, and should be undertaken daily. There is limited evidence regarding any medication's ability to alter the course of disease.

Non-steroidal anti-inflammatory drugs (NSAIDs) should be started in all cases, unless contraindicated. Where symptoms are not controlled additional analgesics (for example, amitriptyline), corticosteroid injections or oral corticosteroids can be used.

Current NICE guidelines state that etanercept and adalimumab can be used in patients with severe AS:

That satisfy the modified New York criteria

Have confirmed, sustained active spinal disease over at least 12 weeks

In whom maximal conventional treatment with two or more NSAIDs has failed

Where there are no contraindications present.

Infliximab is not recommended. The evidence for the use of other disease modifying antirheumatic drugs is weak.

Surgery is occasionally useful to correct spinal or joint deformities.

In the last few years evidence for additional agents has been growing. Golimumab, and anti-TNF alpha agent, has been approved in the USA, and another (certolizumab) is under investigation. Rituximab is also being studied as a treatment.

[Q: 3374] OnExamination 2012 -
Rheumatology

A 67-year-old woman with a long history of rheumatoid arthritis comes to the clinic for review.

Her rheumatoid is poorly controlled and she is receiving regular doses of methotrexate and low dose prednisolone. Most recently she has begun to suffer from increasing pitting oedema.

On examination her BP is 145/84 mmHg and her pulse is 85. She has pitting oedema to the mid shin.

Investigations show

Haemoglobin 11.0 g/dl(11.5-16.0)

White cell count $8.3 \times 10^9/L$ (4-11)

Platelets $159 \times 10^9/L$ (150-400)

Serum Sodium 140 mmol/l (135-146)

Serum Potassium 4.4 mmol/l (3.5-5)

Creatinine 130 $\mu\text{mol/l}$ (79-118)

Serum Albumin 24 g/l (36-50)

Urine protein ++

Which of the following is the most appropriate investigation likely to elucidate the underlying diagnosis?

- 1- Liver biopsy
- 2- Rectal biopsy
- 3- Renal biopsy
- 4- Renal ultrasound scan
- 5- Skin biopsy

Answer & Comments

Answer: 2- Rectal biopsy

This patient has poorly controlled rheumatoid arthritis and her proteinuria and hypoalbuminaemia raises the possibility of systemic amyloidosis.

Secondary amyloid A (AA) amyloidosis is an important complication of rheumatoid

arthritis (RA). It is caused by extracellular accumulation of AA fibrils, derived from the acute-phase-reactant serum amyloid A protein, within various tissues and organs. It is a significant cause of increased morbidity and early death in RA. Studies have shown that deposits of AA fibrils are not uncommon in RA (~20%). Any patient with longstanding RA who develops proteinuria, or intractable diarrhoea, should be investigated for AA amyloidosis.

No blood test is diagnostic for amyloidosis. Diagnosis therefore requires a biopsy and histological examination.

In order to start treatment as early as possible, a high-sensitivity site with a safe technique should be chosen. Subcutaneous fat, spleen, adrenal, liver, labia, salivary gland and gastrointestinal tract are frequent sites of AA amyloid deposition. Non-invasive techniques, such as renal ultrasound, can be useful in assessing organ involvement, but cannot establish whether the findings are definitely related to amyloid.

Gastrointestinal (GI), rectal and subcutaneous fat biopsies are the procedures of choice. The amount of amyloid in fat is low, and therefore it is not used routinely in the UK. GI and rectal are recommended because their sensitivities are high and they can be performed as an outpatient procedure. The incidence correlates strongly with renal biopsy, but the procedure is associated with much lower risk.

The progression of amyloidosis associated with systemic inflammatory disorders is slowed by better control of the underlying condition; as such in this case she should be sent for rheumatology review to determine the most appropriate way to step up her rheumatoid arthritis therapy.

[Q: 3375] OnExamination 2012 -
Rheumatology

A 29-year-old man presents with a painful

swollen right knee one month after an episode of gastroenteritis.

There is no personal or family history of chronic skin diseases and he drinks alcohol occasionally.

On examination there is a right knee effusion, and the knee aspirate shows plenty of leucocytes, no crystals, and no organisms on Gram stain or culture.

What is the next step in his management?

- 1- Commence disease modifying antirheumatic drug (DMARD)
- 2- Intra-articular corticosteroids
- 3- Oral antibiotics for five days
- 4- Oral antibiotics for six weeks
- 5- Oral NSAIDs

Answer & Comments

Answer: 5- Oral NSAIDs

Reactive arthritis (previously known as Reiter's syndrome) is the classic triad of conjunctivitis, urethritis and arthritis which occurs one to three months after an initiating infection.

It commonly occurs following:

Urethritis (C. trachomatis)

Diarrhoea (C. jejuni, Salmonella species)

Upper respiratory tract infections (β -haemolytic streptococcus).

Dermatological manifestations are common, including keratoderma blennorrhagicum, circinate balanitis, nail changes and oral lesions. It is more common in men, and the pathophysiology is not yet fully understood.

In the acute phase, affected joints should be rested and effusions aspirated. Non-steroidal anti-inflammatory agents are first line treatment. Corticosteroids can be given either intra-articular or systemic, particular in

patients who are unresponsive to NSAIDs or who develop adverse effects.

Antibiotics do not change the course of reactive arthritis, even when an infective cause is identified. However, some studies show that they may help to reduce the length of arthritis, particularly if Chlamydia is the triggering infection.

Evidence for the use of disease-modifying anti-rheumatic drugs in reactive arthritis is limited. Sulfasalazine can be beneficial in resistant disease, and TNF α -blockers can be used in aggressive disease.

Typically reactive arthritis is self-limiting with resolution of symptoms within three to 12 months. However, 15% of patients develop a long term arthritis, enthesitis or spondylitis. There is a high incidence of recurrence, especially in patients who are HLA-B27 positive (triggered by infection or stress).

[Q: 3376] OnExamination 2012 - Rheumatology

According to NICE guidelines, which of the following has a role in the treatment of OA?

- 1- Acupuncture
- 2- Chondroitin sulphate
- 3- Glucosamine hydrochloride
- 4- Intra-articular hyaluronic acid
- 5- Transcutaneous electrical nerve stimulation

Answer & Comments

Answer: 5- Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation is recommended by NICE as a supplement to analgesia in osteoarthritis (OA).

According to the NICE guidelines, there is not enough consistent evidence that acupuncture, glucosamine sulphate,

chondroitin hydrochloride, and intra-articular hyaluronic acid are either clinically- or cost-effective in treatment of OA.

[Q: 3377] OnExamination 2012 - Rheumatology

A 30-year-old woman who is 12 weeks pregnant presents with a history of systemic lupus erythematosus (SLE).

With regard to SLE in pregnancy, which of the following is correct?

- 1- Fertility rates are lower in SLE than in the general population.
- 2- If anti-Ro and anti-La antibodies are negative, there is a higher risk of congenital heart block associated with SLE.
- 3- Azathioprine can be continued in pregnancy.
- 4- It is necessary to stop hydroxychloroquine if breast-feeding.
- 5- Risk of pre-eclampsia is the same as in the general population.

Answer & Comments

Answer: 3- Azathioprine can be continued in pregnancy.

A. In general, SLE does not affect the fertility of patients.

However, fertility may be adversely affected in specific subgroups of patients such as those with renal failure, cyclophosphamide treatment, very active disease or high dose corticosteroids.

B. Anti-Ro and anti-La antibodies are associated with increased risk of congenital heart block. The risk is greater with anti-Ro positivity than anti-La positivity. The risk of congenital heart block in the presence of anti-Ro may be up to 5%.

C. Stopping any unnecessary drugs is advisable in pregnancy, however use of

azathioprine, hydroxychloroquine and prednisolone in pregnancy is considered safe if these are necessary for treatment of the mother's disease.

D. Prednisolone and hydroxychloroquine may be taken whilst breast-feeding. Azathioprine, cyclophosphamide, methotrexate and cyclosporin A are contraindicated in breast-feeding mothers.

E. Risk of pre-eclampsia is increased in SLE. It may be difficult to differentiate between pre-eclampsia and renal flare of SLE, and both may coexist. Differentiating features include raised anti-dsDNA antibody, decreased complement levels (C3 and C4) and response to steroids in the case of renal flare.

[Q: 3378] OnExamination 2012 - Rheumatology

A 45-year-old man presented to casualty with a 48 hour history of bilateral swollen ankles. He is known to have a history of an acute gout episode affecting his left first MTPJ.

He had recently been travelling in Europe and returned yesterday. During his trip he had had one episode of night sweats which he put down to the possibility of having caught flu, but he did mention that he had noticed feeling less fit than previously during activities.

Clinically he had a low grade pyrexia of 37.7°C but was otherwise well. Blood results showed an elevated ESR 40 and CRP 15, FBC, renal profile and LFTs were otherwise unremarkable.

Physical examination revealed normal abdominal, chest and cardiovascular findings. There were two patches of raised rash over his knees, which were painful. There were no features of synovitis elsewhere.

Which of the following would be the most appropriate next investigation?

- 1- Ankle aspirate

- 2- Blood cultures
- 3- CXR
- 4- Serum urate
- 5- Skin biopsy

Answer & Comments

Answer: 3- CXR

This man has bilateral swollen ankles with raised erythrocyte sedimentation rate (ESR) and mildly raised C reactive protein (CRP), some constitutional symptoms and a rash suggestive of erythema nodosum. Sarcoidosis is therefore high on the list of differentials.

The typical erythema nodosum (EN) rash consists of a sudden onset of symmetrical, tender, erythematous, warm nodules and raised plaques usually located on the shins, ankles and knees. The description above should therefore lead you to consider EN.

To consider other options of swollen ankle in a patient with a straightforward background history of gout:

- A. Joint aspirate is not the next best investigation as the patient is not clinically septic and has bilateral swelling which decreases the likelihood of septic arthritis.
- B. Blood cultures are not clinically appropriate currently, as the patient is afebrile and not clinically septic.
- C. A chest x ray may show bilateral hilar lymphadenopathy to guide towards a diagnosis of sarcoidosis and is the most appropriate investigation listed here..
- D. The history is not typical of gout and urate levels will not alter treatment nor is this a diagnostic test.
- E. The results of a skin biopsy will take up to a week, and it is therefore not the most appropriate first line investigation. In general, a biopsy will only be taken if the clinical diagnosis is in doubt. If done the

histopathology will show a mostly septal panniculitis, with no vasculitis. The septa of the subcutaneous fat are thickened, and variously infiltrated by inflammatory cells that extend to the periseptal areas of the fat lobules. The composition of the inflammatory infiltrate in the septa varies with the age of the lesion¹. Miescher's radial granulomas (relatively small histiocytes radially placed around a central cleft) may be present, which are a characteristic marker of erythema nodosum².

[Q: 3379] OnExamination 2012 - Rheumatology

A 45-year-old man is referred to the outpatient clinic with a three day history of a painful swollen left knee. He drinks 34 units of alcohol per week. His mother has psoriasis.

Physical examination demonstrates nail pitting. ESR is elevated at 90 mm/hr. White cell count is normal.

What is the next most appropriate step in his management?

- 1- Commence NSAID
- 2- Joint aspiration and analysis of synovial fluid for Gram stain, microscopy and culture
- 3- Commence allopurinol
- 4- Check rheumatoid factor, anticyclic citrullinated peptide antibody and knee radiograph
- 5- Commence oral steroids and a DMARD

Answer & Comments

Answer: 2- Joint aspiration and analysis of synovial fluid for Gram stain, microscopy and culture

This man has presented with an acute onset monoarthritis.

Despite confounders in the history (alcohol use suggesting gout, nail pitting highlighting

the possibility of psoriasis) a destructive septic arthritis is a potential diagnosis and it must be excluded as a matter of urgency.

A. Whilst analgesia is appropriate, alone it risks missing a serious diagnosis.

B. Joint aspirate is the most crucial step in excluding a septic arthritis, and allows the timely commencement of surgical management and appropriate antibiotics.

C. This may be gout, but septic arthritis requires urgent orthopaedic management and you need a joint aspirate to exclude it prior to starting treatment for another condition.

D. This not a typical history of rheumatoid arthritis and waiting for immunological investigation prior to initiating treatment is not appropriate. A radiograph may be appropriate, but in the acute stages of septic arthritis it may be normal.

E. A diagnosis needs to be made prior to commencing such medications. These are used in rheumatoid arthritis which is unlikely to be the diagnosis in this case.

[Q: 3380] OnExamination 2012 - Rheumatology

A 29-year-old male smoker presents with a two week history of cough, fever and haemoptysis.

A chest x ray demonstrates diffuse alveolar infiltrates. A urine dipstick demonstrates red cell casts.

The full blood count shows:

Hb 10.8 g/dl

WCC 5.1×10^9

Plt 376×10^9

ANCA positive at titre 1 in 3600.

Which of the following is the most likely diagnosis?

1- Alport's syndrome

2- Goodpasture's syndrome

3- Polymyositis

4- Relapsing polychondritis

5- Systemic lupus erythematosus

Answer & Comments

Answer: 2- Goodpasture's syndrome

The combination of haemoptysis (with radiological findings consistent with pulmonary haemorrhage) and red cell casts in the urine (indicating glomerular bleeding) should lead you to consider a diagnosis of Goodpasture's syndrome in this case.

Goodpasture's syndrome is an important, and potentially rapidly fatal, cause of alveolar haemorrhage and rapidly progressive renal failure. It is caused by circulating antiglomerular basement membrane antibodies, and typically causes an acute glomerulonephritis. It usually presents in young men in their twenties and men and women in their sixties. Despite treatment the mortality of Goodpasture's is 11% and it has a high morbidity with 60% of patients becoming dependent on dialysis. Renal impairment is caused by a crescentic glomerulonephritis.

It frequently has an eruptive presentation in the young, with

Cough

Fever

Haemoptysis

Haematuria

Proteinuria

Red cell casts.

The pulmonary haemorrhage and glomerular bleeding can result in a drop in haemoglobin.

The most common antibody associated with Goodpasture's is anti-glomerular basement

membrane antibodies (anti-GBM). Anti-GBM antibodies are directed against the Goodpasture antigen, which is part of the non-collagenous domain of the alpha-3(4) collagen chain. However, recently it has been shown that in a significant number of patients with Goodpasture's syndrome anti-neutrophil cytoplasmic antibodies (ANCA) can coexist with anti-GBM antibodies - in one study 30% of patients had positive ANCA serology. In this setting ANCA is usually specific for p-ANCA and is directed against myeloperoxidase. In general, both antibodies can be detected at presentation. This seropositivity has been shown to have important clinical and prognostic implications, and these patients may develop extra-renal and extra-pulmonary manifestations. In addition they are more likely to have recurrent renal or pulmonary disease. Prognosis is debated with some studies saying it is more favourable in patients with positive ANCA and others showing a worse outcome in these patients.

Plasmapheresis and immunosuppression (typically with cyclophosphamide and corticosteroid) is the treatment of choice in Goodpasture's syndrome. This has been shown to reduce anti-GBM antibodies most rapidly, which results in improved morbidity and mortality. Plasmapheresis is typically given daily or on alternate days for 2-3 weeks. Response is assessed by monitoring symptoms and anti-GBM antibody titres. Cyclophosphamide and prednisolone then continues, typically for 6-9 months following remission.

Alport's syndrome is a familial nephritis which presents with haematuria, progressive renal failure, ocular abnormalities and sensorineural deafness. It is caused by mutation within the type IV collagen genes. Inheritance is variable, but the majority are X-linked dominant (85%; 15% are autosomal recessive). There is a high spontaneous mutation rate, which means 20% of patients have no family history.

Polymyositis classically presents with relatively painless progressive proximal muscle weakness. Dysphagia is common but the ocular muscles are very rarely. Diagnosis of polymyositis is confirmed by elevated muscle enzymes (creatine kinase) and typical EMG and muscle biopsy findings.

Relapsing polychondritis is characterised by recurrent episodes of inflammation of cartilaginous structures (joints, respiratory tract, ear, nose) and connective tissue (heart, eye, blood vessels, inner ear). Antibodies to type II collagen may be present.

Systemic lupus erythematosus (SLE) is a heterogeneous, inflammatory, multisystem autoimmune inflammatory disease, in which antinuclear antibodies occur. Its presentation and course are highly variable, ranging from indolent to fulminant. The triad of fever, arthralgia and rash in a woman of childbearing age should suggest the diagnosis.

[Q: 3381] OnExamination 2012 - Rheumatology

An 18-year-old male presents with a six week history of a painful swollen right knee. He had been treated for a sexually transmitted disease three months ago.

On examination there was a large effusion in the right knee. Synovial fluid analysis revealed a white cell count of $16 \times 10^9/L$ (4-11) but culture was negative.

Which one of the following organisms is the most likely cause?

- 1- Human papilloma virus
- 2- Herpes simplex
- 3- Neisseria gonorrhoeae
- 4- Treponema pallidum
- 5- Trichomonas vaginalis

Answer & Comments

Answer: 3- Neisseria gonorrhoeae

Bacteria are the most common cause of monoarthritis.

Staphylococcus aureus and gonococci are the most common causes of septic arthritis.

Neisseria gonorrhoeae typically occurs in young adults. Presentation is either as a bacteraemic form (classic triad of migratory polyarthritis, tenosynovitis, and dermatitis) which is usually polyarticular; or as in this case, a septic arthritis. The septic arthritis form presents with joint symptoms which begin within days to weeks of gonococcal infection. Gram stain is positive in 25% and culture positive in 50%.

This patient has been treated previously for a sexually acquired infection and this may be why the culture is negative.

Reactive arthritis can also result following a sexually acquired infection (usually Chlamydia trachomatis) and can result in mono- or poly-arthritis

[Q: 3382] OnExamination 2012 - Rheumatology

A 52-year-old woman with a three year history of sero-positive erosive rheumatoid arthritis has recently commenced methotrexate therapy initiated at the rheumatology clinic.

Which one of the following agents should she also be receiving in conjunction with her methotrexate?

- 1- Folic acid
- 2- Omeprazole
- 3- Thiamine
- 4- Vitamin C
- 5- Zinc supplements

Answer & Comments

Answer: 1- Folic acid

Methotrexate is a chemotherapeutic agent as well as being an immunosuppressant used as a disease-modifying antirheumatic drug (DMARD). It acts through inhibition of dehydrofolate reductase thus depleting folate concentrations.

To reduce the impact of folate deficiency a dose of 5 mg of folic acid weekly* is recommended in conjunction with methotrexate taking the agent at least two days prior to commencing the methotrexate. Its action in arthritides is not entirely understood but may relate to both anti-inflammatory as well as immunomodulation.

*Some local variations may exist regarding dose and frequency of folate therapy. Please be aware of your local guidelines.

[Q: 3383] OnExamination 2012 - Rheumatology

A 42-year-old woman presents with a six month history of dyspepsia. She has a three year history of Raynaud's phenomenon.

On examination she has telangiectasia. Her investigations reveal an ESR of 40 mm/hr (0-10) and positive anticentromere antibodies.

Which of the following is a typical late complication of this disorder?

- 1- Alopecia
- 2- Butterfly skin rash
- 3- Erosive polyarthropathy
- 4- Myositis
- 5- Pulmonary hypertension

Answer & Comments

Answer: 5- Pulmonary hypertension

The history here is suggestive of a diagnosis of systemic sclerosis.

Systemic sclerosis is a chronic autoimmune disease characterised by increased fibroblast activity and fibrosis in a number of different organ systems. 90-95% of patients have positive antinuclear antibodies. There are two major subtypes: limited cutaneous and diffuse cutaneous. CREST syndrome is an older term for the limited cutaneous form (calcinosis, Raynauds' phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia). Patients with systemic sclerosis can present with skin abnormalities, musculoskeletal changes, gastrointestinal complications, pulmonary disease, renal crisis and dry eyes and mouth. Dyspepsia, restricted distension of the gastric antrum and diffuse gastrointestinal dysmotility are frequent features. This is due both to fibrosis and muscle atrophy, and autonomic neuropathy.

Pulmonary hypertension can present in isolation in systemic sclerosis, or in association with interstitial lung disease or cardiac dysfunction. It is a frequent cause of morbidity and mortality. Despite advances in echocardiography and biomarkers, right heart catheterisation remains the diagnostic test to differentiate pulmonary veno-occlusive disease from hypertension. This is essential because pulmonary vasodilator therapy can increase mortality in veno-occlusive disease. Recent studies have investigated the use of non-invasive screening, but their use remains controversial.

Treatment options are limited, and prognosis is worse than with idiopathic pulmonary hypertension. Median survival is one year from diagnosis. Extrapulmonary disease in systemic sclerosis limit candidacy for lung transplantation. New therapies that target abnormal cellular proliferation in the pulmonary vasculature are currently under investigation.

Erosive polyarthropathy is typically present in the earlier stages of systemic sclerosis, and would not be classified as a late complication.

A malar, or butterfly, rash is classically associated with systemic lupus erythematosus. It involves the bridge of the nose, but spares the naso-labial folds. It is usually well demarcated and macular. It is not pathognomonic of SLE, and can be seen in pellagra and dermatomyositis, but again none of these would account for the symptoms described above.

Alopecia and myositis are not commonly associated with systemic sclerosis.

[Q: 3384] OnExamination 2012 - Rheumatology

A 43-year-old patient with rheumatoid arthritis is sent to the clinic with increasing shortness of breath over a 6 week period.

Lung function tests demonstrate a fall in the FEV₁, which is markedly lower than tests last taken two months ago. The residual volume (RV) is increased by two litres but the measurements of diffusion are normal. The patient is a smoker.

Which of the following is the most likely diagnosis?

- 1- Bronchiolitis obliterans
- 2- Caplan's syndrome
- 3- Chronic obstructive pulmonary disease
- 4- Atypical pneumonia
- 5- Acute interstitial pneumonitis

Answer & Comments

Answer: 1- Bronchiolitis obliterans

All of the possible options can occur in rheumatoid arthritis but a progressive and relentless fall in the forced expiratory volume in one second (FEV₁) is the most characteristic of bronchiolitis obliterans.

Bronchiolitis obliterans, with or without organising pneumonia, can be a fatal complication of rheumatoid arthritis (especially in women taking penicillamine).

Histologically there is a mural concentric narrowing of the lumina of the bronchioles. It can present as severe respiratory insufficiency, and diagnosis is best made with lung biopsy. Inflammation in the small distal airways leads to obstructive spirometry and without treatment this is relentlessly progressive. Air trapping can occur, which leads to increased lung volumes. Corticosteroids can induce a quick response and improvement in symptoms. Rheumatoid serology often worsens with the onset of bronchiolitis obliterans.

Other associations are with solid organ or bone marrow transplantation, and other connective tissue disorders.

Caplan's syndrome is the combination of rheumatoid arthritis with pneumoconiosis related to coal dust. There is a rapid development of basal peripheral nodules, which can progress to severe pulmonary fibrosis.

COPD is a possibility but it is rare for it to progress at the rate described here. The history is too long for an atypical pneumonia.

Acute interstitial pneumonitis is associated with drug-treatment of rheumatoid arthritis, in particular methotrexate.

[Q: 3385] OnExamination 2012 - Rheumatology

A 24-year-old promising athlete is diagnosed with chronic fatigue syndrome.

Which of the following treatments is indicated?

- 1- Graded exercise therapy
- 2- Group therapy
- 3- Prednisolone
- 4- Seroxat
- 5- Thyroxine

Answer & Comments

Answer: 1- Graded exercise therapy

The diagnosis and management of chronic fatigue syndrome (CFS), or myalgic encephalitis, has been reviewed by NICE (2007).

The main features which need to be present to confirm a diagnosis of fatigue are that it:

Is new in onset, persistent or recurrent and unexplained by other conditions.

Is characterised by post-exertional malaise.

Results in a substantial reduction in activity level.

Associated symptoms include:

Hypersomnia or insomnia

Muscle or joint pain without inflammation

Painful lymph nodes without lymphadenopathy

Headaches

Cognitive dysfunction.

Red flag symptoms which suggest another diagnosis include:

Significant weight loss

Inflammatory arthropathy or connective tissue disease

Localising or focal neurological signs.

The diagnosis of CFS is one of exclusion, and features must have been present for at least four months in an adult.

Clinicians should check

Full blood count (FBC)

Urea and electrolytes (U&Es)

Urinalysis

Liver function tests (LFTs)

Thyroid function

Erythrocyte sedimentation rate (ESR)

C reactive protein (CRP)

Blood glucose

Creatinine

Gluten sensitivity calcium

Creatinine kinase and

Ferritin.

Initial treatment should focus on management of symptoms, and minimising their impact on daily activities. Patients must be encouraged to continue work and studies. Any therapy should be person-centred and should aim to improve the patient's capacity to manage their symptoms.

The majority of research evidence is for cognitive behavioural therapy (CBT) and/or graded exercise therapy and these should be offered to all people with mild or moderate CFS.

In addition, patients should be given tailored sleep management advice including how to introduce rest periods into their daily routine. Relaxation techniques should be offered for the management of pain, sleep problems, stress and anxiety.

There is no research evidence to support the experience of some patients with CFS that they are more intolerant of drug treatment. In addition, there is insufficient evidence to recommend the use of complementary therapies or vitamin supplementation.

The following drugs should not be used:

Monoamine oxidase inhibitors

Glucocorticoids

Mineralocorticoids

Dexamphetamine

Thyroxine

Antivirals.

Referral to specialist CFS care should be offered within six months of presentation to people with mild CFS, within three to four months for moderate CFS and immediately for severe CFS.

If chronic pain is a predominant feature, referral to a pain management clinic should be considered. Amitriptyline should be considered for patients with poor sleep or pain.

Patients should be advised that relapses and setbacks are to be expected.

Reference:

Chronic fatigue syndrome / Myalgic encephalomyelitis (or encephalopathy). NICE Guideline CG53. Issued August 2007

[Q: 3386] OnExamination 2012 - Rheumatology

A 53-year-old woman with rheumatoid arthritis was referred with iron deficiency anaemia.

Endoscopy revealed several superficial antral erosions, with small bowel biopsy showing mild villous blunting, apoptotic bodies, occasional eosinophils and mild increase in chronic inflammatory cells. Colonoscopy was reported as normal.

What is the most likely cause of these findings?

- 1- Coeliac disease
- 2- Crohn's disease
- 3- Non-steroidal anti-inflammatory drug therapy
- 4- Small bowel lymphoma
- 5- Whipple's disease

Answer & Comments

Answer: 3- Non-steroidal anti-inflammatory drug therapy

This salient features in this patient's case revolve around the fact that she has rheumatoid arthritis (hence the requirement for NSAIDs), the iron deficiency anaemia and the superficial ulceration on endoscopy with features indicative of inflammation due to the chronic NSAID use.

Coeliac disease is associated with villous atrophy and lymphocyte infiltration.

There is no suggestion on the biopsy of lymphocyte infiltration which argues against lymphoma or coeliac.

[Q: 3387] OnExamination 2012 - Rheumatology

A 70-year-old retired sea captain develops weakness of the shoulders and hips over a four month period. He has also noticed weak finger flexors with normal strength in straightening them. He has had some difficulty swallowing liquids.

There is no past medical history, apart from a sexually transmitted disease picked up in the South Pacific some forty years before. This was treated with antibiotics and he is not sure of the diagnosis.

He smokes a pipe and drinks one or two tots of rum at the weekend.

A creatinine kinase level comes back at 120.

Which investigation is most likely to give a definite diagnosis?

- 1- Anti Jo 1 antibody titres
- 2- CT scan of the chest
- 3- EMG
- 4- Muscle biopsy with electron microscopy
- 5- 24 hour urine collection for myoglobin

Answer & Comments

Answer: 4- Muscle biopsy with electron microscopy

The diagnosis is inclusion body myositis (IBM). This is an inflammatory condition that affects the over 50s.

Proximal muscles and finger flexors are predominantly involved, but distal muscle groups may also be involved. The onset of muscle weakness in IBM is generally gradual (over months or years).

IBM occurs more frequently in men than women. Creatine kinase (CK) may be normal.

Jo 1 titres are often raised in dermatomyositis associated with lung disease.

Electromyogram (EMG) shows a similar pattern in polymyositis and IBM - small short duration motor unit arrhythmias can complicate polymyositis and dermatomyositis, but not IBM.

There is no association of IBM with malignancy.

Polymyositis and dermatomyositis show a much better response to steroids than IBM.

Biopsy in IBM shows intranuclear or cytoplasmic tubofilaments on electron microscopy.

[Q: 3388] OnExamination 2012 - Rheumatology

A 79-year-old female suffers a fracture neck of femur following a fall at home.

Investigations are normal but her x ray shows the bones to be rather 'thin'. It is assumed that she is osteoporotic and she is started on alendronate therapy.

Which of the following is correct concerning this drug?

- 1- Enhances vitamin D action on bone
- 2- Increases absorption of calcium
- 3- Increases osteoblast activity
- 4- Increases the action of oestrogen on bone
- 5- Inhibits osteoclast activity

Answer & Comments

Answer: 5- Inhibits osteoclast activity

The bisphosphonates of which alendronate is one increase bone mineralisation by inhibiting osteoclastic activity.

They have been demonstrated in numerous studies to reduce subsequent risk of fracture.

[Q: 3389] OnExamination 2012 - Rheumatology

A 45-year-old man has noted pain in his right knee for several years. There is no joint swelling. As he moves about during the day, the pain decreases.

The underlying disease process is probably which of the following?

- 1- Osteoarthritis
- 2- Osteochondroma
- 3- Osteomalacia
- 4- Osteopetrosis
- 5- Osteoporosis

Answer & Comments

Answer: 1- Osteoarthritis

Osteoarthritis is one of the most common joint diseases, and its incidence is increasing with the age and weight of the population. It presents with pain, commonly affecting the knees, hips and small joints of the hand. Pathogenesis involves the localised loss of cartilage, with remodelling of adjacent bone. The associated pain is exacerbated by exercise and relieved by rest, although in advanced disease rest and night pain can develop. There may also be joint stiffness, typically in the morning or after rest. Diagnosis is often late, and treatment is usually aimed at reducing pain and improving function rather than targeting the disease process.

Osteoporosis is characterised by progressive deterioration of bone micro-architecture, with associated decrease in bone mineral density. It is typically asymptomatic until the complicated by fracture when pain is exacerbated by movement.

Osteochondroma is a benign tumour of cartilage, which can be located about the knee. However, they commonly present in adolescence as a painless lump which grows with the bone. Pain is not a predominant symptom.

Osteomalacia is caused by a deficiency of vitamin D and presents with widespread bone pain and tenderness (especially lower back and hips), muscle weakness and lethargy,

Osteopetrosis, an uncommon inherited metabolic disorder, leads to 'brittle bones' that predispose to fractures. Isolated joint pain is not typically an associated feature.
